
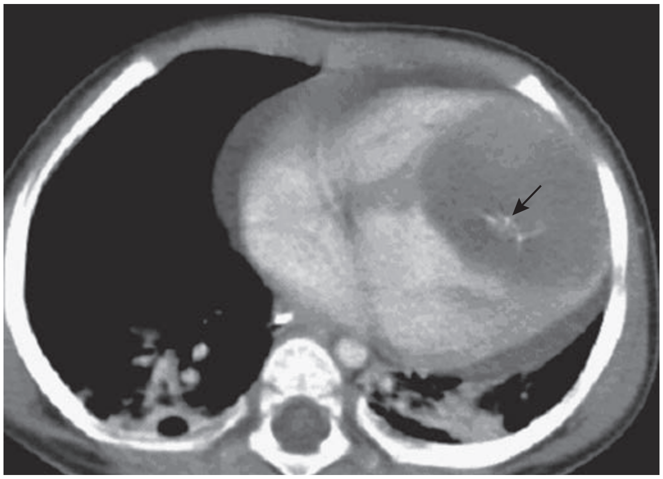
**e-Figure 80.5. Cardiac fibroma in a newborn.** Short axis (A and B) and axial (C and D) MR gradient echo imaging shows a large, well-defined, hypointense mass *(arrows)* arising from the left ventricle associated with a pericardial effusion.



**e-Figure 80.6. Cardiac fibroma.** Contrast-enhanced CT shows calcification *(arrow)* in the low-attenuation mass in the left ventricular apex.

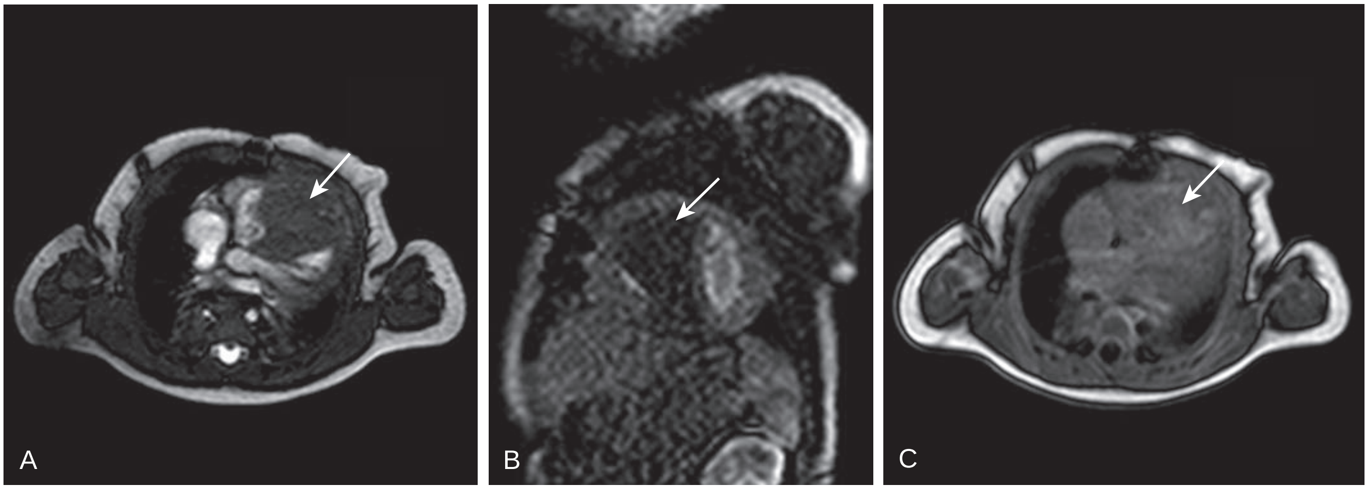


**Figure 80.3. Rhabdomyoma in an infant with neurostigmata of tuberous sclerosis.** A broad-based ovoid mass *(arrow)* extends from the interventricular septum on four chamber steady state free precession MR imaging (A), demonstrating decreased short axis first pass perfusion (B) and no significant delayed enhancement on four chamber phase sensitive inversion recovery (C) imaging.

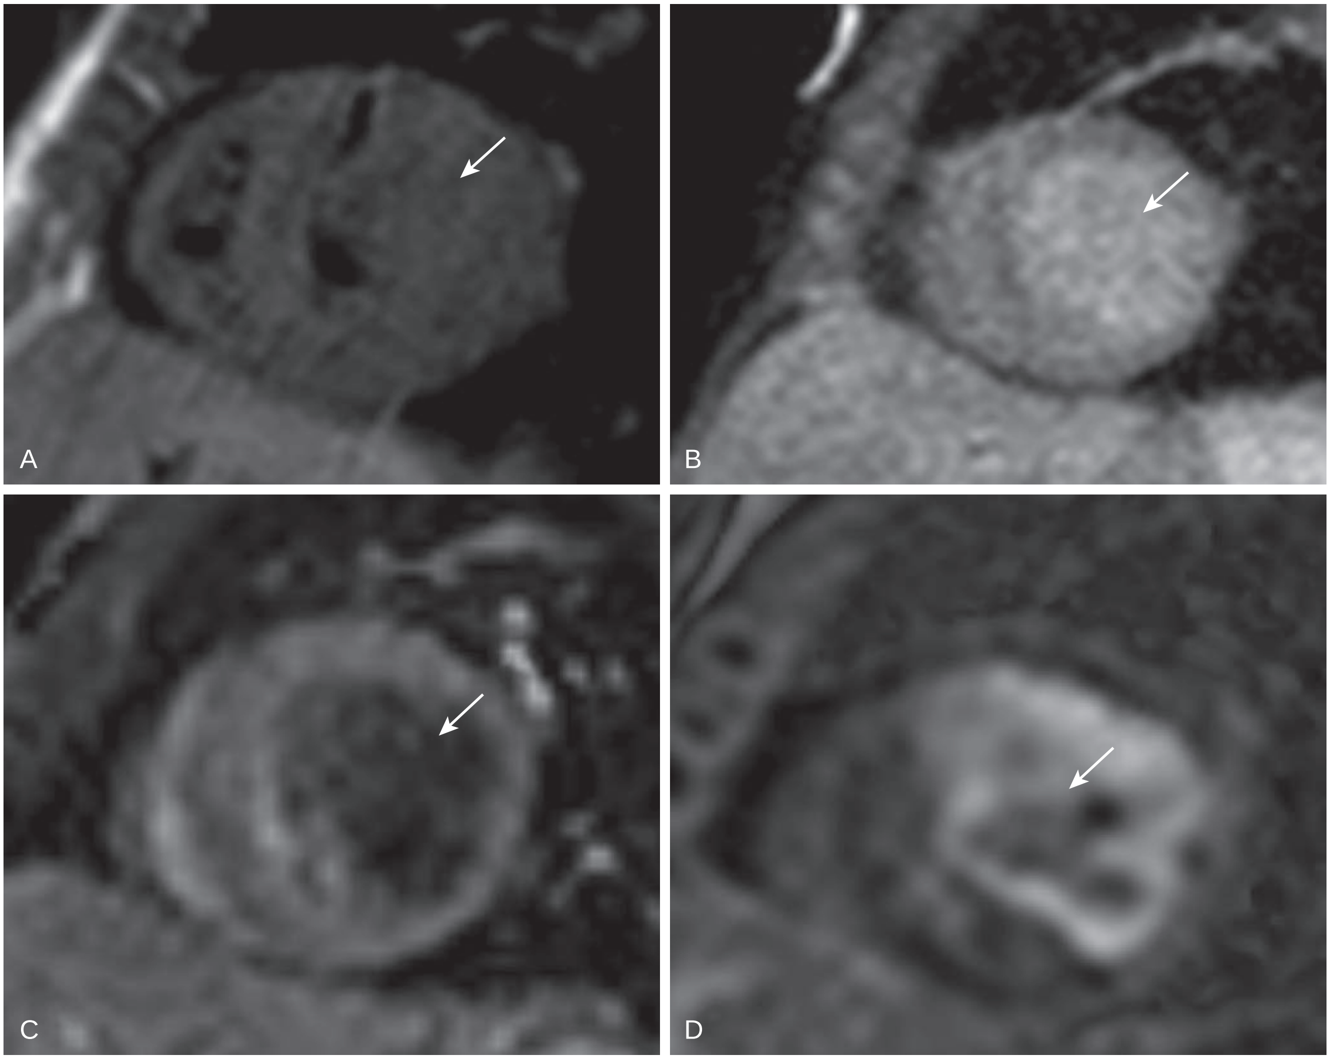

**Figure 80.4. Cardiac fibroma in a 1-year-old boy with ventricular tachycardia.** A mass arising from the mid posterolateral left ventricular wall *(arrow)* is isointense with normal myocardium on T1-weighted MR imaging (A), hyperintense on STIR imaging *(arrow)* (B), has decreased first pass perfusion *(arrow)* (C), and characteristic rim delayed enhancement on phase sensitive recovery imaging *(arrow)* (D).

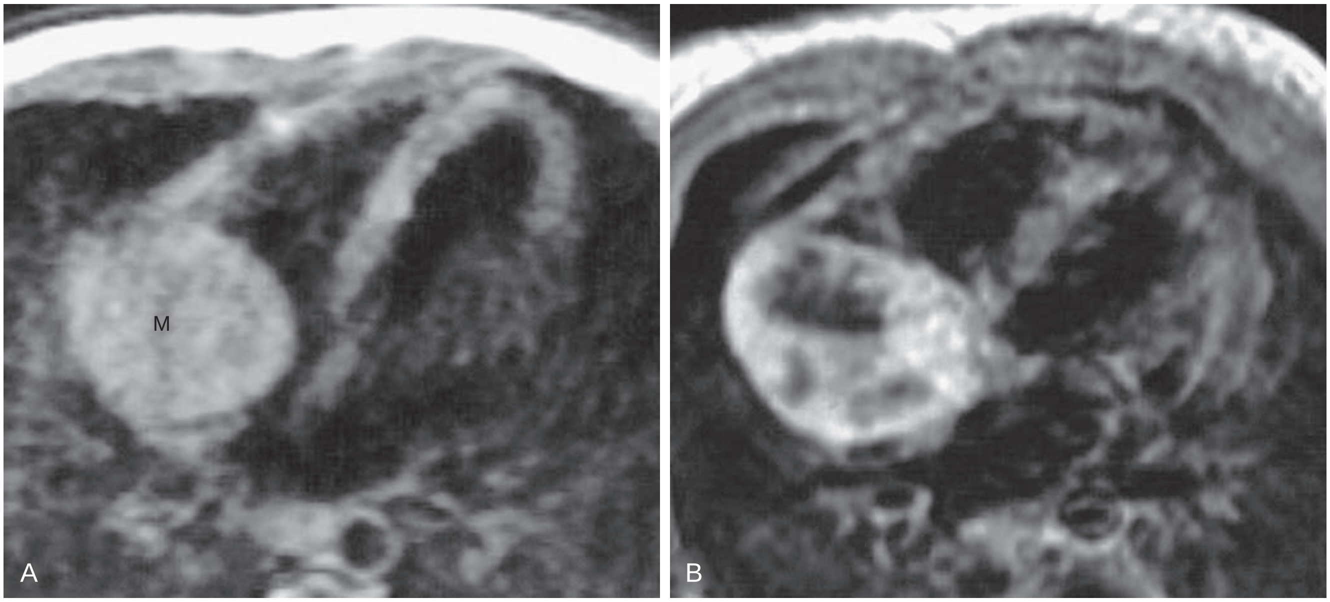

**Figure 80.7. Right atrial myxoma in a child.** (A) Axial T1-weighted MR image shows an intraluminal right atrial mass *(M)*. (B) The mass enhances heterogeneously with gadolinium.

regions, with low signal on T1-weighted imaging, high signal on T2-weighted imaging,[6,7,9,10,12] and postcontrast enhancement (Fig. 80.7). Tumor attenuation is lower than nonopacified blood on CT, and they are often calcified.[10,15]

## TERATOMA

***Pathophysiology and Clinical Presentation.*** Cardiac teratomas, although rare, are the most common pericardial tumors in infants.[3,10,17,18] Teratomas typically are attached to the pulmonary artery and aortic root, and extend into the pericardium;[3,17] rarely, they originate from the myocardium.[19] Pericardial effusions are frequent. Fetal hydrops from caval obstruction can lead to spontaneous fetal loss.

***Imaging.*** Echocardiography shows a heterogeneous, multilocular, cystic mass that may be associated with cardiac chamber compression and pericardial effusion.[3,11] MRI with both T1- and T2-weighted sequences can show high signal within a well-defined pericardial mass (e-Fig. 80.8).[20] Calcifications and fat within these tumors are well defined by CT.[17]

## OTHER CARDIAC TUMORS

Other benign tumors, such as fibroelastomas, hemangiomas, and lipomas, are extremely rare in children. A fibroelastoma is an intracavitary tumor usually attached to a cardiac valve.[21,22] Hemangiomas can occur in the heart and pericardium and are associated with pericardial effusion.[3] Hemangiomas enhance intensely on MRI and CT (e-Fig. 80.9) and are T2 hyperintense (Fig. 80.10).[9,11,23] CT and MRI demonstration of fat allows specific diagnosis of lipoma[20,24] (e-Fig. 80.11).

## MALIGNANT TUMORS

Primary malignant tumors are so rare that they are frequently absent from a series of cardiac tumors in children, appearing only in case reports.[1,2,25,26] Sarcomas have a variable imaging appearance. The presence of infiltration is the most helpful finding (e-Fig. 80.12).[27] Primary cardiac lymphoma is typically restricted to the heart and pericardium (e-Fig. 80.13).[28] Kaposiform hemangioendothelioma can occur antenatally and is associated with pericardial effusion.[29] MRI shows high signal on T2-weighted images. Contrast uptake is similar to hemangiomas with early fill-in on perfusion and postcontrast imaging (e-Fig. 80.14). Metastatic tumors are more common than primary malignancies[20] and may be the result of leukemia, lymphoma, Wilms tumor, hepatoblastoma, neuroblastoma, Ewing sarcoma, and osteosarcoma. Spread may be from direct extension, by extension through the inferior vena cava (e-Fig. 80.15), or via hematogenous metastases.

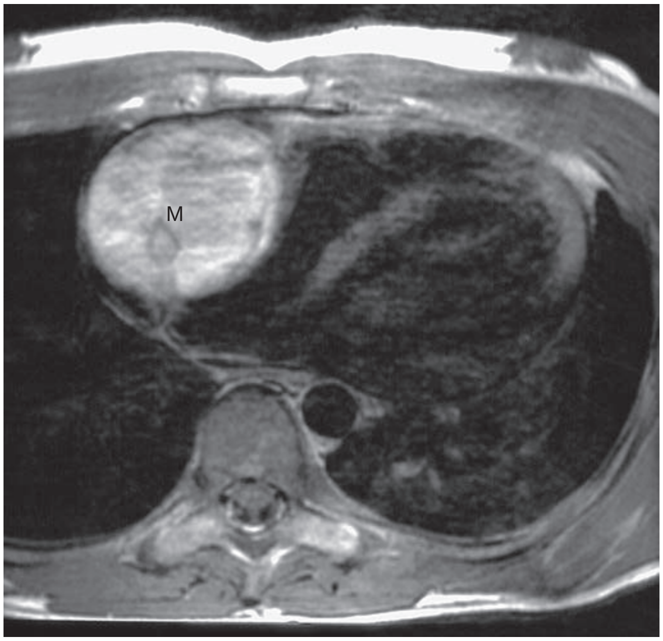

**Figure 80.10. Pericardial hemangioma in an 8-year-old child.** MRI shows a high-signal mass *(M)* on T1-weighted imaging. The mass impinges on the right atrium and ventricle.

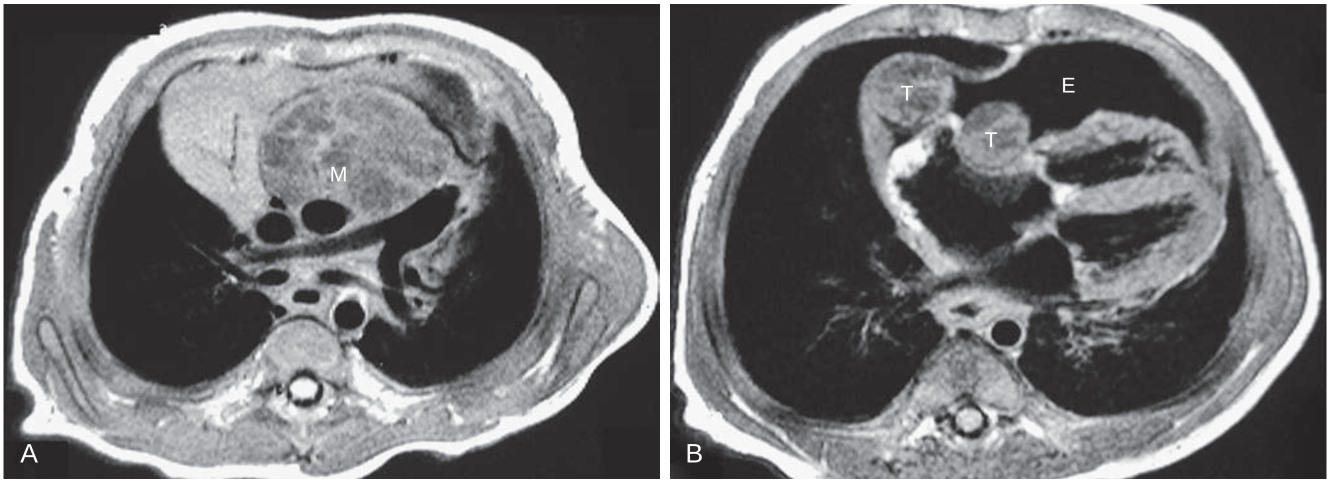
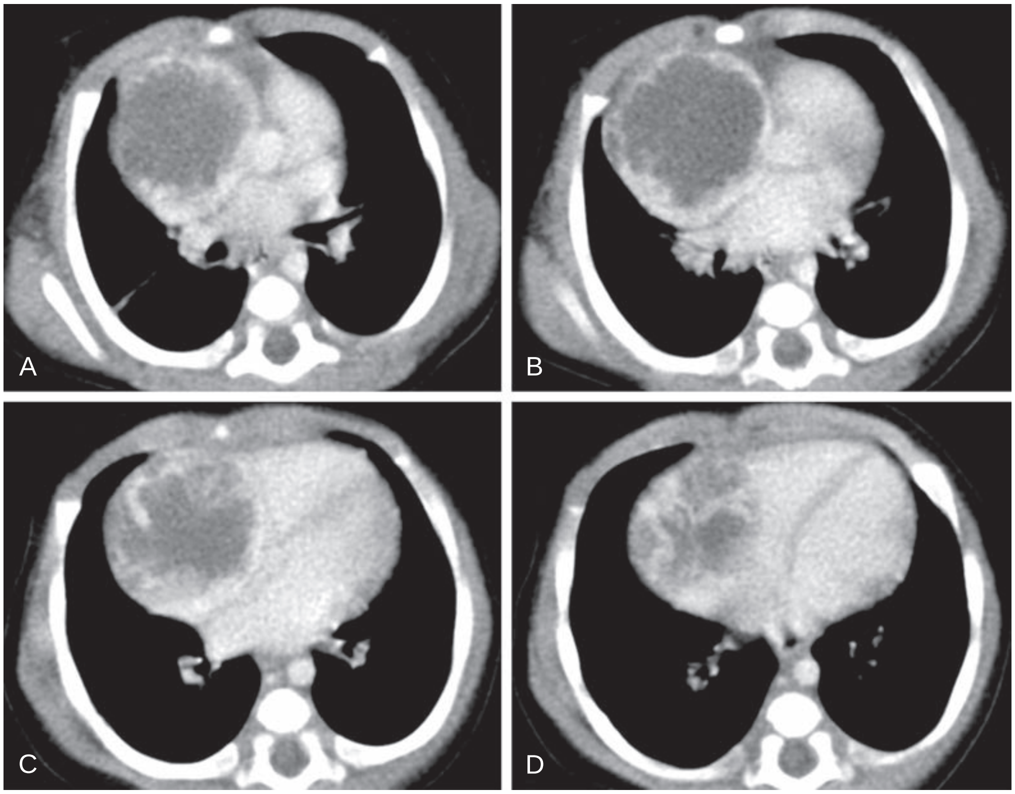
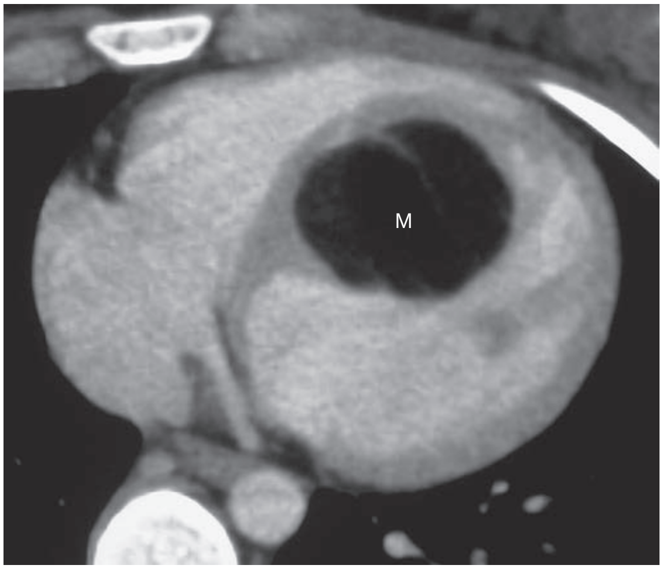


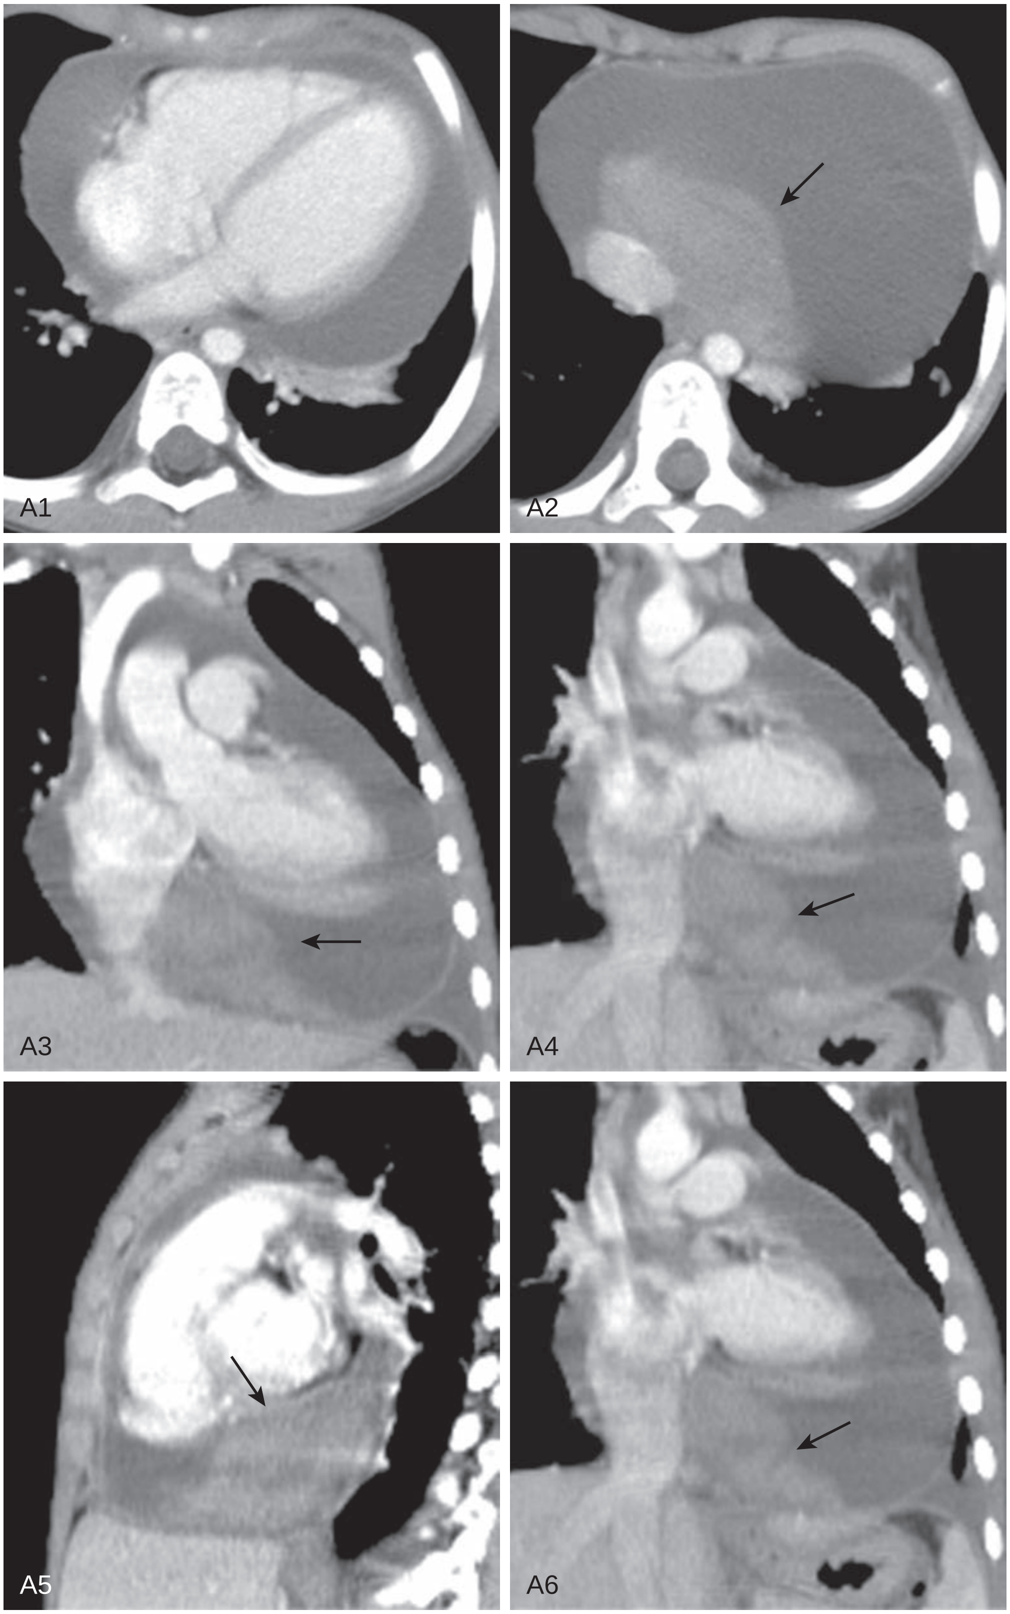
**e-Figure 80.8. Pericardial teratoma in a child.** (A) Axial T1-weighted MR image shows a pericardial mass *(M)* with low-signal cystic components. (B) Daughter tumors *(T)* are present in the pericardial space. Note the large pericardial effusion *(E)*.



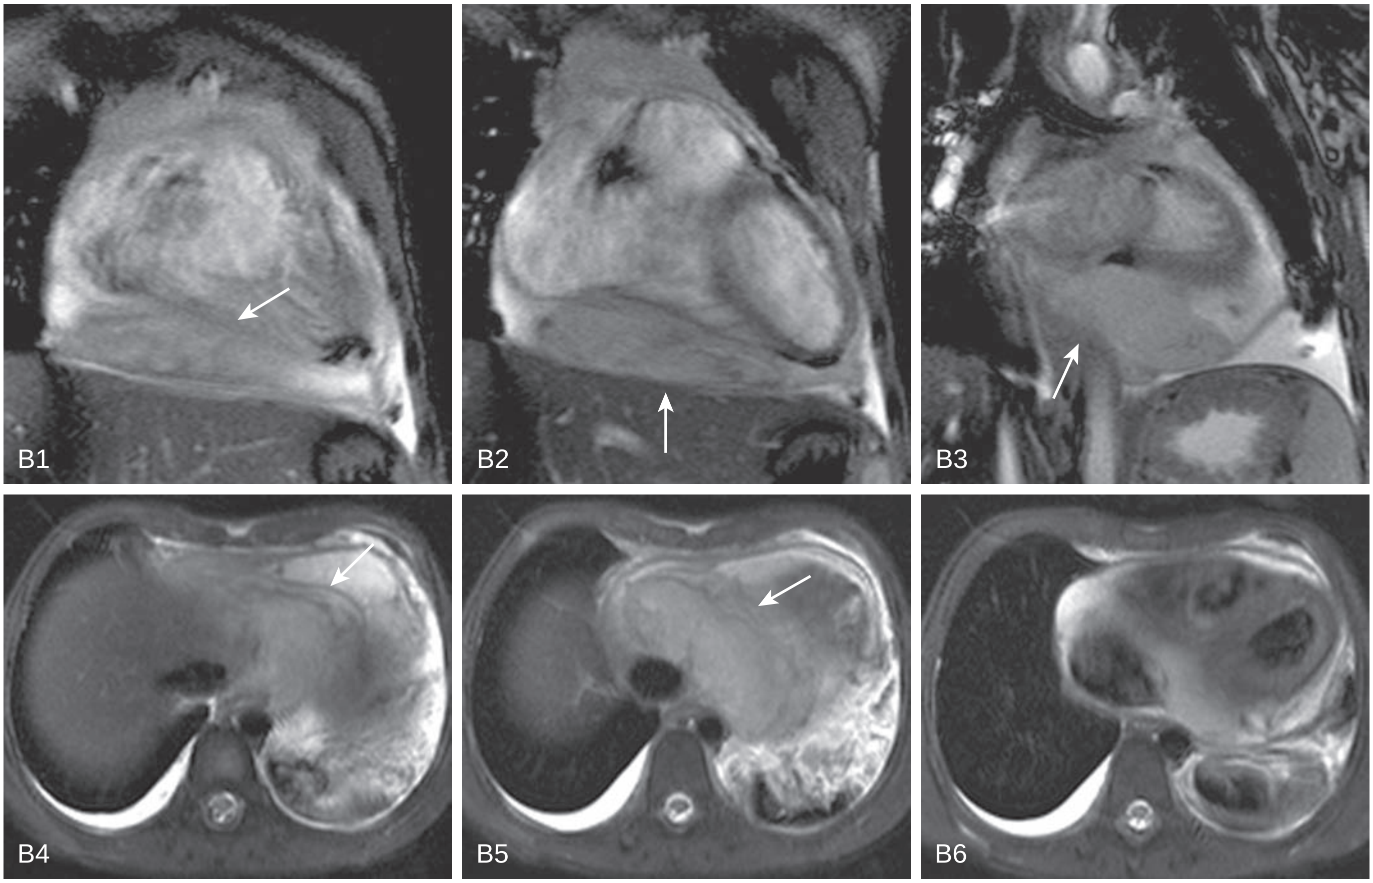
**e-Figure 80.9. Pericardial hemangioma in a newborn.** (A–D) Contrast-enhanced CT images from superior to inferior show a hypodense pericardial mass arising from the right atrial wall that compresses the right atrium. Dense peripheral contrast enhancement is present.



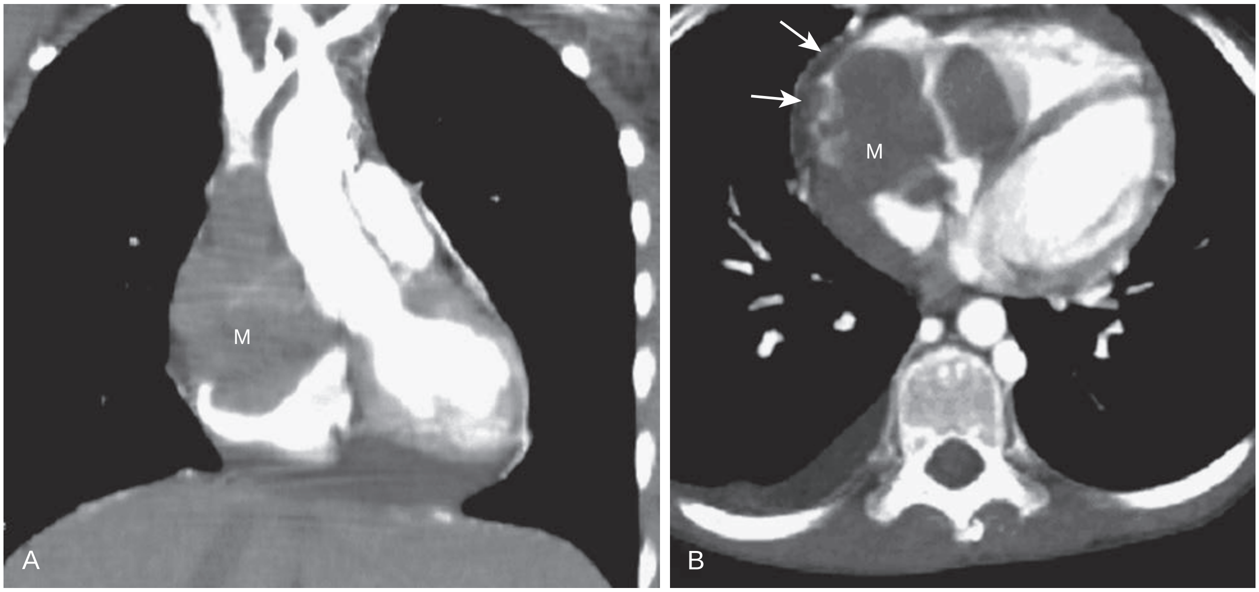
**e-Figure 80.11. Intracardiac lipoma in a teenager.** Contrast-enhanced CT shows a fatty, low-attenuation mass *(M)* extending into the left ventricular lumen from the ventricular septum.



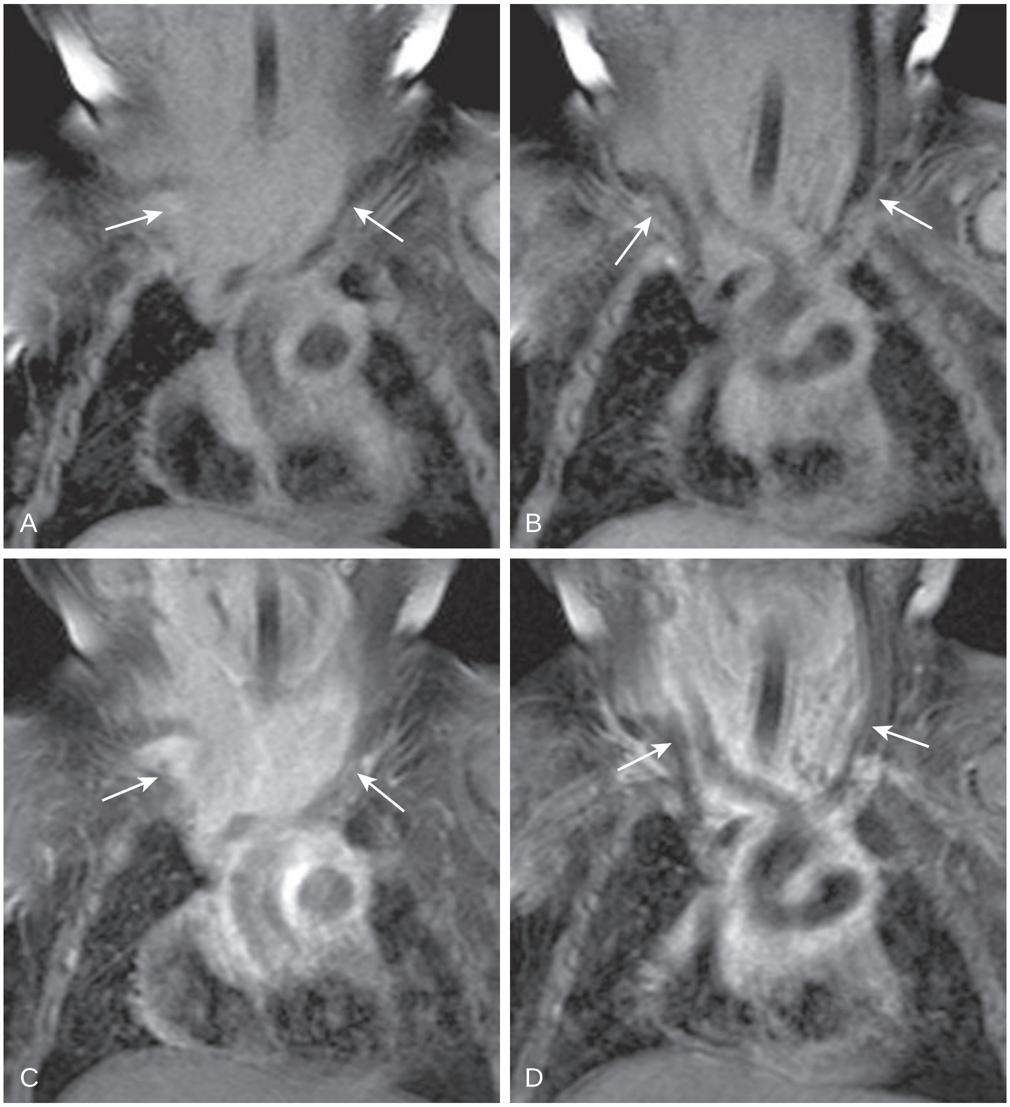
**e-Figure 80.12. Pericardial synovial sarcoma in a 6-year-old child who presented with chest pain.** (A) Contrast-enhanced CT images (A1–A6) show a large pericardial effusion with a focal soft tissue density mass *(arrows)* at the base of the pericardium adjacent to the right atrium. *Continued*



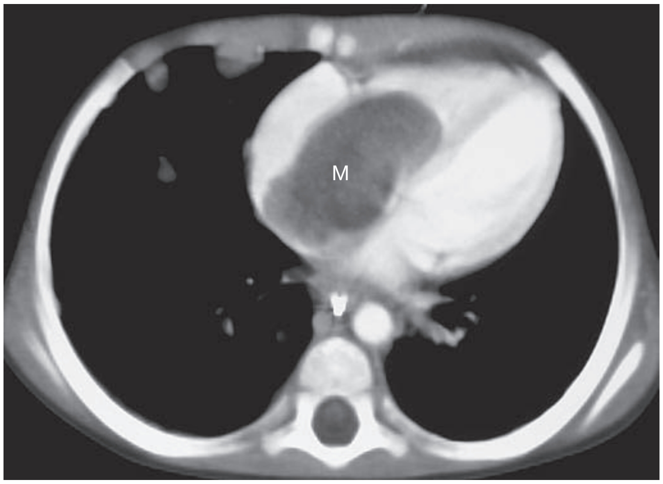
**e-Figure 80.12, cont'd.** (B) Coronal fast spin echo (B1–B3) and axial T2-weighted MR images (B4–B6) show the pericardial effusion and a slightly hyperintense mass *(arrows)* on T2-weighted images.



**e-Figure 80.13. Primary cardiac lymphoma in a child.** Coronal (A) and axial (B) contrast-enhanced CT images show a low-attenuation mass *(M)* involving the pericardium (*arrows* in B) and right heart.



**e-Figure 80.14. Kaposiform hemangioendothelioma in a 1-month-old child who presented initially with a pericardial effusion.** Coronal T1-weighted precontrast (A, B) and postcontrast (C, D) MR images show an infiltrative enhancing vascular mass encasing the great vessels and airway *(arrows)*.



**e-Figure 80.15. Wilms tumor thrombus extending into the heart in a child.** Contrast-enhanced CT image shows a right atrial mass *(M)* that prolapses across the tricuspid valve in a child with Wilms tumor. Lung metastases also are evident in the right lung.

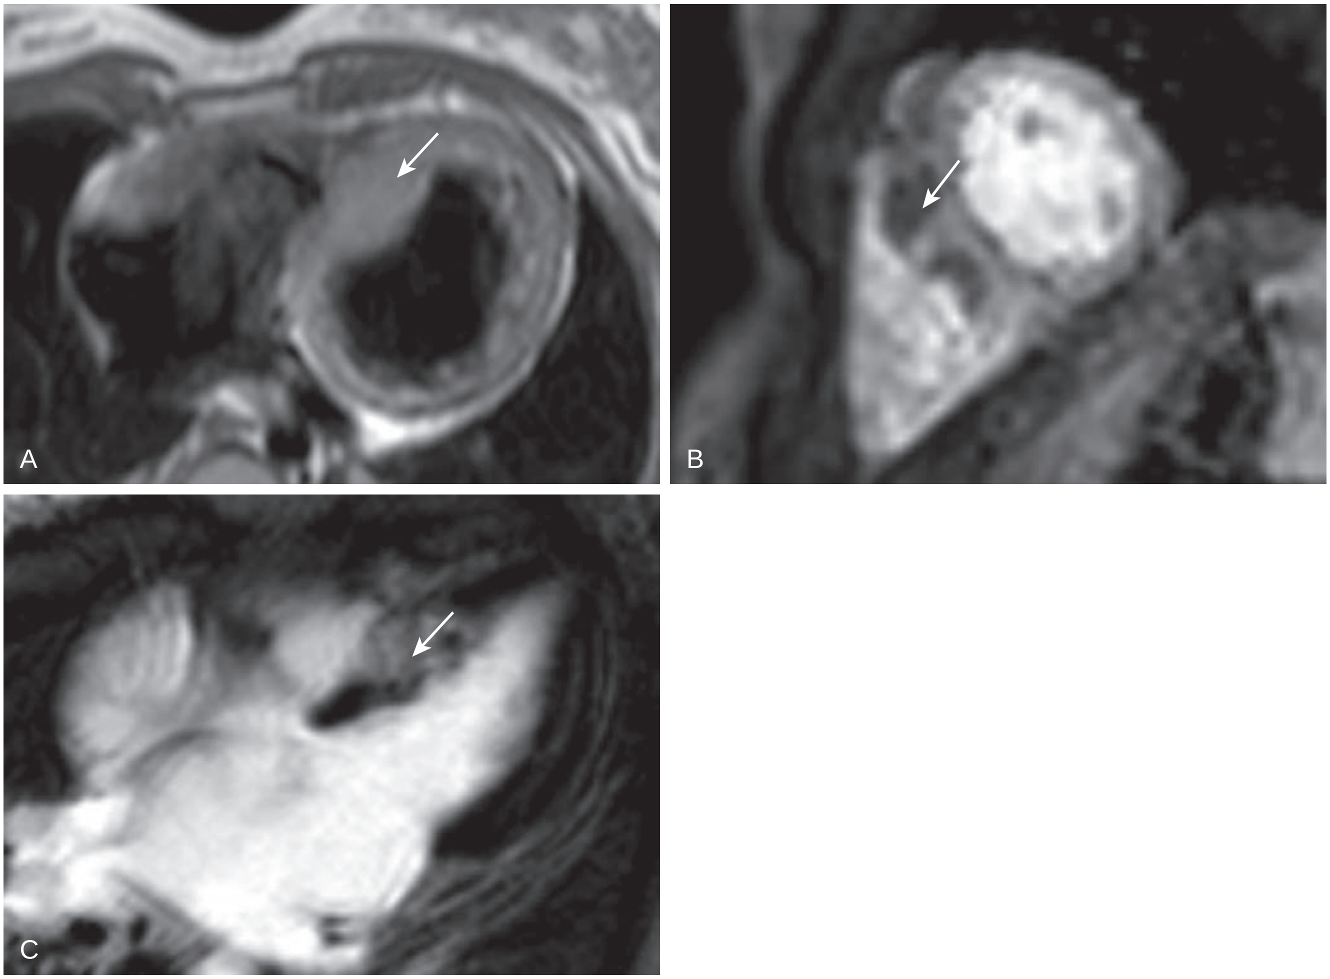


**Figure 80.16. Masslike hypertrophic cardiomyopathy in a 16-year-old girl who presented with cardiac arrest.** MRI shows an interventricular mass *(arrow),* which is (A) isointense to myocardium on T1-weighted imaging, (B) has patchy decreased first pass perfusion, and (C) shows patchy delayed enhancement on phase sensitive inversion recovery imaging.

## NON-NEOPLASTIC MIMICS OF CARDIAC TUMORS

Several entities may be mistaken for a cardiac tumor on echocardiography and on cross-sectional imaging. Masslike hypertrophic cardiomyopathy typically occurs in an older child and may present with or have a family history of cardiac arrest.[30] MRI may show patchy perfusion and delayed enhancement (Fig. 80.16). Adherent thrombus can be mistaken for myxoma on echocardiography. Absence of delayed enhancement on MRI (using standard and prolonged inversion times) is a helpful differentiator.[31] The crista terminalis is a common mimic of a cardiac tumor on CT and can be mistaken for right atrial mass or thrombus.[32] It can be distinguished on CT as a focal low-density attenuation structure.

### KEY POINTS

- Cardiac tumors are rare in children.
- Rhabdomyomas are the most common tumor in children and frequently are associated with tuberous sclerosis.
- Fibromas have a characteristic appearance on postcontrast-delayed imaging.
- Metastatic tumors in children are more common than primary cardiac malignancies.

# 81

# Cardiovascular Involvement by Systemic Diseases

Beverley Newman, Alexander J. Towbin, and Frandics P. Chan

Numerous systemic diseases can affect the heart and great vessels and are important causes of cardiac dysfunction. These systemic diseases include both prenatal and postnatal toxic and infectious exposures (e-Fig. 81.1); adverse effects of therapeutic agents; and various nutritional, metabolic, inflammatory, granulomatous, and autoimmune entities. Endocrine, circulatory, and blood disorders frequently have secondary cardiac effects. Primary cardiac tumors can occur in association with underlying systemic disorders; although rare, neoplasms elsewhere can metastasize to the heart or locally invade the great vessels or pericardium. Congenital and acquired neurologic and musculoskeletal conditions that affect the chest are associated with structural and functional cardiac abnormalities.

These entities and the spectrum of their cardiac effects are outlined in Table 81.1. We have included both common diseases that have cardiovascular features and uncommon lesions in which cardiovascular manifestations are prominent. A small number of selected entities are discussed in the following sections. Many of the lesions outlined in Table 81.1 overlap with other chapters and thus are not specifically discussed here.

## INFECTIOUS, INFLAMMATORY, AND AUTOIMMUNE DISORDERS

### Infectious Aortitis

***Overview.*** Acute infectious aortitis in children is usually caused by bacterial septicemia originating from infected lines and intravascular devices and from valvular endocarditis or occasionally by direct spread from an adjacent infection or abscess.[1] Staphylococci and streptococci are the organisms most frequently responsible for acute infectious aortitis.[1,2] Predisposing conditions include congenital heart disease and an immunocompromised state. Once they are in the bloodstream, virulent organisms may adhere to and invade the aortic wall. The resulting inflammation leads to suppurative necrosis that weakens the aortic wall and forms an aneurysm (Fig. 81.2A). A contained leak may lead to pseudoaneurysm formation (Fig. 81.2B). Staphylococcal aortitis is particularly prone to aneurysm or pseudoaneurysm rupture and is the most serious complication of infectious aortitis. Fungi, especially Aspergillus or Candida, also may be the cause of infectious aortitis, especially in immune-compromised individuals.[3] Syphilitic and tuberculous aortic aneurysms are rare complications of chronic infection by those organisms and are very uncommon in children.

Diagnosis of infectious aortitis is difficult because presenting symptoms are often minor or nonspecific, such as fever and abdominal or back pain. Common laboratory markers of infection can be normal. One adult study showed that blood cultures were negative in 28% of cases and white blood cell counts were normal in 42% of cases; however, an elevated erythrocyte sedimentation rate, a nonspecific finding of inflammation, was found in 92% of patients.[2]

***Imaging.*** Few clinical studies have evaluated the imaging appearance and distribution of infected aortic aneurysms in children. Experience from adult patients suggests that these aneurysms are more often saccular (93%) than fusiform (7%) and can be distributed throughout the course of the aorta: 6% in the ascending aorta, 23% in the descending thoracic aorta, 19% in the thoracoabdominal aorta, 10% in the juxtarenal aorta, and 32% in the infrarenal aorta.[4] Periaortic fluid, stranding, or a soft tissue mass was present in 48% of patients with infectious aortitis. Periaortic gas, a specific sign, was present in only 7%. Rapid progression of aneurysm size was found in infected aneurysms in both adults and children.[4] Computed tomography angiography (CTA) and magnetic resonance angiography (MRA) imaging have largely supplanted conventional angiography in the diagnosis of aortic aneurysms and their complications (see Fig. 81.2). Ultrasound may be an initial screening examination but usually is not definitive enough to support management decisions.

***Treatment.*** Antibiotic treatment with the goal of eradicating the offending organism is the first step in the treatment of infectious aortitis.[2] At the same time, imaging to document stability of the aortic lumen is necessary. If an aneurysm has formed, it should be surgically repaired after an adequate period of antibiotic treatment.[1,2] Deployment of endovascular stent grafts in infected aortic aneurysms has been attempted.[5] Although this is not considered a treatment of choice, it may be useful to act as a bridge to open surgical repair, especially in the presence of low-virulence organisms or rapidly expanding aneurysms.

### Takayasu Arteritis

***Overview.*** Takayasu arteritis, also known as pulseless arteritis, is a chronic inflammatory arteritis of large vessels.[6] The aorta is most commonly involved: 59% to 75% of cases affect the abdominal aorta and branches, and 40% to 56% of cases involve the thoracic aorta. Pulmonary and coronary arteries can also be involved.[7] Takayasu arteritis is a rare disease, occurring in 2.6 per 1 million people in North America.[8] It is more common in patients of Asian descent, and females make up 80% to 90% of patients.

The diagnosis of Takayasu arteritis is based on patient symptoms, physical findings, clinical laboratory values, serologic markers, and vascular findings.[6] The American College of Rheumatology criteria include arm or leg claudication, age less than 40 years, a blood pressure difference between extremities of greater than 10 mm Hg, a subclavian or aortic bruit, a decreased brachial artery pulse, and aortic or branch narrowing.[9] Three of these criteria provide a diagnosis of Takayasu arteritis with a sensitivity of 90.5% and a specificity of 97.8%.[8] Other clinical manifestations of Takayasu arteritis that are not specific diagnostic criteria include fever, headache, stroke, postural dizziness, arthralgias, weight loss, myalgias, and systemic or pulmonary hypertension.[8,10]

Takayasu arteritis has a triphasic pattern: a systemic nonvascular phase, a vascular inflammatory phase, and a quiescent “burnt-out” phase, although the inflammatory and fibrotic changes often overlap.[7,8] In children, the correct diagnosis is frequently delayed, especially when systemic symptoms predominate.[8,10,11]

The lesions of Takayasu arteritis are segmental with a patchy distribution. The vasculitis can lead to stenosis, occlusion, and aneurysm formation.[7] Severe stenosis or occlusive thrombosis of the pulmonary vasculature may lead to pulmonary infarction and pulmonary hypertension.[12] Cardiac symptoms include aortic regurgitation, dilated cardiomyopathy, myocarditis, pericarditis, congestive heart failure, and myocardial ischemia.

***Etiology and Classification.*** The specific cause of Takayasu arteritis is unknown, but it is probably a T-cell–mediated autoimmune

## Abstract:

Cardiovascular disease accompanies many systemic conditions. These include the adverse effects of toxins/drugs, metabolic, infectious/inflammatory and autoimmune diseases as well as nutritional, endocrine, circulatory, neoplastic and neuro/musculoskeletal conditions. A select number of these diseases are discussed and their imaging manifestations illustrated in this chapter. Many other entities with associated cardiovascular manifestations are summarized in tabular form.

**e-Figure 81.1. Fetal alcohol syndrome and aortic coarctation in a 4-year-old boy.** (A) Chest radiograph shows a prominent aortic arch and descending aorta. Notching of the posterior left sixth rib *(arrow)* from an intercostal aortic collateral vessel is present. (B) Oblique sagittal three-dimansional MRA image demonstrates marked coarctation of the aorta *(arrow)* distal to the left subclavian artery. Multiple large intercostal collateral vessels are present, as well as enlarged internal mammary collaterals *(arrowhead).*

**TABLE 81.1** Cardiovascular Manifestations of Systemic Diseases or Disorders

| Disease or Disorder Category | Cardiovascular Manifestations |
|---|---|
| **TOXINS/DRUGS** | |
| Carbon monoxide | Tachycardia, noncardiogenic pulmonary edema |
| Doxorubicin (Adriamycin) | Cardiomyopathy, CHF |
| Fetal alcohol exposure (e-Fig. 81.1) | ASD, VSD, PDA, COA, arch interruption, PA hypoplasia, DORV, DEXTRO, TOF |
| HAART (used to treat HIV) | Cardiomyopathy, CHF |
| Iron | Cardiomyopathy, CHF |
| Lead | Myocarditis, atherosclerosis |
| Radiation | Cardiomyopathy, MI, pericarditis, valvular disease, especially aortic |
| Steroids (chronic) | Cardiomyopathy, CHF, cardiomegaly |
| Theophylline | Arrhythmias |
| **METABOLIC** | |
| Alkaptonuria | CAD, aortic and mitral valvulitis |
| Amyloidosis | Cardiomyopathy, CHF, arrhythmias |
| Carnitine deficiency | Dilated cardiomyopathy, CHF, endocardial fibroelastosis |
| Fabry disease | Cardiomyopathy, mitral valve disease, thromboembolism, arrhythmias, coronary aneurysm |
| Glycogen storage disease | |
| Type II (Pompe disease) | Cardiomyopathy, CHF, outflow tract obstruction |
| Type III | Hypertrophic cardiomyopathy |
| Type IV | Dilated cardiomyopathy |
| Danon disease (lysosomal glycogen-storage disease) | Hypertrophic cardiomyopathy |
| Hemochromatosis | Cardiomyopathy, arrhythmia, CHF |
| Gaucher disease (cerebroside lipidosis) | Cardiomyopathy, MR, MS, AS, coagulopathy |
| GM1 gangliosidosis | Infantile cardiomyopathy |
| Homocystinuria | Vascular stenoses and occlusions, aneurysms, thromboembolic episodes |
| Long-chain acetyl CoA dehydrogenase deficiency | Cardiomyopathy |
| Mucolipidosis III | AR, cardiomyopathy |
| Mucopolysaccharidosis | |
| IH (Hurler syndrome) | Acute cardiomyopathy associated with endocardial fibroelastosis, AR, MR, coronary narrowing |
| IS (Scheie) | AS, MS |
| II (Hunter syndrome) | AR |
| III (Sanfilippo syndrome) | Functional and morphologic mitral valve deterioration |
| IV (Morquio syndrome) | AR, MR, CAD |
| VI (Maroteaux–Lamy syndrome) | AS, MS |
| Oncocytic (histiocytoid) cardiomyopathy (infantile histiocytic cardiomyopathy, Purkinje cell tumor, focal lipid cardiomyopathy, idiopathic infantile cardiomyopathy) | Cardiomyopathy, ASD, VSD, nodular deposits on the ventricular endocardium or valves |
| Pseudoxanthoma elasticum | Premature atherosclerosis, MI, restrictive cardiomyopathy, mitral valve disease, AO dilation, vascular, coronary occlusions |
| Refsum disease (phytanic acid $\alpha$-oxidase deficiency) | CHF, cardiomyopathy, conduction abnormality |
| Sitosterolemia (inherited plant sterol storage disease) | CAD, MI, CHF |
| Uremia | Pericardial effusion, constrictive pericarditis, CHF, cardiomyopathy |
| **GRANULOMATOUS** | |
| Histoplasmosis | Pericardial effusion, tamponade, AR, endocarditis, fibrosing mediastinitis |
| Sarcoid | Infiltrative cardiomyopathy, pericardial effusion, papillary muscle dysfunction, valvular disease, fibrosing mediastinitis, large-vessel vasculitis |
| Tuberculosis | Myocarditis, ventricular aneurysms, calcific/constrictive pericarditis, fibrosing mediastinitis, vasculitis |
| Wegener granulomatosis | Pulmonary vasculitis, pericarditis, coronary arteritis, MI |
| **INFECTIOUS/INFLAMMATORY/AUTOIMMUNE/CONNECTIVE TISSUE DISORDERS** | |
| Aortitis (infectious) (Fig. 81.2) | Abscess, aneurysm, leak, pseudoaneurysm, rupture |
| Behçet syndrome | Aortic, pulmonary and coronary vasculitis and aneurysms, cardiac valvular vegetations |
| Chagas disease *(Trypanosoma cruzi)* | Myocarditis, CHF, apical aneurysm |
| Dermatomyositis | Cardiomyopathy |
| Diphtheria | Cardiomyopathy, myocarditis |
| Enterovirus (Coxsackie B) | Myocarditis |
| Fetal rubella infection | PDA, pulmonary artery stenosis, COA, ASD, VSD, myocarditis, cardiomyopathy |
| HIV | Cardiomyopathy, CHF |
| Juvenile rheumatoid arthritis | Pericarditis, myocarditis, CHF |
| Kawasaki disease | Coronary artery aneurysm, coronary thrombosis, MR, papillary muscle dysfunction, MI, myocarditis, CHF, pericarditis, AR, systemic vasculitis |
| Polyarteritis nodosa | Cardiomyopathy, pericarditis, coronary artery aneurysms, MI, systemic vasculitis |
| Relapsing polychondritis | CM, AO dilation/aneurysm, AR, TR, MR |
| Rheumatic fever | Pancarditis, valve insufficiency, CHF, valvular stenosis (MS, AS, TS), atrial dilation, left atrial thrombus, constrictive pericarditis |
| Scleroderma | CM, pericarditis, myocarditis, conduction abnormality, cor pulmonale |

**TABLE 81.1** Cardiovascular Manifestations of Systemic Diseases or Disorders—cont'd

| Disease or Disorder Category | Cardiovascular Manifestations |
|---|---|
| Systemic lupus erythematosus | Pericarditis, cardiomyopathy, Libman-Sacks endocarditis, heart block, endocardial fibroelastosis, systemic/coronary vasculitis |
| Takayasu arteritis (Fig. 81.3, e-Fig. 81.4, and Fig. 81.5) | Widened mediastinum, AR, CHF, myocarditis, aortitis, pulmonary/coronary vasculitis, aneurysms, stenoses |
| Toxoplasmosis | Myocarditis |
| **MALNUTRITION** | |
| Anorexia | Decreased ventricular mass, MVP |
| Bulimia | Arrest, cardiac rupture, pneumomediastinum |
| Marasmus | Thinning of cardiac muscle, CHF, CHD |
| Obesity | CM, pulmonary hypertension, early atherosclerotic disease |
| Selenium deficiency (Keshan disease) | Congestive cardiomyopathy, cardiogenic shock, CHF |
| Vitamin $B_1$ (thiamine) deficiency (beriberi) | Cardiomyopathy, CHF |
| **CARDIAC TUMORS ASSOCIATED WITH SYSTEMIC DISEASE** | |
| Fibromas (in Beckwith–Wiedemann syndrome, nevoid basal cell carcinoma syndrome, or Gorlin syndrome) | Cardiomyopathy, CHF, mass most commonly originates at the intraventricular septum, occasional calcification in the tumor |
| Myxomas (in Carney complex, LAMB/NAME syndrome) (e-Fig. 81.9) | Attached to atrial septum and mitral apparatus in LA, can prolapse or embolize, multiple, can occur in any cardiac chamber, can recur at distant intracardiac and extracardiac sites, intracardiac valvular obstruction leading to CHF |
| Rhabdomyomas (in tuberous sclerosis) | Multiple intramural hamartomas, present in utero, abnormal valve function, outflow obstruction, cardiomyopathy, spontaneously regress |
| **METASTASES** | |
| Lymphoma | Great vessel obstruction, SVC syndrome, CHF, pericardial infiltration |
| Wilms tumor (hepatoblastoma less commonly) (e-Fig. 81.10) | IVC extension, CHF, cardiomyopathy |
| **ENDOCRINE** | |
| Cushing disease | Cardiomyopathy, blood vessel fragility |
| Diabetes (acquired) | Early CAD |
| Diabetes, gestational (infant of a diabetic mother) (Fig. 81.6) | Cardiomyopathy, cardiovisceral or atrioventricular discordance, outflow tract anomalies, TGA, AVSD, DiGeorge complex |
| Gigantism/acromegaly | Cardiac hypertrophy, LVH |
| Hyperthyroidism | CHF, cardiomyopathy |
| Hypothyroidism | Pericardial effusion, CHF |
| **CIRCULATORY/BLOOD DISORDERS** | |
| Arteriovenous fistula (especially vein of Galen malformation, HHT, and infantile hepatic hemangioma) (e-Fig. 81.11) | CHF, high output; HHT: skin, visceral, single or multiple pulmonary AVM, angiodysplasia, coronary ectasia, Kasabach–Merritt syndrome (platelet trapping and consumptive coagulopathy) |
| Fanconi anemia | PDA, VSD, peripheral PS, cardiomyopathy, ASD, TOF, AS, COA, AO atheromas, hypoplastic AO, double AO arch |
| Hepatopulmonary syndrome (chronic liver disease, hypoxemia, clubbing) | Pulmonary capillary microshunts, vasodilation, CHF—high output |
| Portopulmonary syndrome (Abernethy malformation): hepatopulmonary syndrome with no liver disease, portosystemic shunting | Type I abnormal portal-systemic connection; absent intrahepatic portal vein; associated with VSD, AO arch anomalies<br>Type II abnormal portal-systemic connection; intrahepatic portal vein present |
| Leukemia | SVC syndrome, cardiomyopathy, CHF, pericardial effusion |
| Polycythemia vera | MI, arterial and venous clots, CHF |
| Sickle cell disease (Fig. 81.7) | Cardiomyopathy, MI, acute chest syndrome, CHF, vascular thromboses |
| Thalassemia (Fig. 81.8) | CHF, cardiomyopathy, iron overload |

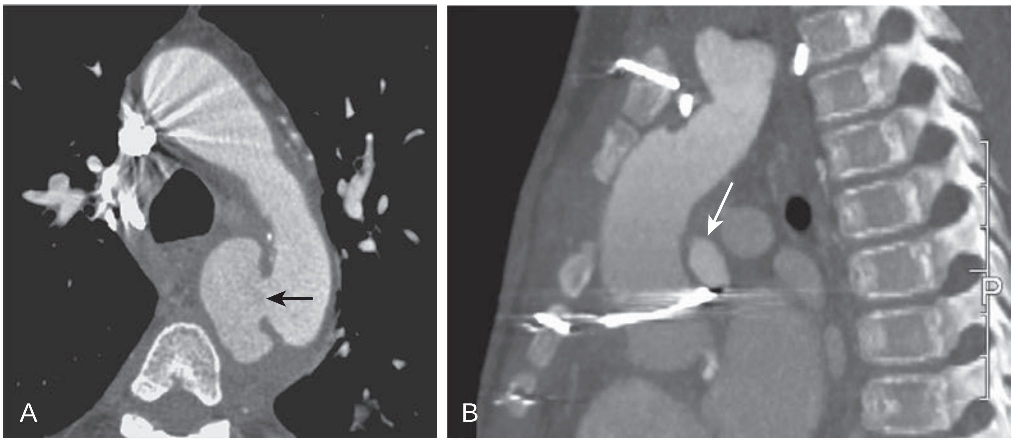

**Figure 81.2. Infectious aortitis.** (A) Axial CTA image shows a thick-walled saccular aneurysm communicating with the aortic arch through a narrow opening *(arrow).* (B) An 8-year-old child after repair of aortic coarctation and aortic stenosis with prosthetic aortic valve replacement whose postoperative course was complicated by *Staphylococcus aureus* mediastinitis. Sagittal maximal-intensity projection image from a gated CTA demonstrates a small posterior aortic pseudoaneurysm *(arrow)* adjacent to the aortic valve. Note diffuse anterior soft tissue edema/inflammation.

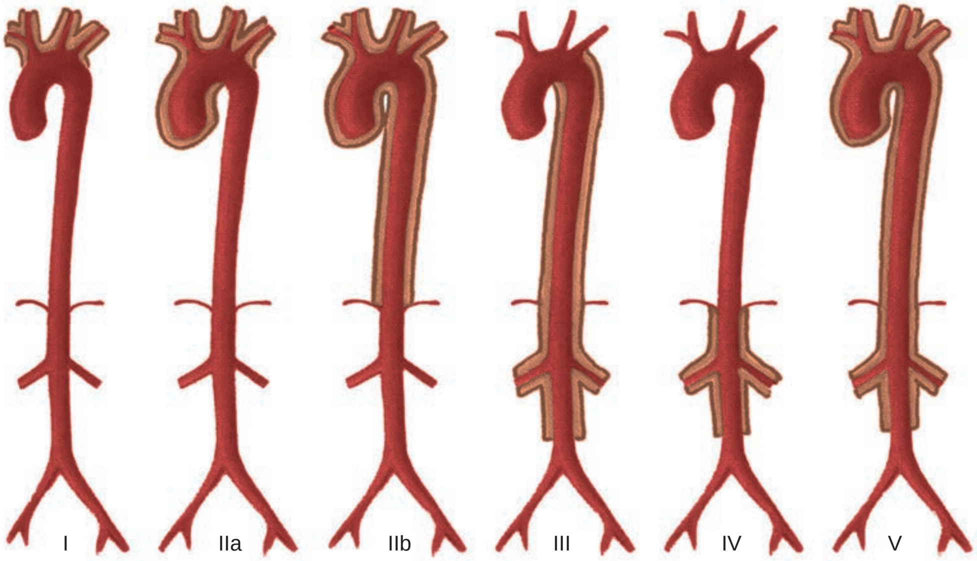

**Figure 81.3. Classification schema of Takayasu arteritis.** Coronary (C+) and/or pulmonary (P+) involvement can occur in all types. Type I involves aortic arch branches only; type IIa involves the ascending aorta, arch, and branches; type IIb involves the descending thoracic aorta, with or without involvement of the ascending aorta, arch, and branches; type III involves the descending thoracic aorta, abdominal aorta, and the renal arteries; type IV involves the abdominal vessels only; and type V is generalized. *(From Nastri MV, Baptista LPS, Baroni RH, et al. Gadolinium-enhanced three-dimensional MR angiography of Takayasu arteritis.* Radiographics*. 2004;24:773–786.)*

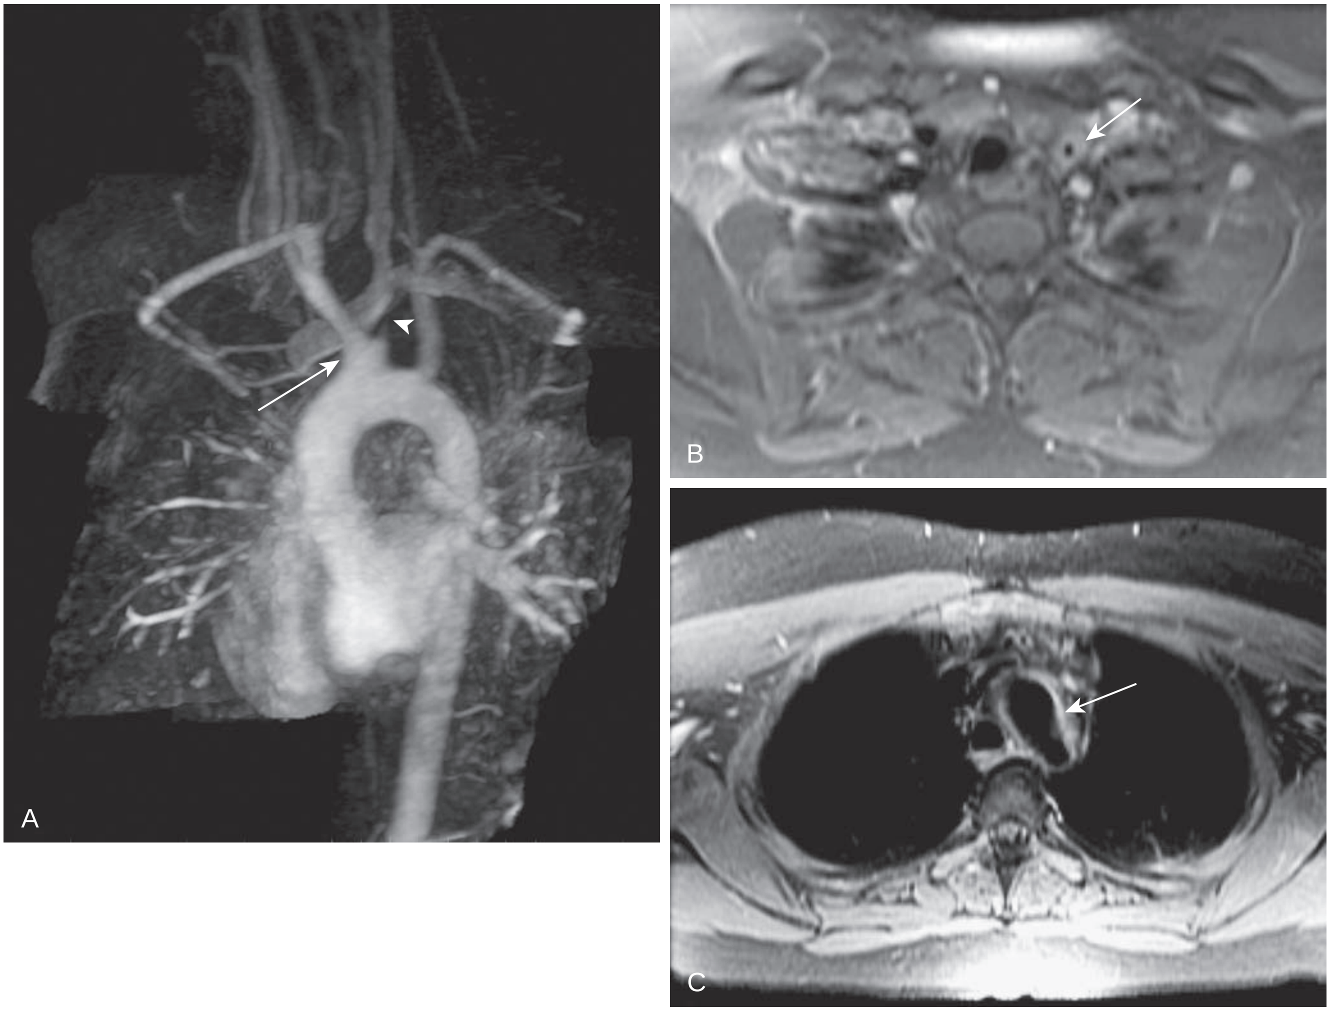
process. Infection, particularly tuberculosis, has been linked to the development of Takayasu arteritis, especially in children.[10] The diseased vessel wall is thickened and shows granulomatous changes from the adventitia to the media. Giant cell (or temporal) arteritis has an identical pathologic appearance to Takayasu arteritis but affects an older population and typically involves the temporal artery.[13]

Takayasu arteritis currently is divided into six types depending on the location of aortic involvement. Coronary (C+) or pulmonary (P+) involvement may occur in all types (Fig. 81.3).[7]

***Imaging.*** Vascular stenosis and aneurysm are the primary causes of mortality and morbidity and therefore should be evaluated with angiographic techniques. Conventional angiography has been the gold standard for diagnosis, but it is being supplanted by MRA (e-Fig. 81.4 and Fig. 81.5).[7,8] MRA has several advantages, including its lack of ionizing radiation, its noninvasive nature, and its ability to show abnormal vascular wall signal and thickening before luminal narrowing becomes apparent.[6] Active inflammation is suggested when a high T2 signal is noted within the vessel wall (Fig. 81.5). Vessel wall enhancement can be seen with the administration of gadolinium and also is used to gauge the activity of the inflammatory process (e-Fig. 81.4).[7,8,11] Inversion recovery delayed enhancement of the vessel wall also may be seen; the significance of this phenomenon is uncertain.[8]



**e-Figure 81.4. Takayasu arteritis type IIa in a 14-year-old girl with active disease.** (A) Oblique sagittal, thin, maximal-intensity projection MRA image shows a common origin of the left common carotid artery and the brachiocephalic artery *(arrow).* Severe stenosis of the left common carotid artery is present at its origin *(arrowhead),* with only a small amount of flow extending superiorly. (B) T1-weighted axial MRI with contrast shows thickening and enhancement of the wall of the left common carotid artery *(arrow).* (C) T1-weighted axial MRI with contrast shows thickening and enhancement of the wall of the aortic arch *(arrow),* suggestive of active inflammation.

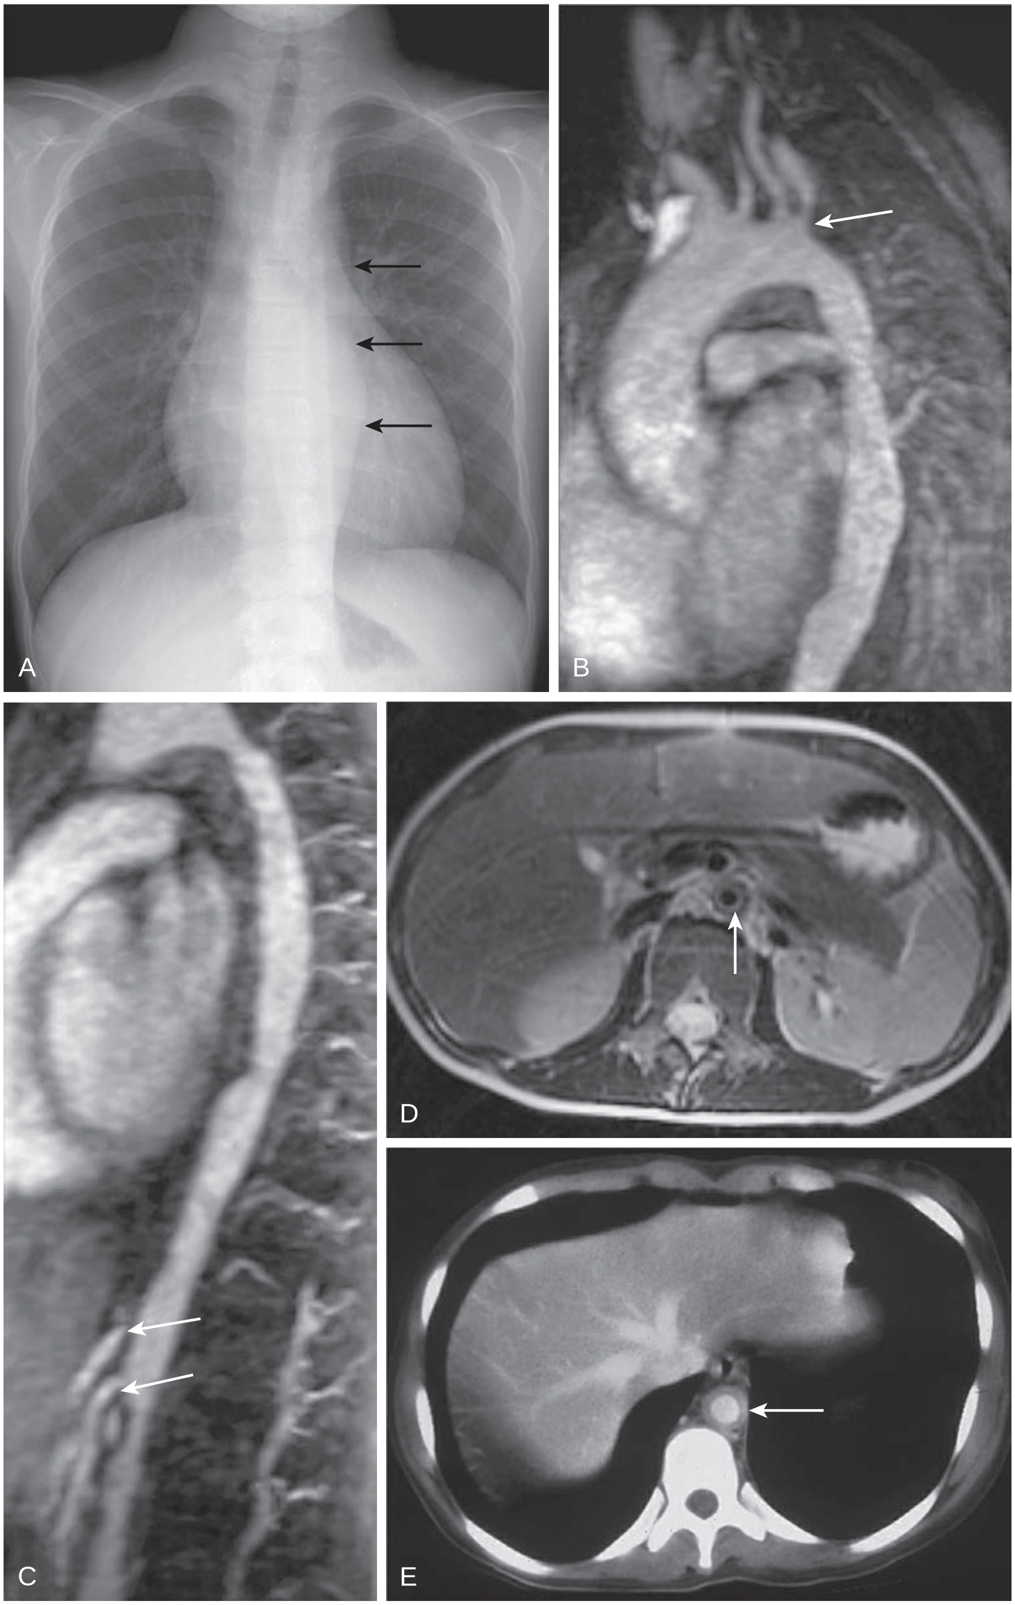


**Figure 81.5. Takayasu arteritis type V in a 11-year-old girl.** (A) Chest radiograph shows a heart that is top-normal in size and there is an abnormal wavy contour to the descending thoracic aorta *(arrows).* (B) Oblique sagittal thin maximal-intensity projection (MIP) MRA image shows four vessels arising from the aortic arch: the right brachiocephalic artery, left common carotid artery, left vertebral artery, and left subclavian artery. Stenosis is present at the origin of the left subclavian artery *(arrow)* along with areas of stenosis and aneurysmal dilation of the visible portions of the descending aorta. (C) Thin sagittal MIP MRA image shows an irregular contour and narrowing of the descending aorta, as well as at the origins of the celiac and the superior mesenteric arteries *(arrows).* (D) T2-weighted axial MRI shows increased signal and thickening of the wall with a narrowed lumen *(arrow)* of the inframesenteric abdominal aorta. (E) A contrast-enhanced CT image of a different patient shows wall thickening and enhancement *(arrow)* of the abdominal aorta.

Ultrasound can show vessel wall thickening and CTA may demonstrate mural thickening and wall enhancement, as well as luminal dilation, narrowing, or occlusion (Fig. 81.5).[6] Fluorodeoxyglucose positron emission tomography uptake also may be useful in evaluating active inflammation.[6,8]

***Treatment and Follow-up.*** Medical therapy of Takayasu arteritis initially focuses on the suppression of the immunologic responses with corticosteroids, methotrexate, azathioprine, and cyclophosphamide. In refractory Takayasu arteritis, the anti–tumor necrosis factor–α agents etanercept and infliximab have been used to achieve sustained remission.[14] Follow-up with MRA or CTA helps document stability or progression of the vascular abnormalities and their complications.[6,11]

Patients with renovascular hypertension, severe coarctation of the aorta, claudication, progressive aneurysm enlargement, coronary artery disease, or cervicocranial vessel stenosis may benefit from surgical revascularization.[10] Bypass grafts, either synthetic or autologous, can be used, but restenosis is common: up to one-third of synthetic graft cases and approximately 10% of autologous vessel cases. Other postoperative complications include heart failure, intractable hypertension, and graft deterioration with pseudoaneurysm formation. Postsurgical anastomotic aneurysm formation is seen in up to 34% of patients. Angioplasty of Takayasu vascular stenoses has an initial success rate of 92% and a restenosis rate of 22%. Surgical options preferably are performed during disease remission.[10]

### Other Vasculitides

Aneurysmal disease of the aorta, which generally afflicts older patients, is a rare complication of systemic lupus erythematosus. The exact pathophysiology of the aortic aneurysm is unknown. It may be caused directly by the systemic lupus erythematosus–related inflammation of the vessel wall or as a result of chronic steroid treatment and the resultant accelerated aortic atherosclerosis.[15] Sarcoidosis has been reported as a rare cause of large-vessel vascular stenosis, and it has been recommended that children with early-onset sarcoidosis be evaluated for occlusive arterial disease.[16]

Other rare causes of vasculitis, especially of the pulmonary artery, include Behçet syndrome and Wegener granulomatosis.[9,17] Behçet syndrome is a multisystem inflammatory disease of unknown cause. Classically, Behçet syndrome describes a combination of recurrent aphthous ulcers, genital ulceration, and uveitis. It also involves the central nervous system in 10% to 30% of cases and the vascular system (including systemic, pulmonary, and coronary vessels) in 10% to 40% of cases. Its prevalence in the United States is probably less than 5 cases per 100,000 people, but it is much more common in Turkey, with an estimated prevalence of 100 cases per 100,000 people. Although Behçet syndrome typically is an adult disease, onset in childhood is well recognized. When the pulmonary artery is affected, the most common lesion is pulmonary artery aneurysm. Other findings include pulmonary artery stenosis and thrombosis, pulmonary infarct, and hemorrhage.[18] These lesions are readily evaluated with pulmonary CTA.[17] Treatment is focused on immunosuppression, and resolution of aneurysms has been observed after remission of Behçet syndrome.[18]

## MALNUTRITION

### Anorexia

Anorexia is a common eating disorder characterized by an intense fear of gaining weight, undue influence of body shape or weight on self-image, the refusal to maintain a body weight of greater than 85% of that predicted, and the absence of at least three consecutive menstrual periods. It is 10 times more common in girls and occurs mostly during adolescence.

Cardiovascular complications occur in up to 80% of patients and are the cause of approximately one-third of deaths in this disorder. The most common cardiac abnormality is decreased ventricular wall thickness caused by a loss of cardiac muscle. Other cardiac manifestations include sinus bradycardia, hypotension, arrhythmias, QT-interval prolongation, and even sudden death.[19] These abnormalities are reversible in the early stages of disease.[19,20]

### Obesity

A worldwide epidemic of obesity is occurring among people of all ages.[21] The Obesity Consensus Working Group reported that the prevalence of overweight status has doubled among children 6 to 11 years of age and tripled in those 12 to 17 years of age from 1980 to 2000. Approximately 15% of all 15-year-olds in the United States can be classified as obese (defined as a body mass index greater than the 95th percentile).

Obesity in children has led to an increase in type 2 diabetes mellitus, hypertension, fatty-related liver disease, and possibly asthma. Heart disease is a significant cause of morbidity in obese persons.[21] Excessive adipose accumulation induces increased blood volume and cardiac output, leading to cardiomegaly. Decreased alveolar ventilation and sleep apnea may contribute to both cardiomegaly and pulmonary hypertension (Pickwickian syndrome). Obesity and type 2 diabetes lead to the development of early atherosclerotic disease. It is uncertain whether childhood obesity increases the risk of myocardial infarction or stroke in adulthood.

The high incidence of obesity has led to a corresponding increase in the number of bariatric procedures used to treat patients, including children. Rapid loss of a large amount of weight and decreased absorption of nutrients postoperatively puts individuals at risk for nutritional deficiencies. Beriberi, a disorder of thiamine deficiency, has been reported after gastric bypass surgery.[22] The wet form of beriberi is associated with cardiac failure and edema.

## ENDOCRINE DISORDERS

### Type 1 Diabetes Mellitus

***Overview.*** Type 1 insulin-dependent diabetes mellitus occurs relatively frequently in the United States, developing in an estimated 3 of 1,000 children by age 20 years. Cardiovascular complications are the most common causes of morbidity and mortality in persons with diabetes in childhood and are mainly the result of atherosclerotic disease.[23] Persons with diabetes are more likely than nondiabetic individuals to have severe narrowing of the coronary arteries, stenosis in all three major coronary vessels, and disease in more distal segments.

***Etiology.*** The precise etiology of diabetes is unknown, but it is thought to be an autoimmune disorder of islet cells, possibly related to a prior viral infection. Most children present with polyuria, polydipsia, polyphagia, and weight loss with hyperglycemia, glycosuria, ketonemia, and ketonuria.

### Gestational Diabetes

Gestational diabetes is associated with congenital abnormalities in infants born to affected mothers. The Baltimore-Washington Infant Study found that maternal diabetes was strongly associated with early cardiovascular malformations and with cardiomyopathy.[24] These malformations include defects in early cardiac development such as laterality and cardiac looping defects, outflow tract anomalies with or without transposed great vessels, and atrioventricular septal defects. Maternal diabetes was not associated with obstructive and simple shunt defects.[24]

Visceromegaly, hypoglycemia, and cardiomegaly occur commonly in neonates born to diabetic mothers (Fig. 81.6). The severity of these findings and of congenital heart defects may be related

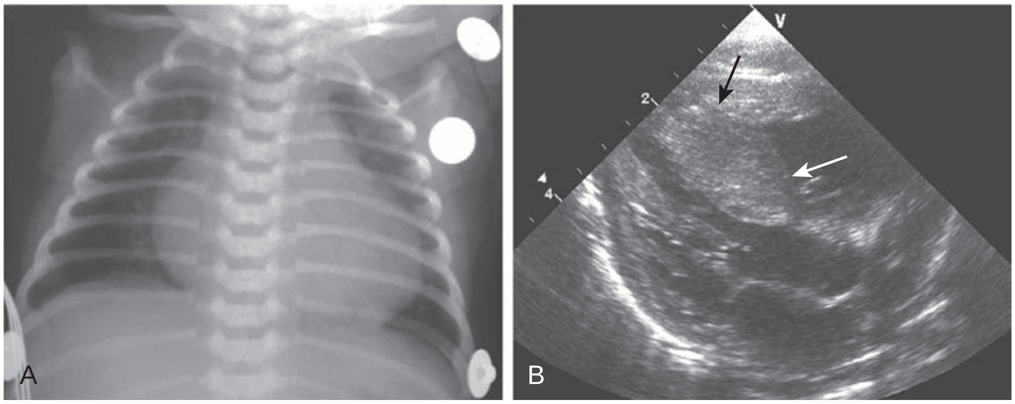

**Figure 81.6. Newborn boy with a diabetic mother.** (A) Chest radiograph shows an enlarged heart and mild congestive heart failure. A hypoplastic left-sided heart malformation was diagnosed on echocardiography. (B) Long-axis echocardiogram from another patient with neonatal diabetic cardiomyopathy shows septal hypertrophy *(arrows),* which partially impinges on the left ventricular outflow tract. *(*B, *Courtesy of Fred Sherman, MD, Children's Hospital of Pittsburgh.)*

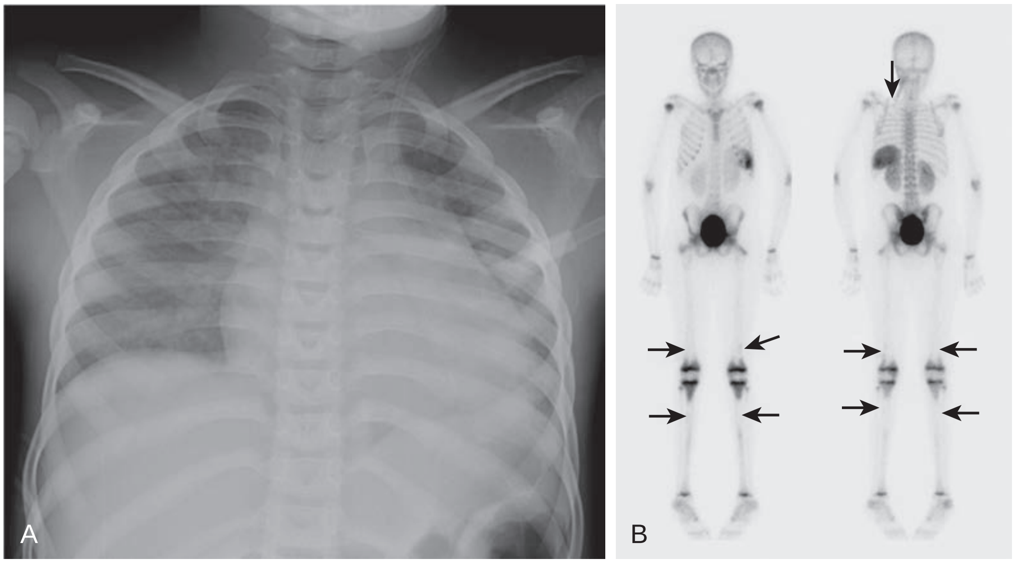

**Figure 81.7. Acute chest syndrome in a patient with sickle cell disease.** (A) Frontal view of the chest in a patient with sickle cell disease shows a new opacity in the left lower lobe and a mildly enlarged heart. (B) Anterior and posterior projection from a technetium-99m methylene-diphosponate bone scan in a different patient shows multiple areas of decreased uptake due to infarcts *(arrows)* in the distal femurs, proximal tibias, and left posterior third rib.

to how well the maternal blood sugar was controlled during pregnancy.[25] Left ventricular septal wall thickening and hypertrophic subaortic stenosis are characteristic and often transient features in affected neonates (Fig. 81.6).

## BLOOD DISORDERS

### Sickle Cell Disease

***Overview.*** Sickle cell disease is the most common single gene disorder of African Americans. Almost 1 in 12 African Americans are heterozygous for the sickle trait. Children with sickle cell disease constitute the largest subgroup of patients with chronic anemia in the United States. Cardiac enlargement is the most common cardiac feature related to the chronic anemia.[26] Cardiomyopathy also may develop from coronary sickling and ischemia, along with cardiac dysfunction resulting from chronic transfusion and myocardial iron deposition.[26,27]

***Imaging.*** Acute chest syndrome is a common cause of hospitalization, morbidity, and mortality in children with sickle cell disease (Fig. 81.7). Clinical presentation includes chest pain, leukocytosis, and fever. Typical chest radiographic manifestations include cardiomegaly, venous congestion, new radiographic opacity (atelectasis or consolidation), and pleural effusion. The inciting etiology is not always apparent, but possibilities include infection, pulmonary sickling and infarction, and fat emboli from marrow infarction. Infection appears to be a more common underlying factor in younger children, whereas infarction is more common in older persons.

Imaging of the chest in children with sickle cell disease depends on the clinical scenario. Plain chest radiographs are the mainstay but can be supplemented with echocardiography, computed

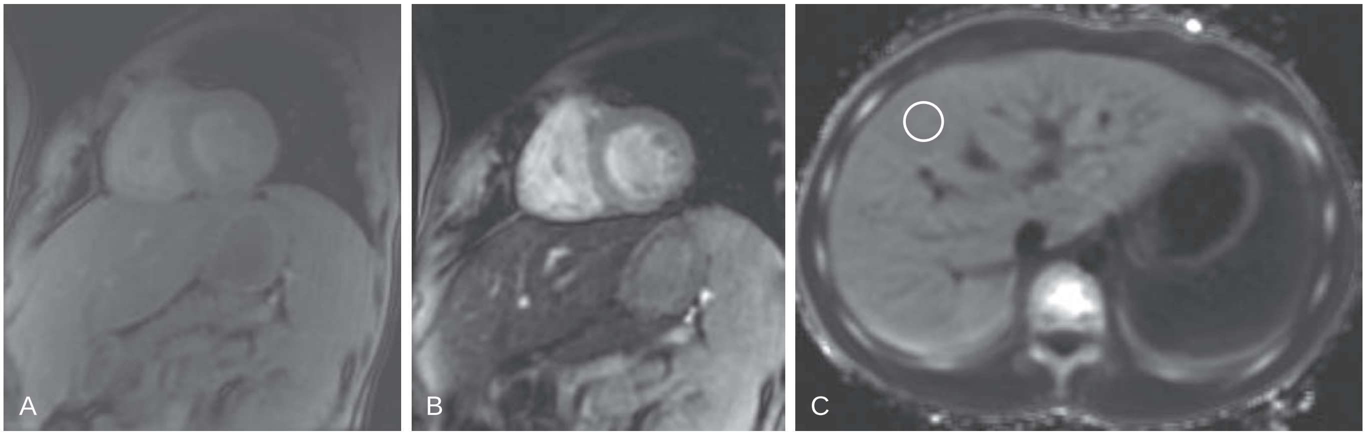

**Figure 81.8. β-Thalassemia in a 14-year-old boy with who has received multiple transfusions.** MRI of the liver and heart was done to evaluate iron deposition. (A and B) Short axis gated, multiecho gradient echo sequence with increasing echo time shows progressive darkening of the liver but not the myocardium. (A) Echo time (TE) 2.2. (B) TE 13.4. (C) An axial R2* map of the liver that was reconstructed from multiple gradient echo images. A region of interest in the liver as shown gave an R2* reading in the liver parenchyma of 124 Hertz. T2* can be calculated as the inverse of R2*, 8.1 msec. This T2* number reflects moderate iron deposition within the liver. Note the absence of iron in the spleen (dark on this image). T2* in the myocardium was similarly calculated (not shown) to be 30 msec (within normal limits).

tomography (CT), magnetic resonance imaging (MRI), or a nuclear scan for such concerns as bone infarcts or osteomyelitis, pulmonary emboli, complicated pulmonary infection, myocardial ischemia or dysfunction, and liver/myocardial iron overload related to repeated transfusion.[27]

Children with sickle cell disease and specific risk factors have been shown to be at risk for myocardial ischemia.[28] Consequences of ischemia include chest pain, heart failure, or a ventricular arrhythmia. Thallium-201 single-photon emission CT scans show that almost one-third of symptomatic children have a fixed perfusion defect. These perfusion defects may not have a specific vascular pattern, suggesting involvement of the cardiac microcirculation.[28]

### Thalassemia

Cardiac manifestations of thalassemia are primarily due to chronic anemia and vary with the severity of the disease.[29] Thalassemia major (homozygous) has more marked hematologic, cardiac, and bone changes than thalassemia minor (heterozygous) and intermedia (the homozygous, milder form). A hyperdynamic circulation and congestive heart failure are the most common clinical cardiac findings.

Cardiomyopathy may develop as a result of ischemia or myocardial iron overload related to chronic transfusion. Widened and coarsely trabeculated rib changes are common in association with red marrow conversion. Extramedullary hematopoiesis occurs commonly in the liver and spleen, as well as paraspinal soft tissues, most often in the lower thoracic region, with resultant visceromegaly and paraspinal soft tissue masses. MRI is useful for serial follow-up of children who undergo chronic transfusion to assess their visceral and myocardial iron burden and cardiac function (Fig. 81.8).

## OTHER SYSTEMIC DISORDERS

Many other systemic disorders affect the cardiovascular system. These disorders are listed in Table 81.1 and e-Figs. 81.9–81.11.

### KEY POINTS

- The diagnosis of infectious and inflammatory vasculitides is often delayed due to nonspecific symptoms.
- MRA and CTA have become the major modalities in evaluating large- and medium-vessel disease.
- Eating disorders and diabetes are increasingly important causes of cardiovascular disease in both the pediatric and adult populations.

# 82 Acquired Diseases of the Thoracic Great Vessels

Cynthia K. Rigsby and Frandics P. Chan

This chapter reviews acquired diseases of the thoracic aorta, venae cavae, pulmonary arteries, and pulmonary veins seen in childhood. Acquired pediatric aortic disease is uncommon, but radiologists and imagers play an important role in the care of these patients. Pulmonary embolism (PE) is the most common acquired disease of the pulmonary artery. The most common acquired abnormalities of the pulmonary veins and venae cavae are obstruction or stenosis caused by luminal occlusion or extrinsic compression from mediastinal pathologies.

## ACQUIRED DISEASES OF THE THORACIC AORTA

Acquired pediatric aortic pathology can be categorized into valvar aortic stenosis (see Chapter 73), aortic aneurysm, aortic dissection, and vasculitis such as Takayasu disease (see Chapter 81).[1] Although aortic diseases may present with one or more of these manifestations, it is the clinical consequences of the abnormalities that determine morbidity and mortality (Table 82.1).

Normally, the caliber of the aorta gradually decreases in size from the sinotubular junction to the aortic hiatus at the level of the diaphragm. An aortic aneurysm is defined as an abnormal dilation of the aorta, which may undergo progressive expansion. An aortic aneurysm may form if aortic wall stress increases, as in the case of systemic hypertension; if the aortic wall is structurally abnormal, as in connective tissue diseases; or due to infection and resultant wall weakening (see Chapter 81). Aortic dissection can occur in children as a complication of trauma or may be related to a connective tissue disease (Fig. 82.1). A dissection is created when blood forces through a tear in the aortic intima and progressively separates the intimal layer from the aortic media, creating a true lumen that originally was connected to the aortic root and a false lumen that was not connected to the aortic root. Dissection can cause end-organ ischemia if the branch arteries supplying the organ are obstructed by the dissection flap. Dissection can weaken the aortic wall sufficiently to cause aortic rupture.

### Trauma

***Overview.*** Trauma is a major cause of death in children and results primarily from motor vehicle accidents, pedestrian versus auto accidents, and falls, although penetrating injuries (Fig. 82.2) and child abuse are other important causes of traumatic death. Survival of a child with a traumatic aortic injury until arrival at the emergency department is rare, accounting for one to two cases per year at large metropolitan level I pediatric trauma centers. Operative treatment involves less than 0.14% of all trauma patients, and only 6% of all traumatic ruptures of the aorta occur in patients younger than 16 years.[2,3] The outcome of traumatic aortic injury in the pediatric population is directly related to timely diagnosis, proper treatment, and hemodynamic status at the time of presentation.

***Imaging.*** Chest radiographic findings such as pleural capping at the left lung apex, obscuration of the aortic arch, mediastinal widening, pleural effusion, pneumothorax, pulmonary contusion, tracheal and nasogastric tube deviation, and upper rib and clavicle fracture in the setting of blunt trauma should raise clinical suspicion for an aortic injury (Fig. 82.3). Historically, the definitive diagnosis of traumatic aortic injury was made by conventional catheter angiography. Today, computed tomographic angiography (CTA) has supplanted catheter angiography as the diagnostic method of choice.[4,5] Care should be taken to identify the location of aortic transection, active extravasation of arterial contrast, a dissection flap extending to major aortic branches, pseudoaneurysm, hemothorax and hemopericardium, and other organ and musculoskeletal injuries.

***Treatment and Imaging Follow-up.*** The goals of treatment of pediatric traumatic aortic rupture are identical to those in adults. The mainstay of treatment is operative repair of the aorta.[6] Patients for whom surgery poses a high risk have been treated successfully with endovascular stent grafts. CTA should be performed immediately after stent placement, with a follow-up study in 48 hours to document the stability of the repair. Observational management has also been utilized in patients with comorbidities too severe to allow intervention.

## ACQUIRED DISEASES OF THE PULMONARY ARTERY

### Pulmonary Embolism

***Overview.*** PE is an uncommon but potentially fatal disease in children.[7] In pediatric patients with deep venous thrombosis and PE, the mortality rate from all causes has been reported to be as high as 16%, whereas the mortality rate directly attributable to deep venous thrombosis or PE is 2.2%.[8] The most common risk factor for PE in children is catheter thrombosis, which develops in as many as 50% of patients with central venous catheters.[9] Other risk factors include peripartum asphyxia, dehydration, septicemia, trauma and burns, surgery, hemolysis, malignancy, immobility, and renal disease such as nephrotic syndrome. Two or more risk factors are often seen in children with PE.[10] Abnormal coagulation factors associated with PE in adults that also have been reported in children are antiphospholipid antibodies, factor V Leiden mutation, and deficiencies in protein S, protein C, and antithrombin III.[11]

The clinical diagnosis of PE is often difficult because, in many cases of venous thrombosis, younger children present with subtle symptoms related to their good cardiopulmonary reserve. Older children most commonly present with pleuritic chest pain. Symptoms of PE may be masked by intrinsic lung disease or other underlying illness. Unlike in adults, a negative D-dimer assay in pediatric patients has not been proven useful to exclude PE. Also, children may have other concomitant illnesses that can raise D-dimer levels, so the specificity of this assay in children is low.[10] A high level of clinical suspicion for PE in the presence of risk factors is imperative.

***Imaging.*** Chest radiographs may show cardiac enlargement, pleural effusions, or peripheral lung opacities, but these findings are not specific for PE. Traditionally, catheter pulmonary angiography was considered the diagnostic gold standard.[12] In current clinical practice, catheter pulmonary angiography has been replaced by noninvasive CT pulmonary angiography (CTPA). The accuracy of the detection of PE by CTPA in an adult population has been studied in the Prospective Investigation of Pulmonary Embolism Diagnosis II trial.[13] With use of CT technology available before 2003, the sensitivity and specificity in this trial were reported as 83% and 96%, respectively.

CTPA is the primary modality used to diagnose PE in children (Fig. 82.4), although its accuracy in children has not been studied by rigorous clinical trials. CTPA in children can be technically

## Abstract:

This chapter reviews acquired diseases of the thoracic aorta, venae cavae, pulmonary arteries, and pulmonary veins seen in childhood. Acquired pediatric aortic disease is uncommon, but radiologists and imagers play an important role in the care of these patients. Pulmonary embolism (PE) is the most common acquired disease of the pulmonary artery. The most common acquired abnormalities of the pulmonary veins and venae cavae are obstruction or stenosis caused by luminal occlusion or extrinsic compression from mediastinal pathologies.

## Keywords:

Pulmonary embolism
aortic trauma
superior vena cava syndrome
acquired pulmonary vein stenosis

**TABLE 82.1** Principal Etiologies of Acquired Aortic Diseases

| Manifestation | Causes |
|---|---|
| Aortic aneurysm | Infectious aortitis |
| | Inflammatory aortitis |
| | Takayasu syndrome (acute, chronic) |
| | Systemic lupus erythematosus |
| | Sarcoid |
| | Connective tissue disease |
| | Marfan syndrome |
| | Ehlers–Danlos syndrome (vascular type) |
| | Loeys–Dietz syndrome |
| | Arterial tortuosity syndrome |
| | Neurocutaneous disease |
| | Tuberous sclerosis |
| | Trauma or postsurgical (pseudoaneurysm) |
| Aortic dissection | Connective tissue disease |
| | Marfan syndrome |
| | Ehlers–Danlos syndrome (vascular type) |
| | Trauma |
| Aortic stenosis | Inflammatory aortitis |
| | Takayasu syndrome (chronic) |
| | Congenital rubella syndrome |
| | Radiation |
| | Neurocutaneous disease |
| | Neurofibromatosis (type I) |
| | *PHACES* syndrome |
| | Postsurgical |
| | Coarctation repair |
| | Aortopulmonary shunts |

*PHACES,* Posterior fossa malformations, hemangiomas, arterial anomalies, cardiac defects, eye abnormalities, sternal cleft and supraumbilical raphe.

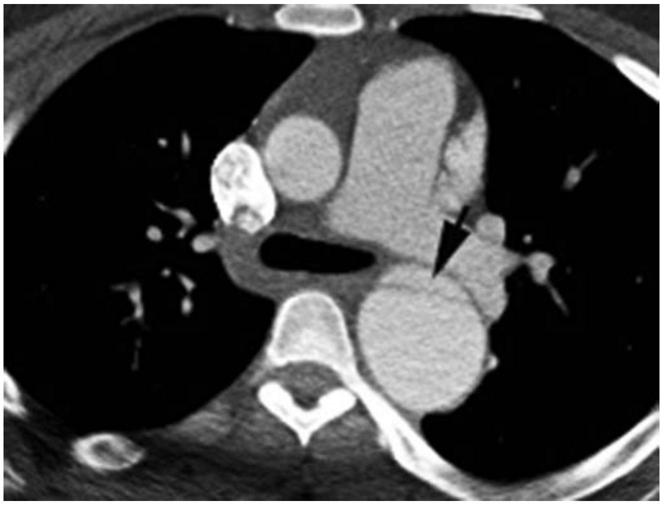

**Figure 82.1. Aortic dissection in a 16-year-old male with Marfan syndrome who presented with chest pain.** Axial CTA image shows the dissection flap *(arrow)* in the dilated proximal descending aorta. The dissection involved the descending aorta from the level of the left subclavian artery through the diaphragm.

challenging because of the size of the pulmonary arteries in small children, their inability to cooperate with breath-holding, and concerns about radiation exposure. The principal strategy for reducing radiation dose is to lower exposure factors such as x-ray tube voltage and tube current. Both maneuvers increase image noise and can confound visual detection of PE. As a result, the CTPA protocol for children requires meticulous attention to optimize spatial resolution, scan speed, and exposure factors.

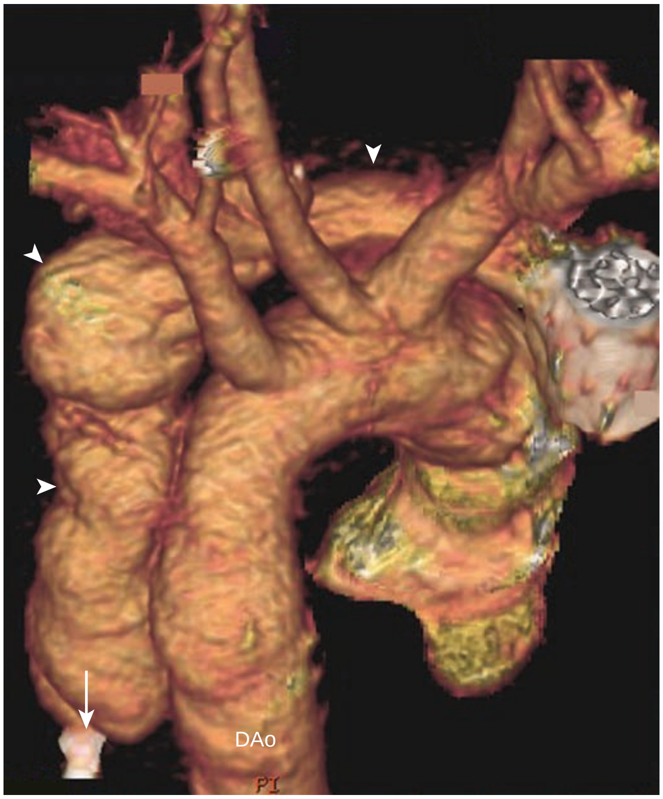

**Figure 82.2. False aortic aneurysm from a gunshot wound in an 18-year-old male.** Volume rendering of a CTA study shows a false aneurysm *(arrowheads)* that follows the track of a bullet. The bullet first entered the chest horizontally, parallel to the aortic arch, rupturing the aorta. Then it was deflected downward and came to rest *(arrow)* adjacent to the descending aorta *(DAo)*.

Dual-energy CT has been recently introduced for evaluation of lung perfusion. This technique involves acquisition of CT data with two different kilovolt potentials and allows for post-acquisition analysis of lung tissue components. For imaging of pulmonary embolism, lung perfusion can be quantified by mapping the injected iodine contrast medium distribution throughout the lungs to assess for perfusion defects. This technique is complimentary to standard CTPA as peripheral perfusion defects can be seen with dual-energy CT that locate smaller peripheral thrombi that may not be seen on standard CTPA. Dual-energy image data can also be selectively analyzed for central pulmonary arteries tissue characterization for the presence of thrombus.[14] MRA has been performed for assessment of PE, but has lower sensitivity (88% relative to CT in adults) for its detection.[15] Scintigraphic ventilation-perfusion scanning was historically used for PE detection, but its use has been supplanted by CTPA.

***Treatment and Follow-up.*** Anticoagulation is the mainstay of medical therapy for PE. Thrombolytic therapy is reserved for patients with hemodynamic instability. Surgical or interventional pulmonary thrombectomy has been successful for treating central or saddle emboli.

PE can also be caused by materials other than bland thrombus. Septic emboli can be the result of endocarditis and of thrombophlebitis. Lemierre syndrome describes jugular vein thrombosis associated with anaerobic infection of the head and neck (classically by *Fusobacterium necrophorum*), and more than 50% of these cases are complicated by septic emboli to the lungs.[16] Tumor emboli may be seen in patients with Wilms tumor, neuroblastoma, osteosarcoma, and hepatocellular carcinoma, because occasionally

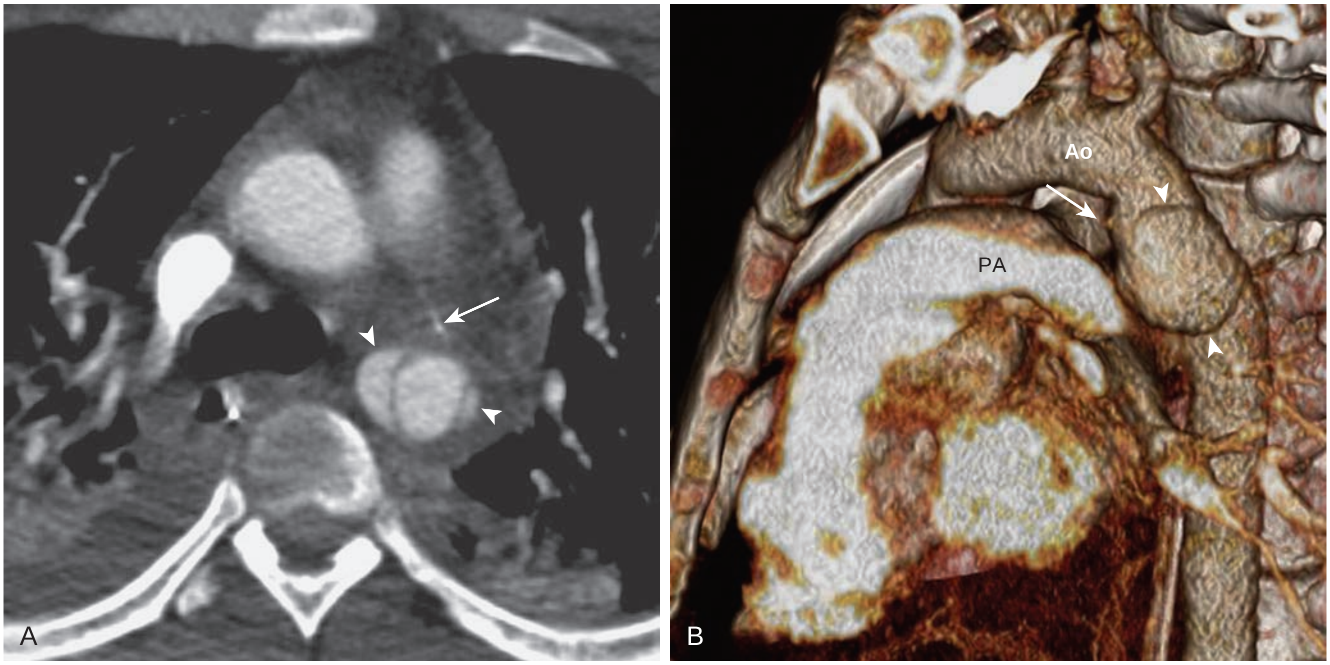

**Figure 82.3. Aortic rupture in a 16-year-old boy as a result of a motor vehicle accident.** (A) Axial CTA image shows a ruptured descending aorta at the level of the ligamentum arteriosum *(arrow)* and two pseudoaneurysms *(arrowheads)* extending beyond the aortic wall. (B) Volume-rendered image from the CTA study shows the relationship between one of the pseudoaneurysms *(arrowheads)* and the ligamentum arteriosum *(arrow)* between the aorta *(Ao)* and the pulmonary trunk *(PA)*.

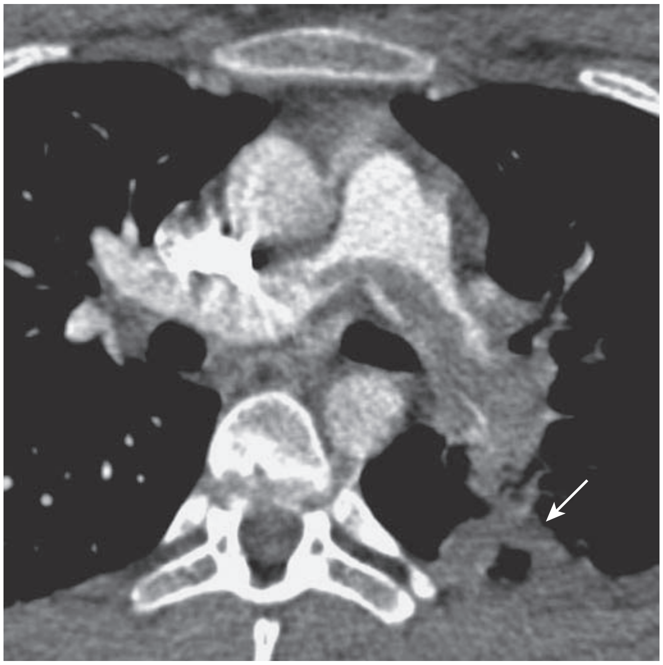

**Figure 82.4. Saddle pulmonary embolus in a 15-year-old girl who recently started taking oral contraceptive pills.** Computed tomography pulmonary angiography (CTPA) image shows a large saddle pulmonary embolism as a filling defect spanning the left and right pulmonary arteries. A peripheral consolidation *(arrow)* is a pulmonary infarction.

these tumors invade the inferior vena cava (IVC) or embolize to the lungs. Rarely, tumor emboli originate from primary cardiac tumors, such as atrial myxomas. Foreign bodies that embolize to the lungs include broken catheter tips and guide wires, misplaced embolization coils, and other endovascular devices. Finally, fat emboli may occur after major orthopedic trauma or surgery.

## ACQUIRED DISEASES OF THE VENAE CAVAE

### Superior Vena Cava Syndrome

***Overview.*** Superior vena cava (SVC) syndrome is a clinical manifestation of gradual obstruction of SVC flow, leading to elevated central venous pressure of the upper extremities and the head, interstitial edema and swelling of the upper body, and development of venous collaterals to the IVC. In children, SVC syndrome is a medical emergency because swelling of the neck can compress and obstruct their small airway more easily than in adults. The most common pediatric cause of SVC syndrome is extrinsic compression of the SVC by non-Hodgkin lymphoma.[17] The SVC can be compressed by other mediastinal masses, infectious lymphadenopathy, aortic aneurysm, and mediastinal fibrosis.[18] Intrinsic stenosis of the SVC can be caused by scarring from a chronic indwelling catheter and by infusion of caustic agents. Luminal occlusion (Fig. 82.5) can be the result of a thrombus forming around a central venous catheter or pacemaker wires, of venous thrombosis secondary to a hypercoagulable state, or with a vasculitis involving the venous system as can be seen in Behçet syndrome (see Chapter 81). Finally, SVC flow may be obstructed within the atrial baffle after the atrial switch or the Mustard/Senning procedure (see Chapter 75).[19] Obstruction of the SVC above the azygos return precludes decompression by retrograde flow into the azygos vein and leads to more severe symptoms.

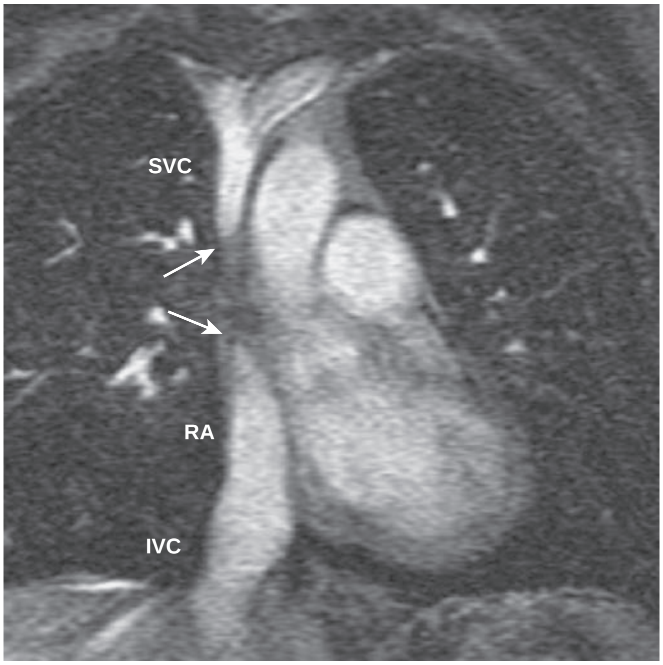

**Figure 82.5. Superior vena cava occlusion in a 14-year-old girl who had a long-term central venous catheter placed in the SVC.** Coronal MRA reconstruction shows a complete obstruction *(arrows)* between the SVC and the right atrium *(RA)*, whereas the inferior vena cava *(IVC)* drains freely into the RA.

***Imaging and Treatment.*** The gold standard for the diagnosis of SVC syndrome is catheter venography, with which the level of SVC obstruction, the presence of venous collaterals, and the central venous pressure can be assessed. Noninvasive tomographic techniques such as CT and magnetic resonance (MR) venography can define the SVC stenosis and are helpful in evaluating for an extrinsic mass.[20] An advantage of MRI is that venography can be done without use of a contrast agent through use of phase-contrast or time-of-flight inflow enhancement techniques. Treatment of SVC syndrome depends on the underlying cause. Radiation or chemotherapy that reduces tumor size may relieve SVC obstruction due to tumor. Central venous catheters causing venous thrombosis may be removed and residual thrombosis or stenosis treated with selective thrombolysis and venous stenting as needed.

### Inferior Vena Cava Obstruction

***Overview.*** Reasons for acquired obstruction of the IVC are similar to those of the SVC. Thrombosis of the IVC can be the result of catheter access, placement of a caval filter, severe illness including sepsis and dehydration, and other hypercoagulopathy. The IVC can be obstructed at its entrance to the right atrium by direct extension from abdominal tumors, such as Wilms tumor, neuroblastoma, hepatoblastoma, and hepatocellular carcinoma. Obstruction can be caused by thrombus or an IVC web. The Budd–Chiari syndrome classically is attributed to hepatic venous obstruction, but the intrahepatic portion of the IVC can be involved, resulting in symptoms of hepatomegaly, ascites, and abdominal pain (Fig. 82.6).[21]

***Imaging and Treatment.*** Imaging evaluation can be performed with abdominal ultrasound, CT, and MRI, with the investigation focused on the location and severity of the obstruction and on the presence of a thrombus or extrinsic mass. Treatment is directed to correcting the underlying conditions. In the short term, patency of the IVC can be maintained with an endovascular stent.

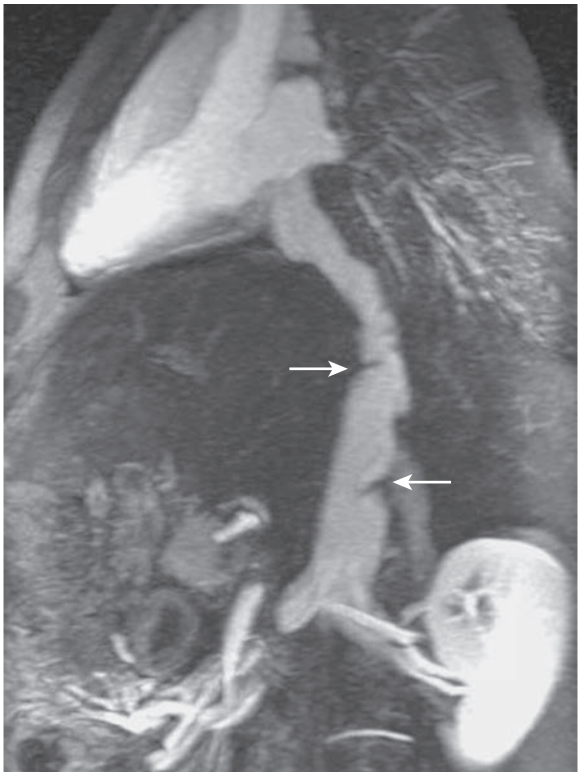

**Figure 82.6. Inferior vena cava (IVC) stenosis in a 13-year-old boy who developed Budd–Chiari syndrome after trauma.** Sagittal MRA reconstruction shows a narrowed IVC with multiple webs *(arrows)* protruding into the caval lumen.

### Superior Vena Cava Aneurysm

***Overview.*** Although a true SVC aneurysm is very rare, dilation of the SVC is more commonly seen with elevated central venous pressure as a result of right heart failure or severe tricuspid valve regurgitation.[22] Dilation of the SVC also is associated with mediastinal lymphatic malformation, although the pathophysiology is not known.[23] Patients with saccular SVC aneurysms may be at risk for SVC thrombosis and PE.

***Imaging and Treatment.*** Surgical resection of an SVC aneurysm has been performed successfully. CT and MRI can help aid surgical planning by defining the extent of the aneurysm and detecting involvement of other draining veins.

## ACQUIRED DISEASE OF THE PULMONARY VEINS

### Pulmonary Vein Stenosis

***Overview.*** Acquired pulmonary vein stenosis in children is uncommon but can be seen in children with complications of surgical repair of congenital pulmonary vein anomalies. Children who undergo repair of total anomalous pulmonary venous connection (Fig. 82.7) and scimitar syndrome are at increased risk for acquired pulmonary vein stenosis. Pulmonary vein stenosis develops in up to 10% of infants who undergo repair of total anomalous pulmonary venous connection.[24] These patients are often ill from pulmonary edema and poor oxygen saturation, with a mortality rate as high as 50%. The prognosis is worse for patients who have coexisting complex cardiac anomalies, often as part of the heterotaxy syndrome. Other acquired causes of pulmonary vein stenosis include mediastinal fibrosis and extrinsic compression by mediastinal tumors.

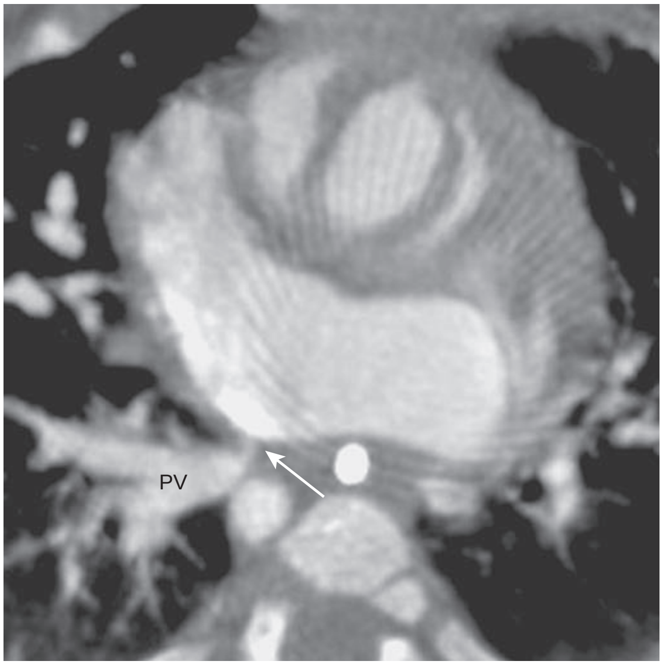

**Figure 82.7. Pulmonary venous stenosis after surgical repair for total anomalous pulmonary venous connection in a 6-month-old girl.** Axial CTA image shows a tight stenosis *(arrow)* at the origin of a right pulmonary vein *(PV)*.

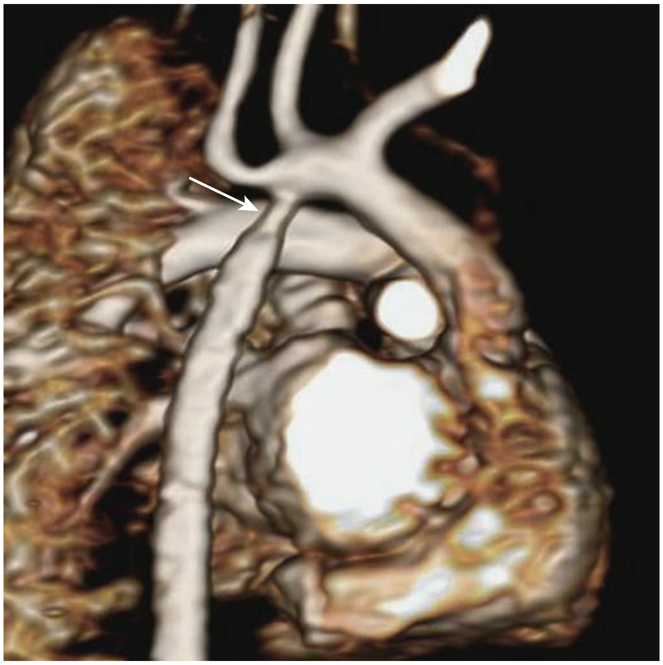

**Figure 82.8. Aortic restenosis 5 months after a surgical repair for coarctation in a 6-month-old boy.** Volume CTA rendering shows a segmental, circumferential narrowing *(arrow)* at the surgical site.

***Imaging and Treatment.*** CTA and MRA can define the anatomy of the venous obstruction. CTA has the added advantage of evaluating the pulmonary parenchyma and related complications. Catheter angiography is used in anticipation of an intervention to define the location of the pulmonary venous obstruction and to evaluate the severity of the stenosis by measuring the pressure gradient across the stenosis.

Pulmonary vein stenosis has been treated with angioplasty, endovascular stent placement, and surgical repair.[24,25] Despite immediate postprocedural or postoperative success, restenosis often occurs, and mortality is not substantially improved. The pathophysiology of pulmonary vein restenosis is not well understood. Medial fibrosis of the injured pulmonary veins, endothelial ingrowth into the stent, and abnormal reactivity of the pulmonary vascular bed have been proposed as possible mechanisms of restenosis.

## Pulmonary Vein Varix

***Overview.*** Pulmonary varices are rare aneurysmal dilations of the pulmonary veins and may be congenital or acquired.[26] Acquired pulmonary varices usually are the result of pulmonary venous hypertension caused by central pulmonary vein stenosis, mitral regurgitation, mitral stenosis, and coarctation. Pulmonary varices generally are benign and require no specific treatment. They usually regress with correction of the underlying abnormality. However, it is important to distinguish pulmonary varices from pulmonary arteriovenous malformations, which can have a similar appearance. Pulmonary arteriovenous malformations carry the risk of stroke and other embolic events and require surgical removal or catheter embolization.

***Imaging.*** Both CTA and magnetic resonance angiography (MRA) can detect pulmonary varices. In difficult cases, catheter angiography may be needed to differentiate varices from arteriovenous malformations.

## Neoplasms of the Great Vessels

***Overview.*** Primary tumors of the great arteries are rare.[27] Secondary involvement of the great vessels by metastatic disease, invasion or compression from a nearby tumor or by radiation vasculitis from radiation treatment can occur.[28,29]

***Imaging and Treatment.*** Because most great vessel tumors occur as a result of metastatic disease or infiltration due to adjacent disease, the tumor cell types and origins usually are known. The primary roles of imaging are to determine favorable sites for tumor biopsy, evaluate the extent and the degree of vascular obstruction in preparation for vascular intervention, and monitor changes in vascular involvement after treatment. In most cases, either CT or MRI is used for evaluating the disease process.[30]

## Postoperative Complications

***Overview.*** Pseudoaneurysm and stenosis can develop as complications of surgical repair or interventional treatment of pediatric thoracic great vessels, of which coarctation is the best studied. The average restenosis rates are 15% and 2% for balloon angioplasty and surgical repair of coarctation, respectively (Fig. 82.8).[31] Other surgical procedures that can be complicated by aneurysm or stenosis are surgical aortopulmonary and central shunts.[32] The Blalock-Taussig shunt, which classically connects the right subclavian artery to the right pulmonary artery, can lead to stenosis or obstruction of the right pulmonary artery (Fig. 82.9). The Potts shunt, which connects the descending aorta to the left pulmonary artery, often results in left pulmonary artery stenosis. The Waterston shunt connects the ascending aorta to the pulmonary trunk. Excessive shunt flow can create aneurysms of the pulmonary artery.[32]

***Imaging and Treatment.*** Noninvasive imaging by CTA or MRA has largely supplanted catheter angiography for the purpose of detecting and characterizing these thoracic vascular lesions before surgical or interventional treatment. Catheterization is reserved for angioplasty and stenting of stenotic lesions and for stent graft deployment to exclude an aneurysm.

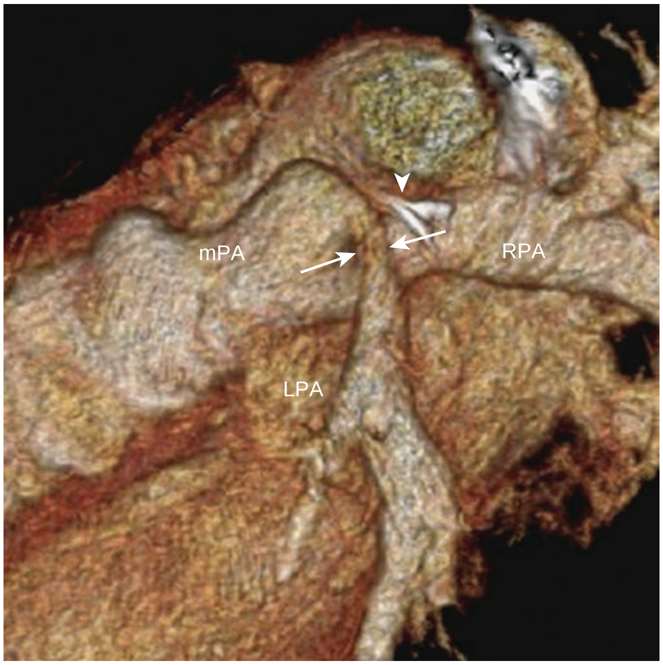

**Figure 82.9. Postsurgical pulmonary artery stenosis in a 10-year-old boy.** Volume CTA rendering shows evidence of an arteriopulmonary shunt, now closed, identified by a surgical clip *(arrowhead)*. Adjacent to this clip is a kink and a focal narrowing *(arrows)* of the left pulmonary artery *(LPA)*. *mPA,* Main pulmonary artery; *RPA,* right pulmonary artery.

## KEY POINTS

- Acquired aortic pathology can be categorized as aortic aneurysm, aortic dissection, or aortic stenosis, and the clinical consequences of these three diagnostic entities directly determine mortality and morbidity.
- The most common risk factor for PE in children is catheter thrombosis, which develops in as many as half of patients with central venous catheters.
- A negative D-dimer assay in pediatric patients does not exclude PE.
- SVC syndrome is a medical emergency in children because swelling of the neck can cause compression and obstruction of the airway.
- Restenosis of the pulmonary vein(s) in children is common after surgical or interventional treatment and can be diagnosed with CTA or MRA.

## PART 1 Overview

# 83

# Embryology, Anatomy, and Normal Findings

*Amie M. McPherson and Evelyn Y. Anthony*

## ABDOMINAL WALL AND PERITONEAL CAVITY

During the third week of gestation, the intraembryonic mesoderm differentiates, forming the lateral plates.[1,2] Mesoderm from paravertebral myotomes invades the lateral plates during the sixth week. The leading edges of the lateral plates will differentiate into the right and left rectus abdominis muscles. The main portion of the mesoderm splits into three layers and forms the external oblique, internal oblique, and transverse abdominis muscles. Approximation of the right and left recti is complete by the 12th week except for the umbilical ring.

The aponeurosis of the external oblique muscles forms the anterior and posterior rectus sheaths.[1] These sheaths join in the midline to form the linea alba. The lowest portion of the aponeurosis ends in the inguinal ligament. The external inguinal ring is an opening in the aponeurosis between the inguinal ligament inferiorly and the tendinous portion superiorly. The spermatic cord in males and the round ligament in females pass through the inguinal canal.

Closure of the cephalic, caudal, and lateral folds leads to the formation of the intraembryonic coelom.[3,4] The mesoderm surrounding the coelom splits into two layers, the somatic mesoderm and the splanchnic mesoderm. The somatic layer forms the parietal peritoneum, which lines the inner abdominal wall, and the splanchnic layer forms the visceral peritoneum, which covers the abdominal organs. The space between the parietal and visceral peritoneum is the peritoneal cavity.

## HEPATIC AND BILIARY SYSTEM

The liver, gallbladder, and biliary duct system arise as a ventral outgrowth from the caudal end of the foregut early in the fourth week of development (Fig. 83.1).[5,6] This outgrowth, known as the *hepatic diverticulum*, extends into the septum transversum, which is the future diaphragm. The hepatic diverticulum grows rapidly and divides into cranial and caudal portions. The larger cranial portion forms the primordium of the liver parenchyma. Proliferating endodermal cells develop into cords of hepatocytes and into the epithelial lining of the biliary system. The connective tissue, hematopoietic cells, and Kupffer cells are derived from the mesoderm of the septum transversum. The caudal portion expands to form the gallbladder, and its stalk becomes the cystic duct. The two major intrahepatic ducts join to form the common hepatic duct. The stalk connecting the hepatic and cystic ducts to the duodenum becomes the common bile duct.

The liver grows rapidly, with the right lobe growing faster than the left lobe. Intrahepatic ducts appear in the region of the hilus and grow peripherally. This ductal system is complete by the 10th week of gestation, and bile formation is seen in the 12th week. The extrahepatic biliary tree initially is formed as a solid cord that canalizes by the 10th to 12th week of gestation. Bile is excreted into the duodenum via the common bile duct and is responsible for the characteristic dark green color of meconium.

The superior portion of the liver is in direct contact with the diaphragm and is termed the *bare area* because it is not covered by the peritoneum. The inferior vena cava, distal esophagus, and right adrenal gland abut the posterior margin of the liver, which inferiorly is bordered by the right and transverse colon, right kidney, and gallbladder. The visceral surface of the liver contains the biliary and vascular structures of the porta hepatis. Hepatic segmental anatomy has been defined by several nomenclature systems. The Couinaud system is most frequently used today as it is based on biliary vascular anatomy and surgically resectable segments (Fig. 83.2).[7] The middle hepatic vein and the Cantlie line, a plane between the inferior vena cava and the gallbladder fossa, split the liver anatomically into right and left lobes. Each lobe is further divided into four segments based on a vertical plane through the hepatic vein to that lobe and a horizontal plane through the corresponding portal vein branch. Hence, the left hepatic lobe has lateral segments designated II cranially and III caudally with the medial segments labelled IVA and IVB. The right hepatic lobe segments are numbered in a clockwise fashion starting at the gallbladder fossa as VIII, V, VI, and VII. The caudate lobe is named segment I. It lies between the main portal vein and the inferior vena cava and has its own unique vascular supply, separate from the remainder of the liver.

## SPLEEN

The spleen begins to develop during the fifth week of gestation.[8,9] It is derived from a mass of mesenchymal cells in the dorsal mesogastrium that coalesce to form the spleen. Failure of these cells to fuse completely gives rise to accessory spleens, which are quite common. As the stomach's greater curvature rotates to the left, the spleen is carried with it into the left upper quadrant. It lies in a niche formed by the diaphragm, the stomach, the left kidney and adrenal gland, the phrenicocolic ligament, and the chest wall. The splenic hilum is a depression along the medial surface through which the splenic artery, vein, and nerves pass. The two major ligaments that hold the spleen in place are the gastrosplenic and the splenorenal ligaments. Other ligaments that support the spleen are the splenophrenic, splenocolic, splenopancreatic, colophrenic, and pancreaticocolic ligaments.

The spleen is an important lymphatic organ and plays a role in providing protection from infection caused by encapsulated organisms. The spleen also filters damaged red blood cells and foreign particles and acts as a reservoir for platelets. Lymphocytes begin to appear in the spleen around 11 weeks of gestation.

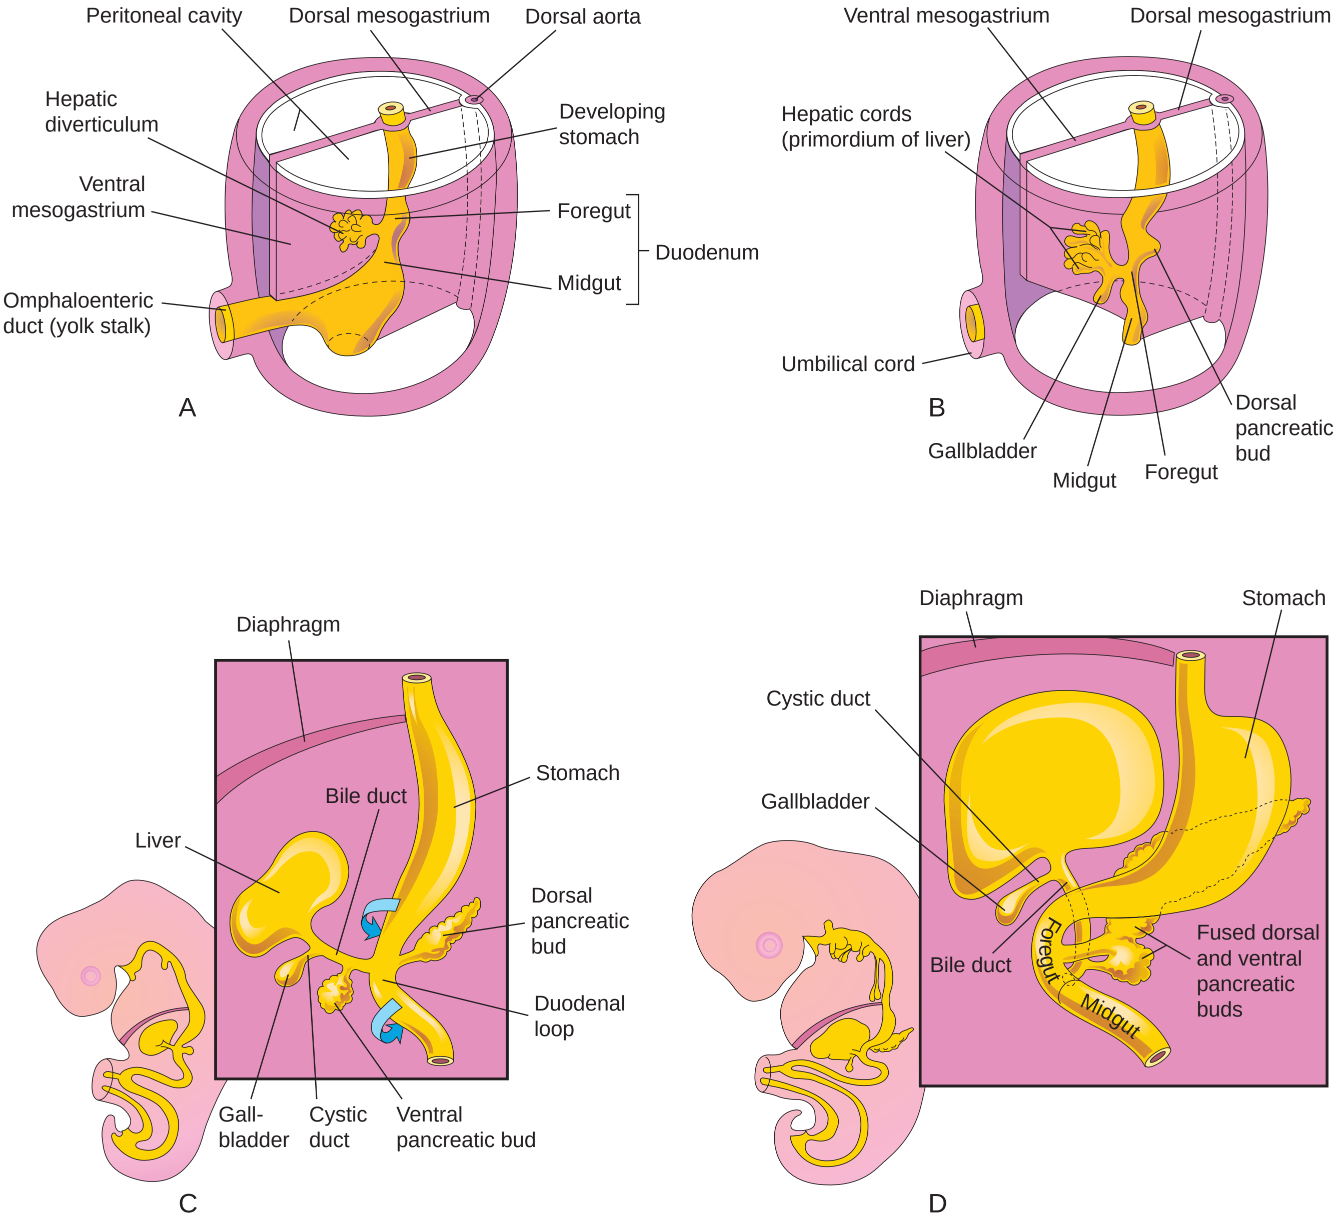

**Figure 83.1. Schematic illustrations of hepatic embryology.** (A) Hepatic embryology at 4 weeks. (B and C) Hepatic embryology at 5 weeks. (D) Hepatic embryology at 6 weeks. Note hepatic diverticulum extending into the ventral mesentery and dividing into cranial (liver primordium) and caudal (gallbladder and common bile duct) buds. Also note that the entrance of the bile duct into the duodenum shifts gradually to a posterior position, which explains why the bile duct passes posterior to the duodenum. *(From Moore KL, Persaud TVN. The digestive system. In: Moore KL, Persaud TVN, eds.* The Developing Human: Clinically Oriented Embryology. *8th ed. Philadelphia: WB Saunders; 2007.)*

## PANCREAS

The development of the pancreas is closely related to duodenal development. The dorsal pancreatic bud arises from the dorsal side of the duodenum, and the ventral pancreatic bud arises from the hepatic diverticulum (Fig. 83.3).[10–12] The larger dorsal bud appears first and arises cranial to the smaller ventral bud. It will form the tail, body, and part of the head of the pancreas. The ventral bud develops at the site of entry of the common bile duct and forms part of the pancreatic head and the uncinate process. As the duodenal loop rotates, the ventral bud is carried dorsally to lie in a position posterior to the dorsal bud, with which it fuses. After fusion of the pancreatic buds, the duct systems anastomose. Thus the proximal portion of the main pancreatic duct is formed from the ventral bud and the distal portion is formed from the dorsal pancreatic bud. The proximal portion of the dorsal duct either disappears or persists as the accessory pancreatic duct. Islet cells appear at the end of the second month of gestation, and acinar cells develop during the third month. The islet cells secrete insulin, glucagon, somatostatin, and pancreatic polypeptide. Acinar cells produce digestive enzymes that are secreted into the second portion of the duodenum.

The pancreas lies horizontally in the retroperitoneum. The body of the pancreas is in contact with the stomach anteriorly; the splenic artery and vein run along the superior and dorsal margin of the pancreas, and serve as markers on cross-sectional imaging.

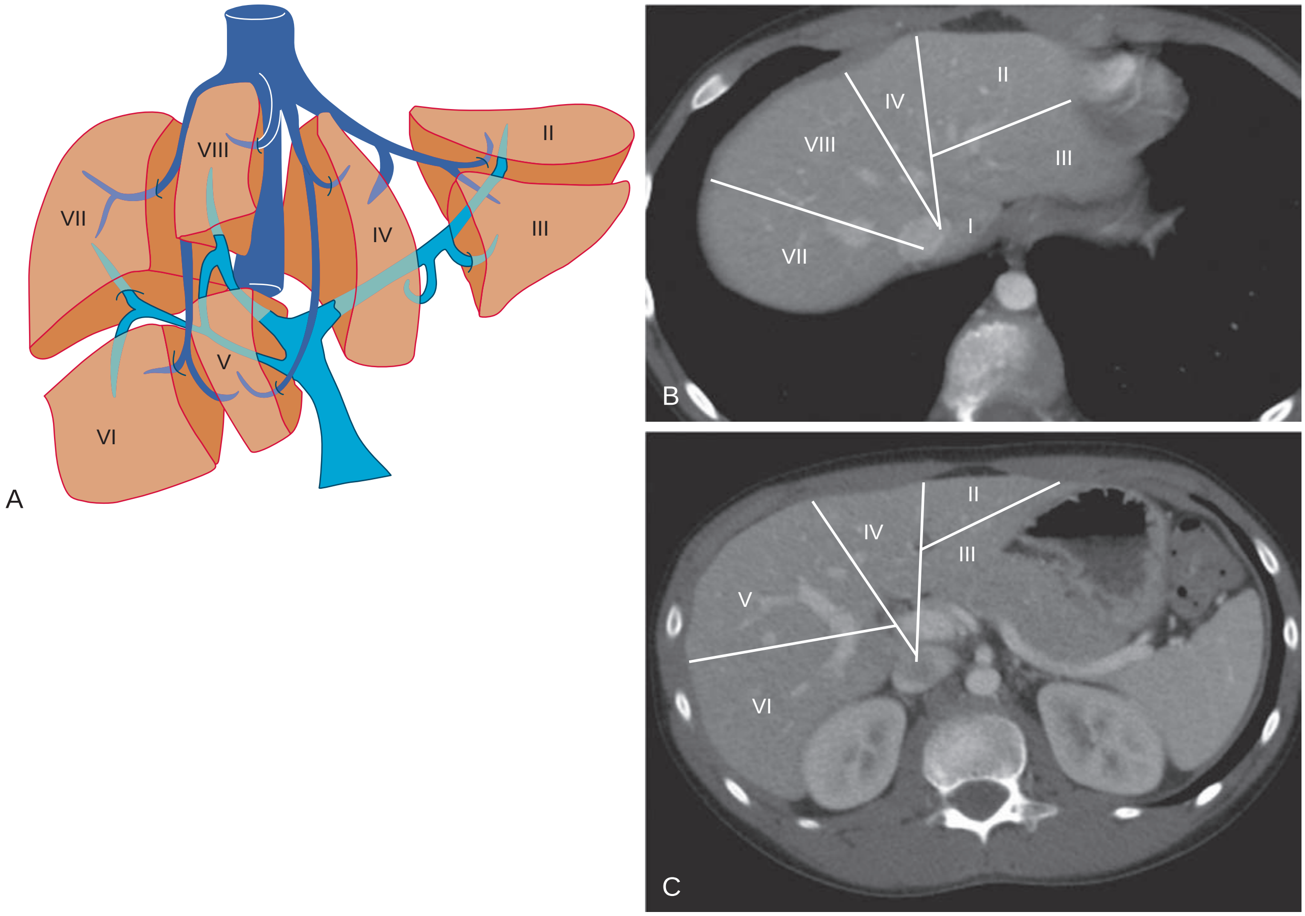

**Figure 83.2. Schematic illustration of hepatic segmental anatomy according to Couinaud.** (A) The portal venous supply to each segment is in light blue, and the hepatic veins draining each segment are in dark blue. Not shown are the bile ducts, which follow the course of the portal veins. (B and C) Segmental anatomy as seen on computed tomography. *(A, Modified from Gazelle GS, Lee MJ, Mueller PR. Cholangiographic segmental anatomy of the liver.* Radiographics. *1994;14:1005. Reprinted with permission;* B *and* C, *Courtesy of Marta Hernanz-Schulman, Nashville, TN.)*

The head of the pancreas lies to the right of the midline in the curve of the duodenum, whereas the tail is in contact with the gastric surface of the spleen and the splenic surface of the colon. The uncinate process is an extension of gland substance at the junction of the inferior and left margins of the pancreatic head.

## GASTROINTESTINAL TRACT

The primitive gastrointestinal tract forms during the third to fourth week of gestation.[13–16] It is marked by the oropharyngeal membrane at the cranial end and the cloacal membrane caudally (Fig. 83.4). It is divided into three parts: the foregut, midgut, and hindgut. The foregut includes the esophagus, stomach, and proximal duodenum, and receives most of its arterial supply from the celiac axis, with the exception of the esophagus that is proximal to the lower esophageal sphincter. The midgut is supplied by the superior mesenteric artery and includes the distal duodenum, jejunum, ileum, cecum, appendix, ascending colon, and approximately two-thirds of the transverse colon. The hindgut is supplied by the inferior mesenteric artery and comprises the remainder of the transverse colon, the descending and sigmoid colon, and the upper two-thirds of the rectum.

### Esophagus

The esophagus begins as a ventral diverticulum from the primitive foregut that will give rise to the trachea and the esophagus.[15–18] As this diverticulum elongates, a partition forms, the tracheoesophageal septum, which ultimately leads to separation of the esophagus from the trachea at 34 to 36 days of gestation. Elongation of the esophagus initially occurs cranially, and the final proportionate length of the esophagus is reached at 7 weeks. Epithelial proliferation with partial to complete obliteration of the esophageal lumen occurs, which normally recanalizes by the 10th week. The muscular coat of the esophagus is derived from the surrounding splanchnic mesenchyme. In the upper third of the esophagus, striated muscle innervated by the vagus nerve is present, whereas the lower two-thirds contains smooth muscle innervated by the splanchnic plexus.

The esophagus begins at the level of C7 and ends at the esophagogastric junction, which is usually at the T10–11 vertebral body level (Fig. 83.5). The caliber varies with peristaltic activity but is slightly narrower at both ends than along its intrathoracic course. Extrinsic impressions are caused by the aorta, the left mainstem bronchus, and the diaphragm (Fig. 83.6).

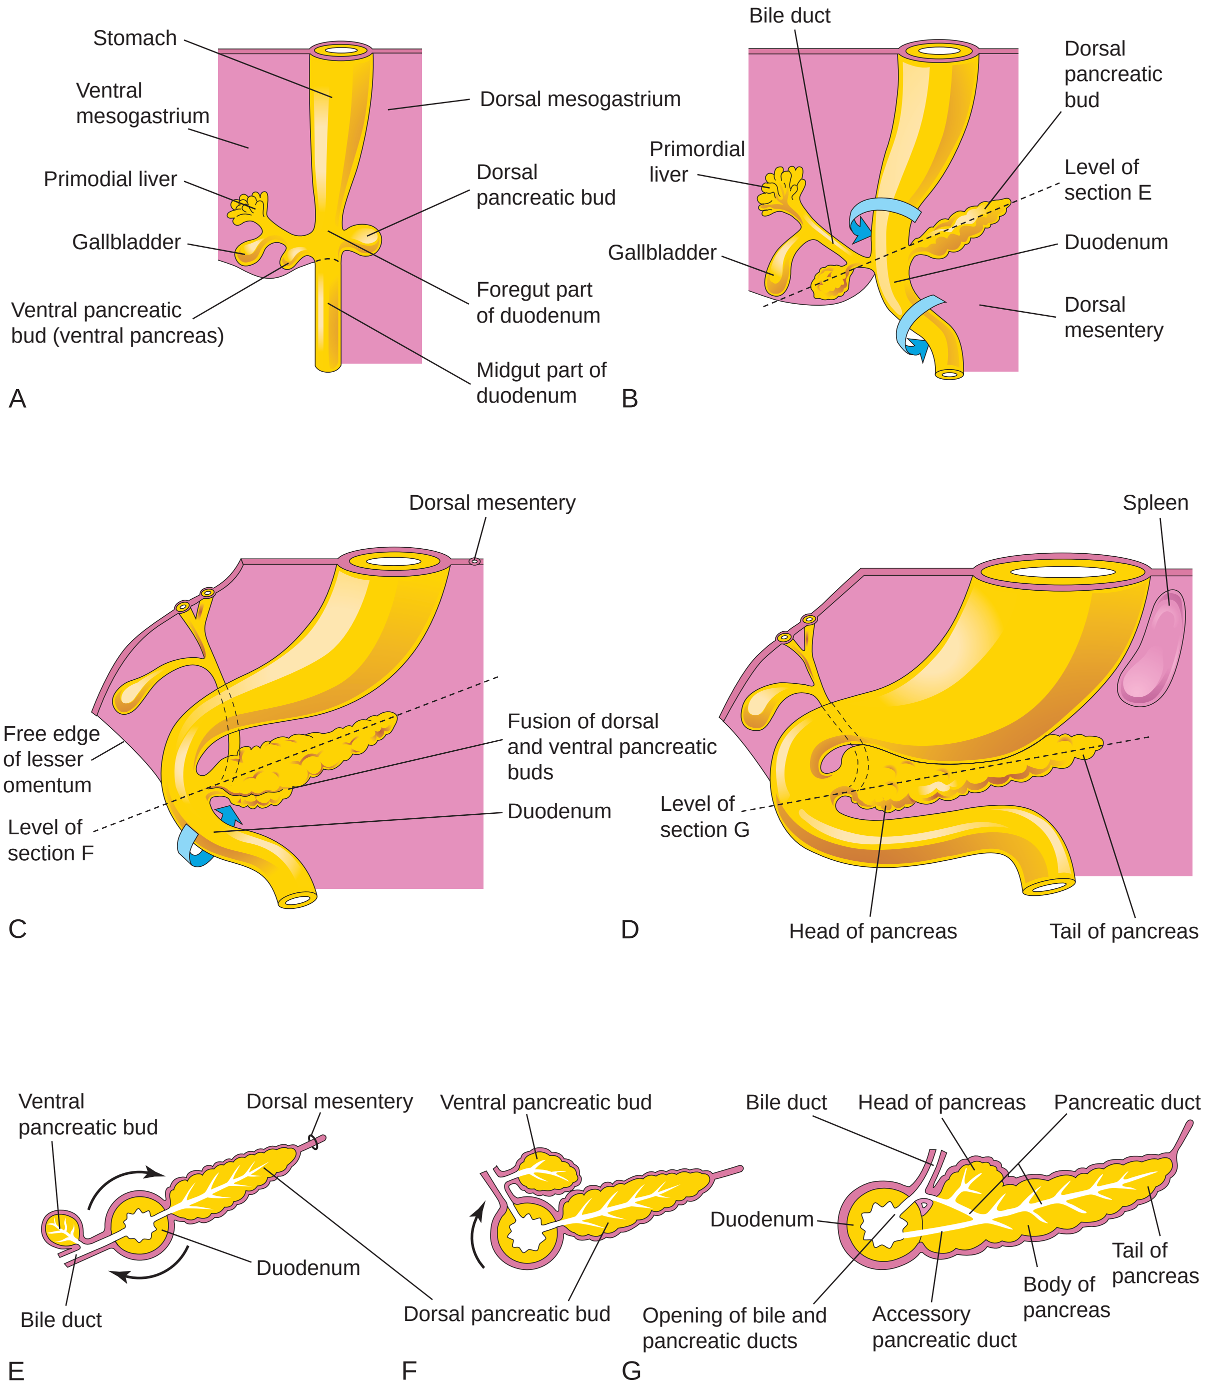

**Figure 83.3. Development of the pancreas.** (A–C) Illustrations of successive stages in the development of the pancreas from the fifth to the eighth weeks. (D–G) Transverse sections through the duodenum and the developing pancreas. Growth and rotation *(arrows)* of the duodenum bring the ventral pancreatic bud toward the dorsal bud; these two structures subsequently fuse. Note that the bile duct initially attaches to the ventral aspect of the duodenum and is carried around to the dorsal aspect as the duodenum rotates. The pancreatic duct is formed by the union of the distal part of the dorsal pancreatic duct (duct of Santorini) and the entire ventral pancreatic duct (duct of Wirsung). The proximal part of the dorsal pancreatic duct usually is obliterated, but it may persist as an accessory pancreatic duct, as labeled in the figure. *(From Moore KL, Persaud TVN. The alimentary or digestive system. In: Moore KL, Persaud TVN, eds.* Before We Are Born: Essentials of Embryology and Birth Defects. *7th ed. Philadelphia: Saunders Elsevier; 2008.)*

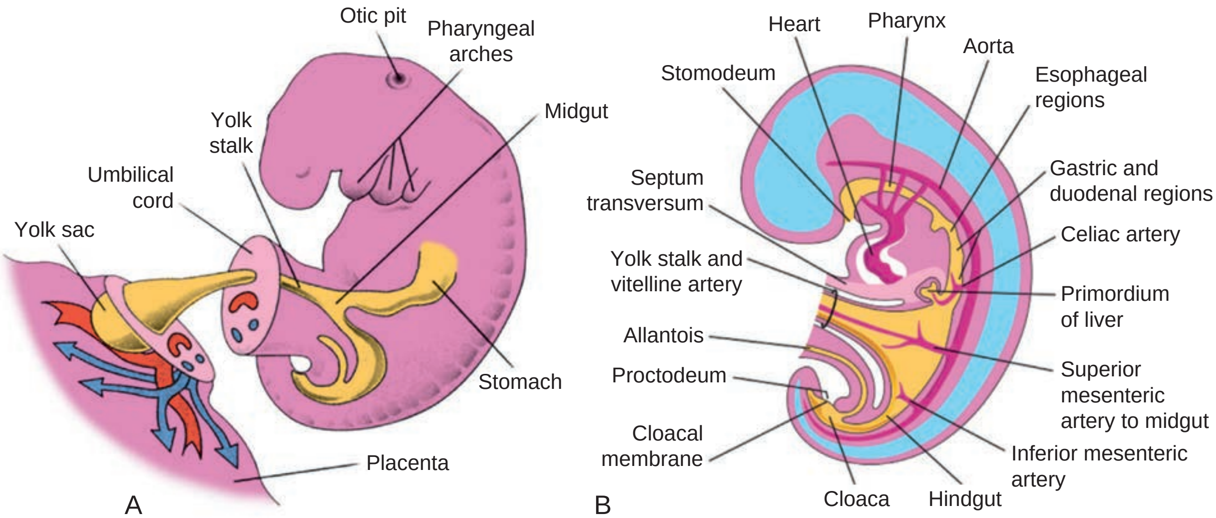

**Figure 83.4. Early digestive tract.** (A) A drawing of a median section of the embryo showing the early digestive system and its blood supply. The primordial gut is a long tube extending the length of the embryo. Its blood vessels are derived from the vessels that supplied the yolk sac. (B) The primordial gut is a long tube extending the length of the embryo from the stomodeum to the cloaca. Note again the blood supply from the vitelline artery via the yolk stalk and the relationship of the developing celiac axis, superior mesenteric artery, and inferior mesenteric artery to the primordial gut segments. *(From Moore KL, Persaud TVN, eds.* Before We Are Born: Essentials of Embryology and Birth Defects. *7th ed. Philadelphia: Saunders Elsevier; 2007.)*

The esophageal mucosa normally has thin, smooth longitudinal folds that flatten when the esophagus is distended by gas or barium. When fully distended, the distal esophagus enlarges and forms a fusiform shape commonly termed the *esophageal vestibule* or *phrenic ampulla*. The upper margin of the vestibule is radiographically delineated by a transient contractile area that forms bilateral, semilunar indentations termed the *A ring*, *inferior esophageal sphincter*, or *Wolf ring*. The lower margin is also delineated by a transient contractile region termed the *B ring*, *transverse mucosal fold*, *lower esophageal ring*, *Schatzki ring*, or *lower esophageal diaphragm*. In young infants, the vestibule spans the diaphragmatic hiatus so that the upper part lies within the thorax and the lower part lies within the abdomen.

## Stomach

The stomach arises as a tubular dilatation at the distal end of the foregut at 4 to 5 weeks of gestation.[13,15,16,19] The dorsal border grows more rapidly than the ventral border, leading to a 90-degree clockwise rotation on its longitudinal axis. As a result, the dorsal border rotates to the left and becomes the greater curvature, whereas the ventral border rotates to the right and becomes the lesser curvature of the stomach. The left and right vagal nerve branches rotate with the stomach, such that the left vagal nerve innervates the anterior gastric wall and the right vagal nerve innervates the posterior wall.

The stomach lies below the left hemidiaphragm with its long axis transverse to the long axis of the body.[19] The stomach is relatively fixed proximally by the esophagogastric junction and distally by the fixed retroperitoneal position of the first portion of the duodenum. The stomach also is fixed to neighboring structures by four major peritoneal folds or ligaments: gastrophrenic, gastrohepatic, gastrosplenic, and gastrocolic ligaments.

The stomach is divided into four major regions. The cardia is a small, ill-defined area immediately adjacent to the esophagogastric junction and just to the left of the midline. The fundus is the most bulbous portion of the stomach. It projects upward, above the cardia and gastroesophageal junction, and is in contact with the left hemidiaphragm and the spleen. The body is the largest part of the stomach and is bounded by the greater and lesser curvatures. The incisura angularis, a sharp indentation two-thirds of the distance down the lesser curvature, marks the beginning of the gastric antrum. The antrum in turn is divided by the sulcus intermedius into the pyloric vestibule more proximally, and the pyloric antrum, which extends to the junction with the duodenum.[20] The normal size, shape, and position of the stomach vary with the volume of gastric content and the age of the individual. In infancy, the stomach is high and transverse, whereas in older children and adults it is more longitudinal and J-shaped.

## Duodenum

The duodenum is derived from the caudal portion of the foregut and the cranial portion of the midgut.[13,15,16] The junction of these two parts is just distal to the common bile duct. The duodenal segment elongates rapidly, forming a C-shaped loop. As the stomach rotates, the duodenal loop rotates to the right, causing the duodenum to be pressed against the posterior abdominal wall, which leads to fusion and resorption of peritoneal layers such that the duodenum becomes a retroperitoneal structure. Because it is derived from both foregut and midgut, the duodenum receives its blood supply from both the celiac and superior mesenteric arteries. Unlike the rest of the midgut, the duodenum does not herniate into the extraembryonic coelom.

The duodenum is the most proximal portion of the small intestine.[19] The first portion of the duodenum begins at the pylorus and ends at the neck of the gallbladder. It is loosely attached to the liver by the hepatoduodenal portion of the lesser omentum; the second, third, and fourth portions are retroperitoneal. The second or descending portion extends from the neck of the gallbladder and is in contact with the head of the pancreas. The common bile duct enters in its midportion. The third portion is horizontal and courses to the left across the midline, anterior to the spine, aorta, and inferior vena cava. Anteriorly, the third portion is covered by peritoneum and is crossed by the superior mesenteric artery and vein. The fourth portion ascends along the left side of the aorta and turns ventrally to become the jejunum at the level of the duodenojejunal flexure. The duodenojejunal flexure is retroperitoneal and is also fixed by the ligament of Treitz.

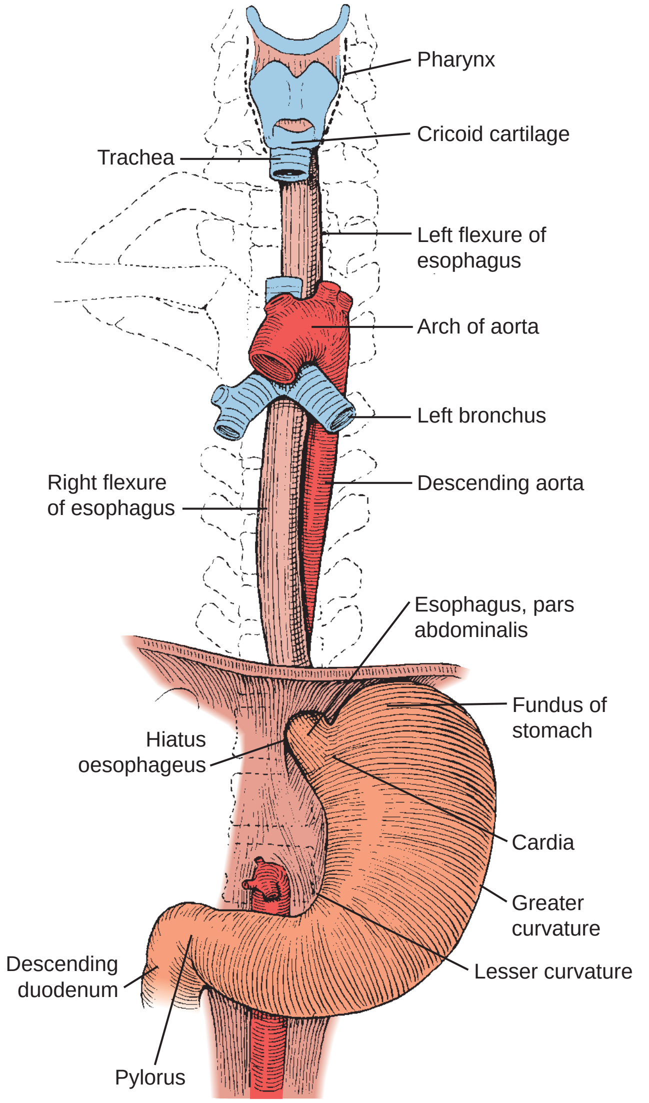

**Figure 83.5. Normal esophagus.** Semi-schematic drawing of the normal esophagus depicting its relation to the trachea, aorta, diaphragm, and stomach. *(Modified from Schaegger JP.* Morris' Human Anatomy. *10th ed. New York: McGraw-Hill; 1943. Reprinted with permission.)*

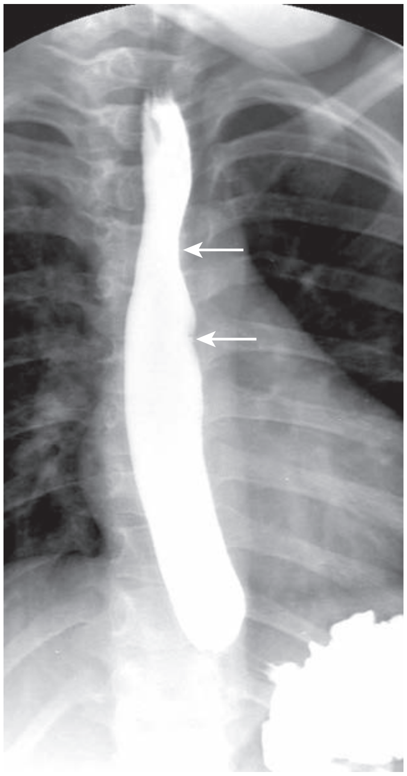

**Figure 83.6. Normal esophageal impressions.** Barium swallow study demonstrates the impression of the aortic knob *(upper arrow)* and the left main stem bronchus *(lower arrow)* on the barium-filled esophagus. These impressions are normal and are not to be confused with mediastinal abnormalities.

## Midgut

The midgut is the portion of the gut that opens ventrally into the yolk sac and undergoes a 270-degree counterclockwise rotation (see also Chapter 102).[13,16,18] It elongates rapidly so that, by the beginning of the sixth week, it forms a U-shaped ventral loop that projects into the extraembryonic coelom, herniating into the umbilical cord. The stalk at the apex of the loop is the omphalomesenteric duct (Fig. 83.7). The midgut proximal to the apex of the loop is small bowel and the midgut distal to the apex is colon. A Meckel diverticulum is the result of persistence of the proximal portion of the omphalomesenteric duct, which is the most common congenital malformation of the gastrointestinal tract. During the sixth week of gestation, a diverticulum forms on the antimesenteric border of the distal portion of the midgut, which will give rise to the cecum and appendix.

While the bowel is in the extraembryonic coelom, it undergoes a 90-degree counterclockwise rotation around the superior mesenteric artery (see Fig. 83.7B). During this rotation, the jejunum and ileum grow more rapidly than the colon; this rotation brings the proximal midgut (jejunum and ileum) to the right and the distal portion (large intestine) to the left. The bowel abruptly returns to the abdominal cavity at about 10 weeks of development (see Fig. 83.7C and D). The forces responsible for this sudden return are unknown. The small bowel enters first, passes posterior to the superior mesenteric artery, and ultimately occupies the central part of the abdomen. As the large intestine returns to the abdominal cavity, it undergoes a 180-degree counterclockwise rotation, with the cecum ending up below the liver. Further growth of the ascending colon forces the cecum down into the right lower quadrant (see Fig. 83.7E).

Fixation of the midgut begins during the twelfth week of gestation. The mesenteries of the ascending and descending colon fuse with the posterior abdominal wall and become retroperitoneal. As a result of the fusion of the mesenteries of the ascending and descending colon and of the duodenum to the posterior abdominal wall, the small bowel mesentery becomes fan-shaped, with a broad-based attachment extending from the left upper quadrant to the right lower quadrant (Fig. 83.8). This broad attachment limits the mobility of the mesentery and prevents a midgut volvulus around the superior mesenteric artery. Failure to complete this rotation, which is known as *malrotation*, leads to a narrow mesenteric pedicle, which, in conjunction with the lack of mesenteric attachments, may result in midgut volvulus (see Chapter 102).

## Hindgut

The hindgut is supplied by the inferior mesenteric artery, begins in the mid to distal transverse colon and terminates at the cloaca.[13,16,21] The watershed region between the superior and inferior mesenteric arteries is located in the mid to distal transverse colon.

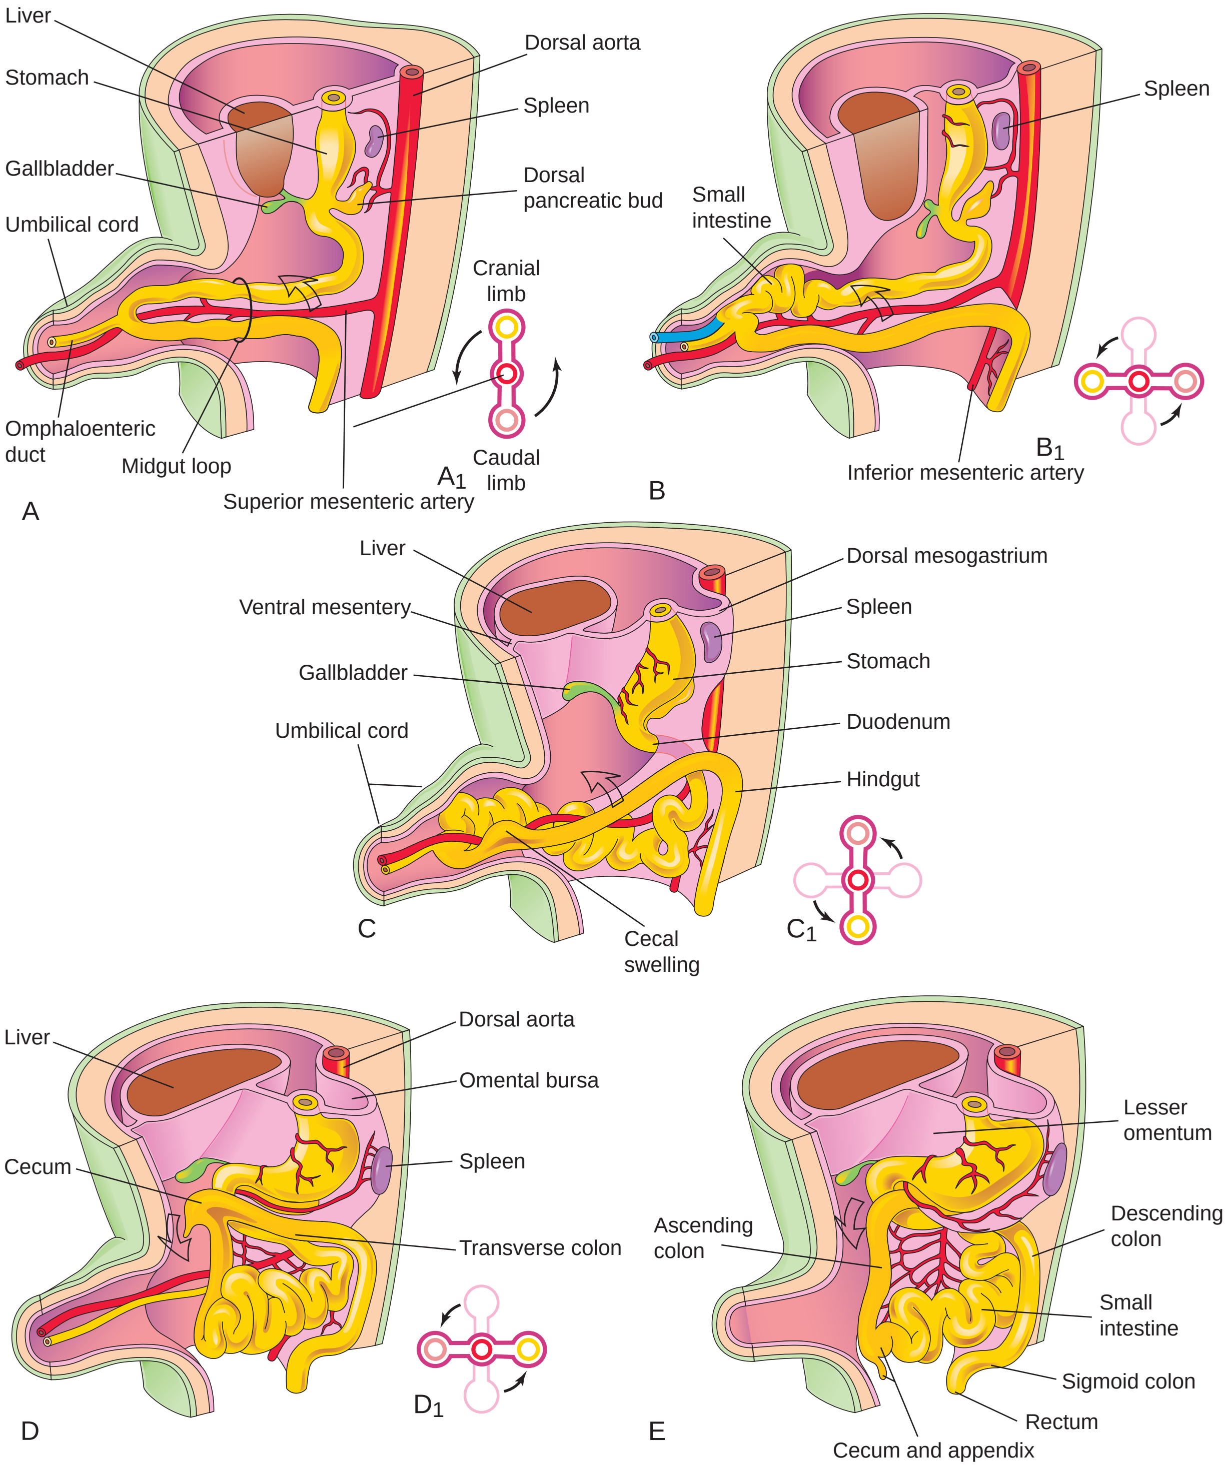

**Figure 83.7. Illustrations of the rotation of the midgut, as seen from the left.** (A) During the sixth week, the midgut loop is situated in the proximal part of the umbilical cord. ($A_1$) Transverse section through the midgut loop, showing the initial relationship of the limbs of the midgut loop to the superior mesenteric artery. (B) A later stage, showing the beginning of midgut rotation. ($B_1$) Illustration of the 90-degree counterclockwise rotation that carries the cranial limb of the midgut to the right. (C) At approximately 10 weeks, the intestines return to the abdomen. ($C_1$) Illustration of a further rotation of 90 degrees. (D) By approximately 11 weeks, all of the intestines return to the abdomen. ($D_1$) A further 90-degree rotation of the gut, for a total of 270 degrees. (E) The later fetal period showing the cecum rotating to its normal position in the lower right quadrant of the abdomen. *(From Moore KL, Persaud TVN. The alimentary or digestive system. In: Moore KL, Persaud TVN, eds.* Before We Are Born: Essentials Of Embryology and Birth Defects. *7th ed. Philadelphia: Saunders Elsevier; 2008.)*

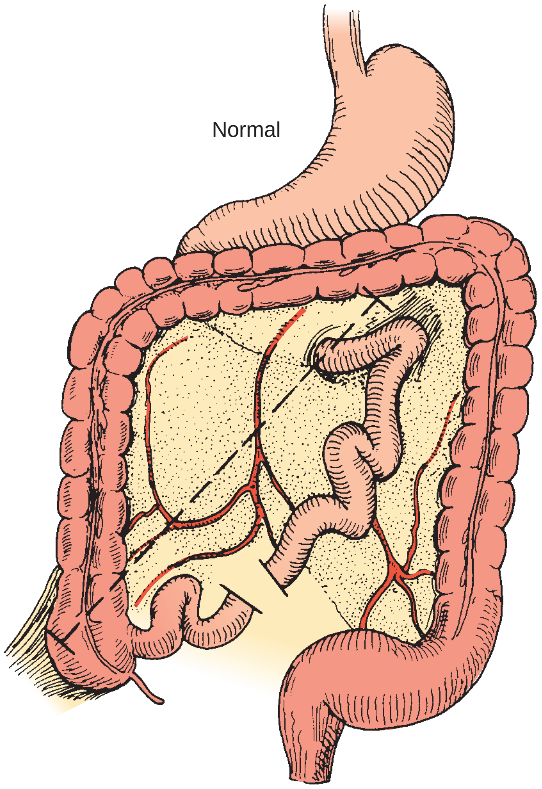

**Figure 83.8. Normal rotation and fixation of the midgut.** Note the broad-based fixation between the left upper and right lower quadrants, which fixes the superior mesenteric artery and prevents volvulus of the vascular pedicle. *(From Ross AJ III. Organogenesis, innervation, and histologic development of the gastrointestinal tract. In: Polin RA, Fox WW, eds.* Fetal and Neonatal Physiology. *2nd ed. Philadelphia: WB Saunders; 1998.)*

Around day 13 of gestation, a ventral diverticulum of the hindgut, the allantois, forms. The hindgut distal to the allantois disappears around the sixth week of gestation (Fig. 83.9). The junction of the allantoic stalk and the hindgut is the site of the cloaca. The cloaca, which is lined with endoderm, is in direct contact with the ectodermally lined proctodeum (anal pit). The area of contact between these two surfaces is the cloacal membrane. A wedge of mesenchyme, the urorectal septum, develops in the angle between the allantois and the hindgut (see Fig. 83.9C and 83.9D). As the urorectal septum grows toward the cloacal membrane, it produces infoldings of the lateral walls of the cloaca. These folds grow toward each other and fuse, forming a partition that divides the cloaca into two parts: the rectum and upper anal canal dorsally and the urogenital sinus ventrally. The area of fusion of the urorectal septum with the cloacal membrane forms the perineal body. The anal membrane ruptures at the end of the eighth week, allowing the intestinal tract to communicate with the amniotic cavity.

## NORMAL ANATOMY OF THE SMALL INTESTINE

The small intestine is a tubular structure within the abdominal cavity that is located between the stomach and the colon,[23] and consists of the duodenum, jejunum, and ileum. The length of the small intestine increases from approximately 200 cm at birth to 6 m in the adult.

The anatomy of the duodenum is discussed earlier in this chapter. Jejunum comprises the proximal two-fifths of the small bowel; the remainder is ileum. No morphologic demarcation exists between the two segments. The jejunum and ileum are suspended by a broad-based mesentery attached to the posterior peritoneal wall and thus are freely mobile within the abdominal cavity, although secured at both ends. Generally, the proximal third of the small bowel occupies the left upper quadrant; the middle third is in the midportion of the abdomen and right upper quadrant; and the distal third lies on the right side of the abdomen and pelvis. The location of any portion of the small bowel from the duodenojejunal junction to the cecum can vary over time due to the broad, fanlike mesentery and bowel peristalsis. The caliber of the small intestine tapers as it progresses distally, with the diameter of the terminal ileum being about one-third smaller than the first portion of the jejunum. The external surface is smooth while the internal surface has transverse and spiral folds that are covered by villi. The jejunum has more visible folds than the ileum (Fig. 83.10).

## NORMAL ANATOMY OF THE COLON

The colon extends from the ileocecal valve to the anus and is divided into the ascending, transverse, descending, and sigmoid portions as well as the rectum and anus.[23,24] In the newborn, it is 30 to 40 cm long, and it reaches 1.5 m in length in the adult. The cecum is the beginning of the ascending colon; it lies in the right lower quadrant, although it often is higher in infants, even above the iliac crest. The appendix is a blind outpouching of the cecum.

The retroperitoneal ascending colon extends upward along the right side of the peritoneal cavity to the underside of the liver. The colon turns medially at the hepatic flexure and emerges into the peritoneal cavity as the transverse colon. It courses right to left to reach its highest point in the left upper quadrant at the splenic flexure. The transverse colon is suspended by the mesocolon and is freely mobile. At the splenic flexure, the colon again becomes retroperitoneal and turns caudally to become the descending colon, running along the left lateral abdominal wall to the pelvic brim. At this point, it emerges into the peritoneal cavity as the sigmoid colon. The sigmoid colon is an S-shaped, redundant segment of variable length. The narrowest portion of the colon is in the sigmoid segment. In children, the redundancy of the sigmoid may cause the apex to extend to the right upper quadrant and the distal portion to loop into the right lower quadrant. The rectum begins at the peritoneal reflection and follows the curve of the sacrum, ending at the anal canal. The distal one-third of the rectum is retroperitoneal.

### KEY POINTS

- The liver and gallbladder arise during the fourth week of gestation from a ventral outgrowth of the caudal end of the foregut.
- The gastrointestinal tract begins to form during the third week of gestation.
- The foregut receives blood supply from the celiac axis, the midgut from the superior mesenteric artery, and the hindgut from the inferior mesenteric artery.
- The midgut returns to the abdominal cavity from the extraembryonic coelom between the 10th and 11th weeks of gestation.
- Normal rotation of the bowel leads to a broad-based mesentery with proximal and distal attachments; incomplete rotation (malrotation) leads to a narrow mesentery without attachments, a situation conducive to midgut volvulus.
- The urorectal septum divides the cloaca into the urogenital sinus anteriorly and the anorectal canal posteriorly. The cloacal membrane ruptures into the amniotic cavity in the seventh week of gestation.

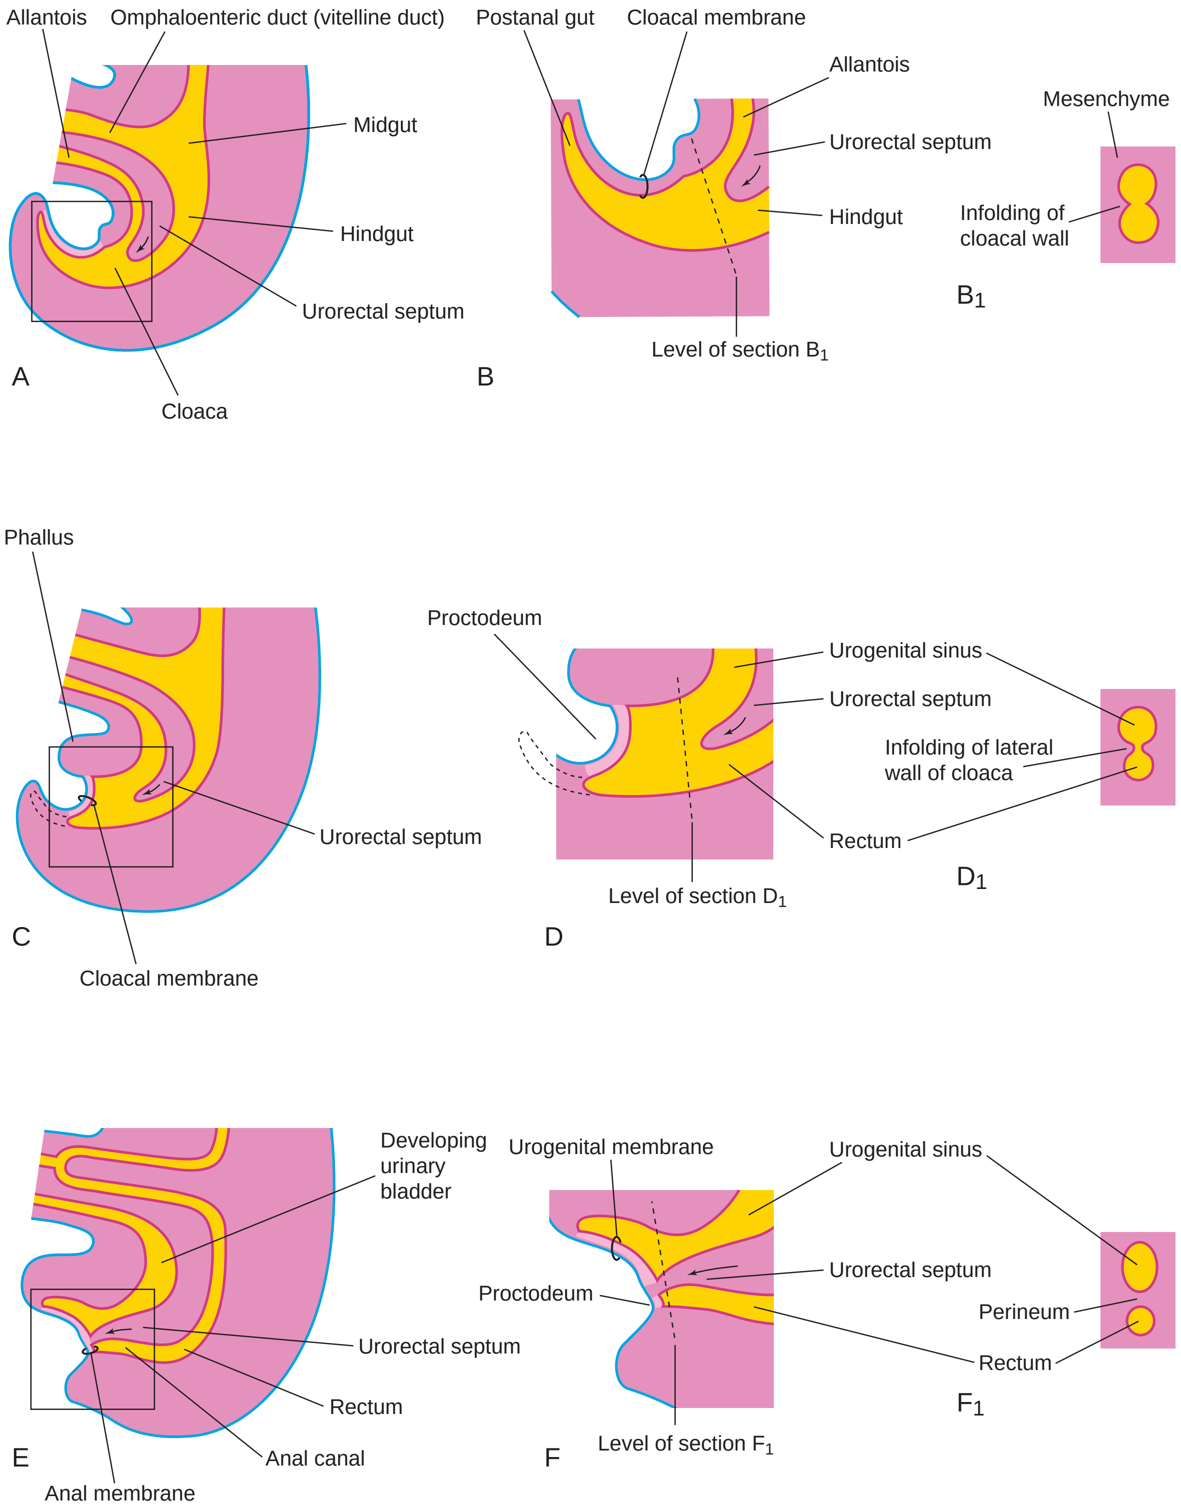

**Figure 83.9. Illustrations of successive stages in the partitioning of the cloaca into the urogenital sinus and the rectum by the urorectal septum.** (A, C, and E) Views from the left side at 4, 6, and 7 weeks, respectively. (B, D, and F) Enlargements of the cloacal region. ($B_1$, $D_1$, and $F_1$) Transverse sections of the cloaca at the levels shown in (B, D, and F), respectively. Note that the postanal gut, or tailgut (shown in B), degenerates and disappears as the rectum forms from the dorsal part of the cloaca (shown in C). The *arrows* indicate the growth of the urorectal septum. *(From Moore KL, Persaud TVN. The alimentary or digestive system. In: Moore KL, Persaud TVN, eds.* Before We Are Born: Essentials of Embryology and Birth Defects. *7th ed. Philadelphia: Saunders Elsevier; 2008.)*

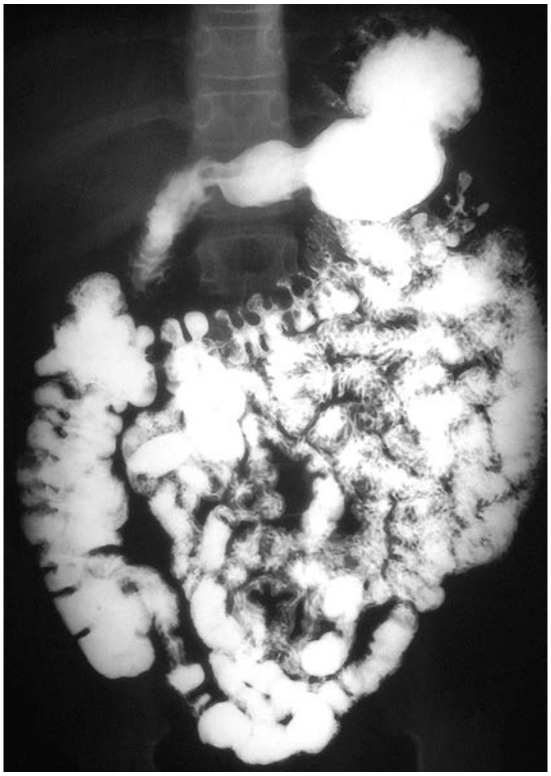

**Figure 83.10. Normal small intestine.** Frontal radiograph from an upper gastrointestinal series with small bowel follow-through shows contrast in the stomach, duodenum, jejunum, ileum, and ascending portion of the colon. The jejunal loops in the left upper quadrant have a feather-like fold pattern, while the ileum is relatively featureless.

## OVERVIEW

When the first edition of this textbook was published in 1945, its title was *Caffey's Pediatric X-ray Diagnosis*, denoting the single modality available at the time. In the intervening seven decades, there have been twelve additional editions of the book, and the title has changed to *Caffey's Pediatric Diagnostic Imaging* to reflect the diversity of tools now available to the pediatric radiologist. This expansion has been coupled with increasing awareness of radiation safety (as exemplified by the Image Gently Alliance) and concern for safety profiles of contrast agents and anesthetics, further adding to the complexity of choosing and implementing optimal pediatric imaging. This chapter is an overview of the various modalities available to image the pediatric gastrointestinal (GI) tract, with detailed applications addressed in the organ-specific chapters.

## RADIOGRAPHY AND FLUOROSCOPY

### Overview

Evaluation of the GI system includes the hollow viscera: from esophagus to rectum; solid viscera: liver, spleen, and pancreas; and the peritoneal cavity and retroperitoneal spaces in which all are contained. Although there can be considerable overlap among various modalities and newer applications continue to be defined, radiography and fluoroscopy are often used for initial imaging of the GI system.

Air is the inherent contrast medium in plain film diagnosis, and the abdominal series is based on distribution and movement of gas. The basic radiographic evaluation typically consists of supine and horizontal-beam images. Left-side-down decubitus and upright views evaluate for free intraperitoneal air and air-fluid levels. The left-side-down decubitus further directs air toward the right colon for evaluation of the right lower quadrant and into the rectum for evaluation of obstruction. Prone positioning is more effective in directing gas to the rectum when there is concern for bowel obstruction, with a horizontal-beam film (cross-table lateral) of the rectum often particularly helpful.

Fluoroscopy remains an important tool in further assessment of suspected pathology of the hollow viscera. Pulsed fluoroscopy can substantially decrease radiation dose while enhancing image sharpness and detectability of moving objects.[1,2] Capture and storage of the fluoroscopic images (fluorostore) can document such findings as viscus distension, course of contrast, and peristaltic activity, with spot films reserved for areas in which greater anatomic detail is of diagnostic importance, such as mucosal abnormalities and potential leaks.

### Contrast Media

In most GI fluoroscopic studies, enteric contrast is required for diagnosis, and it is important to choose the correct contrast medium for the clinical setting. Choices are usually barium or water-soluble iodinated media, which in turn are subdivided into high and low osmolality agents.[3,4] Barium, an inert substance that is not absorbed and has physical properties well suited to the roentgen ray, remains the major fluoroscopic contrast medium, particularly in older children. Barium is administered orally in evaluation of the esophagus and upper GI tract, or rectally for contrast enema. Several barium preparations are available: barium sulfate powder (96% w/w) can be diluted with sterile water for infant UGI examinations to the desired concentration of 40% to 60% w/v. Premixed suspensions (60% w/v) can be used in older children and adolescents as well as in adults. Enema kits containing 97% barium w/w can be mixed with water to a final concentration of 15% to 33% barium w/v for infants, older children, and adolescents. Adverse reactions to barium products are rare, typically related to any one of several additives such as methylparaben and carboxymethylcellulose, or even latex allergy to the enema tip.[5–7] Reaction rates are reportedly 2 per million or less,[5] but they do occur and may present as a rash, loss of consciousness, and anaphylaxis. Aspiration of barium in small quantities is tolerated but can be fatal if aspirated in a large volume.[8–10]

Barium is not indicated in cases in which viscus perforation is possible or suspected. In such cases, low-osmolality, nonionic water-soluble iodinated media are indicated (Table 84.1).

It is important that hypertonic media, such as ionic or high-osmolality media (diatrizoate, iothalamate), not be used orally due to the risk of aspiration and consequent pulmonary edema and chemical pneumonitis.[11–13] Further, such hypertonic media have been associated with risk of mucosal injury and with large fluid shifts, which are potentially dangerous, particularly in young infants, patients with obstruction, or those with tenuous cardiac or renal function,[14] as major fluid shifts into the bowel lumen can lead to a decrease in intravascular volume, an increase in serum osmolarity, and a decrease in cardiac output. The intraluminal contrast dilution generated by these fluid shifts also renders them generally unsuitable for small bowel evaluation, particularly in patients with suspected obstruction.[15,16]

Iohexol is a nonionic, water-soluble, iodinated contrast medium, which is available in concentrations of 140, 180, 240, 300, and 350 mg/mL of iodine. It is poorly absorbed from the intact GI tract, with renal excretion of 0.1% to 0.5% of administered dose. Iopamidol (Isovue) has also been used in the evaluation of the pediatric GI tract, but currently only iohexol is officially approved for this purpose. It must be emphasized that the osmolality of both of these media is greater than that of blood, and no agent is safe in the tracheobronchial tree. Therefore great care and close fluoroscopic monitoring is necessary in all patients in whom aspiration is a potential complication.[17]

Barium is the standard agent in evaluation of the colon. However, in cases of potential perforation, water-soluble agents are used and can be diluted to approximate the tonicity of serum. For example, iothalamate meglumine 30% with an osmolality of 600 can be diluted 1:1 with water to achieve a nearly iso-osmolal solution, with an iodine concentration that remains diagnostic for most purposes. Higher osmolality contrast media are used rectally for therapeutic purposes in cases of uncomplicated meconium ileus, after diagnosis with a low osmolarity agent. Gastrografin™ (diatrizoate meglumine and diatrizoate sodium) was the original agent described for this purpose.[18] However, this can be associated with large fluid shifts and systemic complications in severely ill infants.[15] Full-strength iothalamate meglumine 30% can also be used successfully for this purpose. Close attention to water and electrolyte balance, and surgical standby, are mandatory.

Air can also be used as a contrast during fluoroscopic procedures. For example, it is an excellent way to distend a viscus during

## Abstract:

To describe the various modalities available in Pediatric Imaging. Review of the relevant current literature, and include relevant illustrations and examples. Radiography, Fluoroscopy and the various fluoroscopic imaging examinations, CT are described, discussing appropriate use, technique and radiation optimization. Ultrasound and its various uses in abdominal imaging is also described and illustrated. Magnetic resonance imaging, indications, protocols, patient preparation, pulse sequences, contrast media are described and illustrated. Finally nuclear medicine examinations are described as an overview and individually

fluoroscopic transpyloric tube placement without obscuring the tube or adjacent bowel loops, and it is the preferred agent in reduction of intussusception.

## Specific Procedures, Indications, and Imaging Techniques

### Esophagram and Upper Gastrointestinal Examination

These two procedures are usually performed in conjunction and include evaluation of swallowing, the esophagus, stomach, and duodenum to the duodenojejunal junction.

The examination is begun with the child lying on his/her left side to maintain the ingested contrast agent within the fundus of the stomach. Images of the esophagus include from the nasopharynx to the esophagogastric junction, with special attention paid to nasopharyngeal aspiration, tracheal aspiration, masses, fistulas, and esophageal peristalsis and distensibility. The child is then placed supine, and the esophagus is examined in the anteroposterior projection. When the evaluation of the esophagus is completed, the barium in the fundus will be directed into the duodenum by laying the child in the prone right anterior oblique (RAO) position. Gastric emptying is assessed, along with distensibility of the antrum, the pylorus, duodenal bulb, and descending duodenum. Once the contrast has reached the junction of second and third portions of the duodenum, the infant is rapidly placed in the supine position for assessment of the duodenojejunal junction, visible through the air-filled antrum. This should lie to the left of the spine at approximately the same level as the duodenal bulb. Once this is accomplished, the child is again quickly turned, this time into a lateral projection, for documentation of the posterior course of ascending and descending limbs of the normally rotated retroperitoneal duodenum. Presence or absence of gastroesophageal reflux (GER) is assessed throughout the procedure, although the upper GI is not the optimal procedure to diagnose or exclude reflux. A final image documents gastric emptying (Fig. 84.1). Most of the findings in this examination are documented with fluorostore images, with exposures reserved for patients in whom abnormalities necessitating particularly high detail are evaluated.

Small bowel follow-through studies usually require ingestion of a larger amount of contrast agent, typically barium, although in premature infants a nonionic water-soluble contrast agent can be used. Radiographs are obtained at regular intervals based on the course of the contrast media through the bowel, with fluoroscopic evaluation when indicated. Images of the terminal ileum with and without compression are obtained if necessary once the contrast has reached the cecum. In ill infants in the neonatal intensive care unit who do not require visualization of the ligament of Treitz, a small bowel follow-through can be done with the contrast administered at the bedside, and portable radiographs obtained at the appropriate intervals.

### Contrast Enema

Although for many prior indications such as inflammatory bowel disease and colonic polyps, the contrast enema has been superseded by other procedures, such as endoscopy, computed tomography (CT), and magnetic resonance imaging (MRI) this examination remains extremely useful in many pediatric clinical settings. These include evaluation of distal bowel obstruction in the neonate, evaluation of surgical complications, sequela of disease such as necrotizing enterocolitis, and reduction of ileocolic intussusception.

The choice of contrast medium and the technique used for the contrast enema vary with the clinical indication and are discussed in the general fluoroscopy section above. Barium is the mainstay contrast medium used unless perforation is suspected, in which case near iso-osmolal water-soluble media is employed. In newborns suspected of distal bowel obstruction, near-iso-osmolal concentration water-soluble media is used with a change to hyperosmolal media if meconium ileus is encountered. Air is the contrast of choice for fluoroscopic intussusception reduction because of the rapidity of reduction, the decreased complications compared with liquid media in cases of perforation, and the lower radiation exposure.[19–22]

To perform an enema, a small tip catheter is placed in the rectum, and secured with tape to both buttocks, which are then taped together using manual pressure. Use of a balloon-tipped catheter is usually unnecessary, and some believe that it is inadvisable in young infants due to the potential for rectal injury. Fluorostore images can be recorded liberally to document the progression of the contrast medium and to document any findings dependent upon temporal change; spot filming is needed in areas requiring greater definition, such as mucosal detail, or if a subtle leak or perforation is suspected.

## ULTRASOUND

### Overview

Ultrasound (US) has become an extremely useful modality for evaluating patients with GI symptoms. It is particularly useful in children, because their small body size allows the use of higher frequency transducers leading to extraordinary resolution and detail in many clinical circumstances; harmonic imaging allows improved resolution with decreased artifacts. Beyond real-time gray-scale imaging, US includes spectral and color Doppler information on vascularity, ability to capture fleeting information via cine loops and to document motion such as peristalsis and diaphragmatic

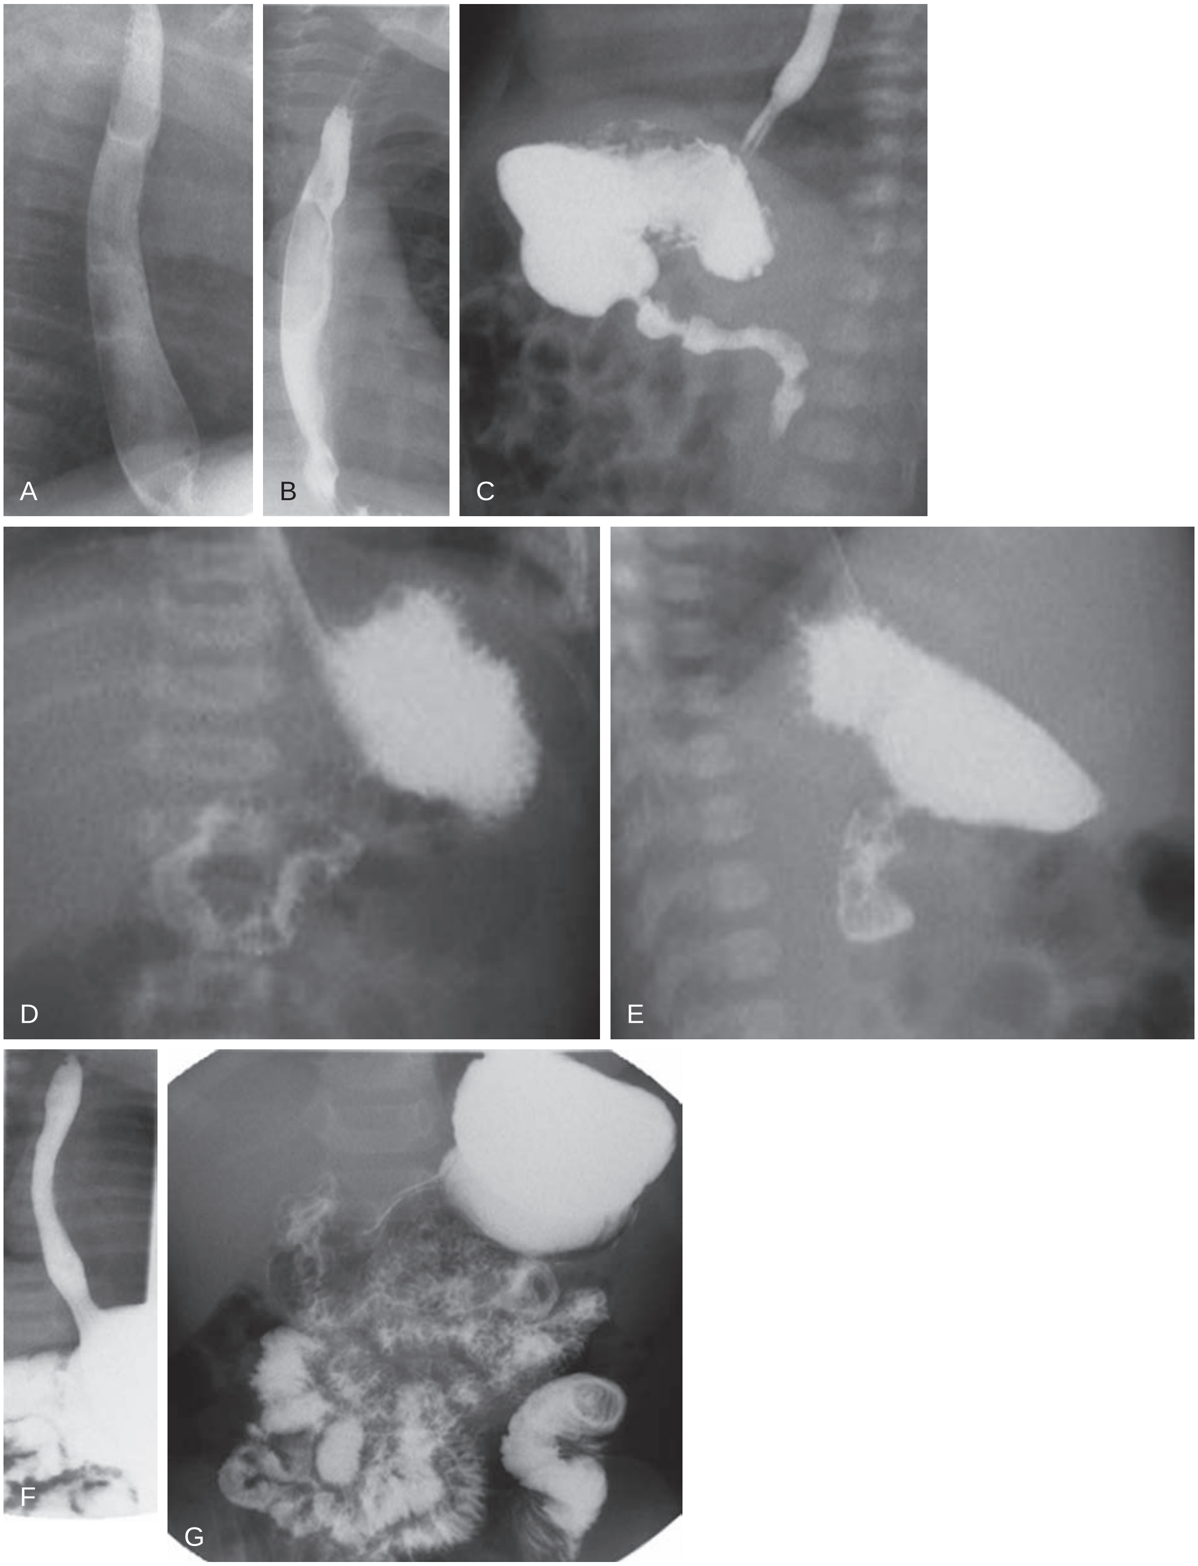

**Figure 84.1. (A–G) Typical UGI showing reflux in otherwise normal infant.** All are fluorostore images. (A and B) Lateral and anteroposterior views of esophagus during drinking show full distensibility without intrinsic or extrinsic mass lesions. (C) Oblique imaging (right anterior oblique) directs barium to gastric outlet and shows prompt emptying, normal pylorus, and first and second portions of the duodenum. (D) Anteroposterior image immediately following (C) shows progress of contrast to normally located gastroduodenal junction at the ligament of Treitz. (E) Subsequent lateral view of duodenum shows its posterior location anterior to the spine. (F) After further drinking and gastric filling, an episode of reflux to the cervical esophagus is documented. Note the wide-open gastroesophageal junction, a typical appearance during reflux. (G) Image recorded at the completion of the study shows good progress of contrast through the small bowel.

excursion. Extended field-of-view or panoramic imaging can outline large structures and masses on a single image, helpful in assessing pathology in context, or entirely. Newer technologies include ability to assess organ stiffness with elastography. US elastography has been found useful in pediatric patients as a marker for liver fibrosis[23] and in specific entities including biliary atresia,[24,25] liver transplantation,[26] and liver pathology developing after Fontan palliation of single ventricle anatomy,[27] with normal pediatric values available.[28] Elastography should be performed with the child NPO for at least 2 to 4 hours, without sedation, as both eating and anesthesia can transiently increase liver stiffness. More recently, the United States Food and Drug Administration (FDA) has approved intravenous US contrast media for pediatric liver imaging. Because of the very high temporal resolution of real-time US, use of intravenous contrast agents allows remarkable evaluation of perfusion dynamics not available with other modalities. The safety profile of the sonographic contrast agents compares favorably with that of CT and magnetic resonance (MR) contrast agents, and their utility has been documented in several areas, including characterization of liver masses and detection of complications of liver transplantation.[29–33]

## Indications

The utility and application of US in the pediatric patient is extensive and increasing (Box 84.1). Application of US to pediatric patients suspected of pyloric stenosis and appendicitis occurs daily in pediatric radiology practices (e-Fig. 84.2).[34–37] US is also useful in evaluation of mesenteric adenopathy (e-Fig. 84.3), assessment of the bowel (Fig. 84.4) and bowel wall,[38] small and large bowel intussusception (e-Fig. 84.5),[39] and coupled with Doppler allows accurate estimation of disease activity in Crohn disease.[40–43]

**BOX 84.1** Common Indications for Abdominal Ultrasound

- Bowel: pyloric stenosis, appendicitis, inflammatory bowel disease, intussusception
- Liver: masses, infection, biliary disease, congenital anomalies
- Spleen: heterotaxy, splenic masses, wandering spleen
- Pancreas: pancreatic ductal dilatation, pancreatic masses, pseudocysts
- Peritoneum: ascites, loculated collections
- Doppler: portal hypertension, portosystemic shunts, vascular congenital malformations, tumors
- Elastography: hepatic fibrosis
- Intravenous contrast: liver masses, vascular anomalies

The role of US in diagnosis of solid organ pathology is also extensive and can be the final diagnostic tool in many abnormalities. Indications include evaluation of hepatic, biliary, splenic, and pancreatic abnormalities. Liver masses are often first diagnosed and evaluated by US, allowing refinement of any subsequent CT or MRI protocol.

Although vascular structures are easily seen with contrast-enhanced CT, the direction and velocity of flow can be evaluated with Doppler sonography, often rendering the findings in these modalities complementary. Analysis of waveform pattern can identify hepatofugal flow in collateral vessels in patients with portal hypertension or vascular stenoses. In patients with heterotaxy, US is helpful in assessing splenic mass (located along the greater curvature of the stomach) and the associated vascular anomalies, such as interruption of the inferior vena cava, preduodenal portal vein, and infradiaphragmatic total anomalous pulmonary venous connection.[44,45]

## Practical Technical Points

The type and frequency of the transducer used is particularly important in pediatric imaging, as patient size can vary from 500 grams to 150 kilograms or larger. In general, the patient should be scanned with the highest frequency transducer that will penetrate the anatomy to be imaged; linear transducers are preferred if the access window will allow it. We typically image the bowel in neonates with a linear transducer operating at frequencies of 10 to 18 MHz. If overview and detail are both needed, more than one type of transducer may be necessary in many patients; for example, imaging of the abdomen in a 3-year-old child may be accomplished with a curved transducer operating at 6 MHz for overview, but additional images of detailed hepatic parenchyma or of the bowel can be performed with a linear transducer operating at higher frequency.

# COMPUTED TOMOGRAPHY

## Overview

CT is a particularly useful modality in pediatric abdominal imaging and has become a surrogate for many exploratory laparotomies

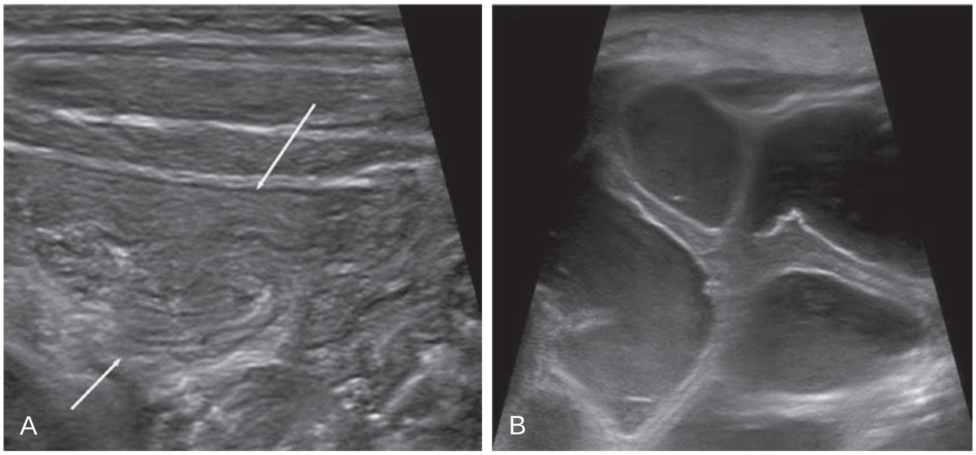

**Figure 84.4. Bowel ultrasound.** (A) Abdominal sonogram in 3-month-old demonstrates normal, collapsed loops of small bowel *(arrows)*. (B) Abdominal sonogram in 2-month-old ex-premature infant status-post bowel perforation and complex surgical history reveals dilated fluid-filled loops of bowel.

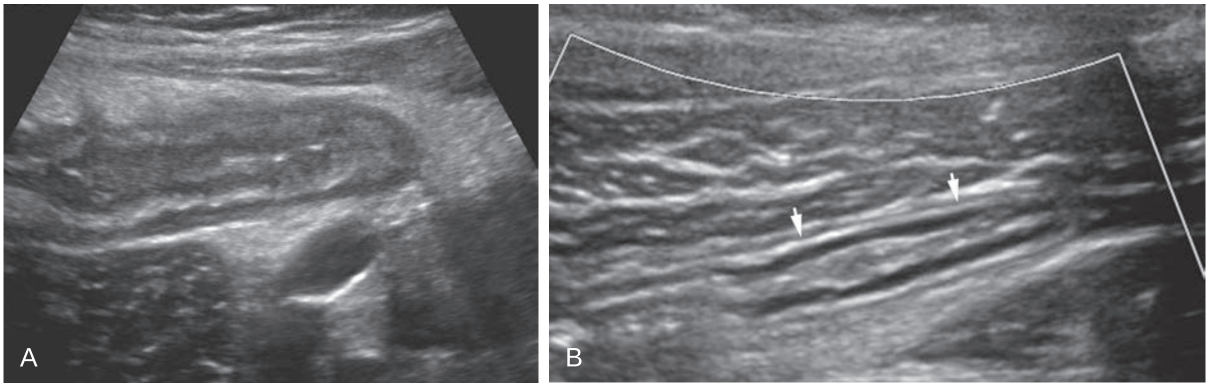
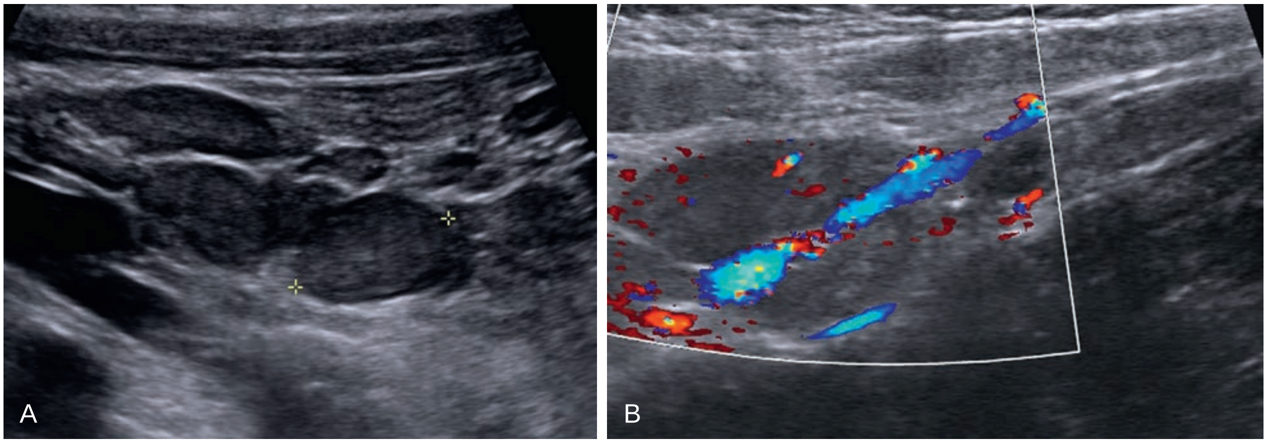
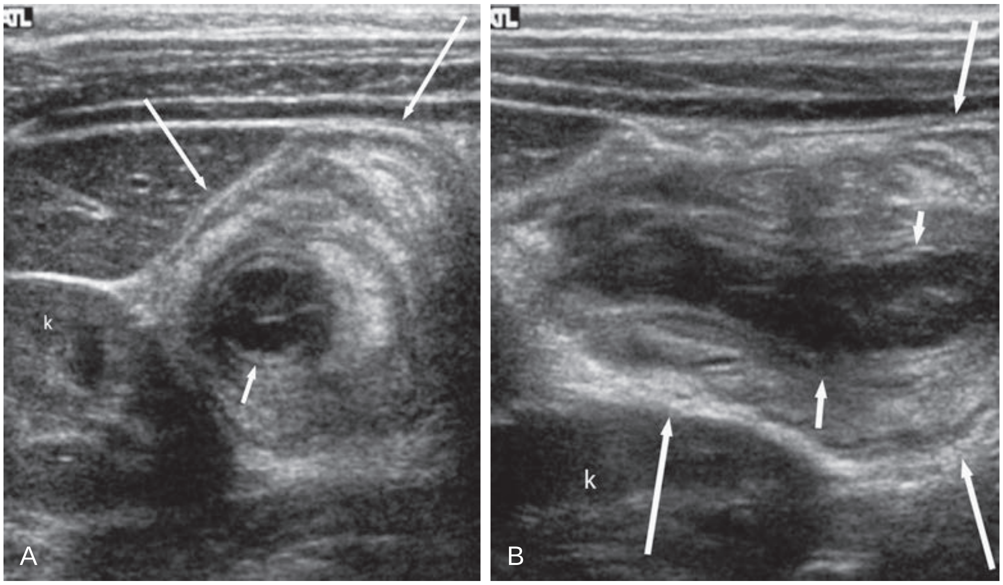


**e-Figure 84.2. Appendicitis and normal appendix.** (A) Longitudinal sonogram of acute appendicitis shows that the appendix measures 8 mm in diameter, is fluid-filled, and is surrounded by hyperechoic material consistent with periappendiceal edema. (B) Longitudinal sonogram of a normal appendix *(arrow)*.



**e-Figure 84.3. Mesenteric adenopathy.** (A) Transverse sonogram through right lower quadrant with linear transducer demonstrates multiple enlarged mesenteric nodes in 8-month-old child with gastroenteritis. (B) Doppler interrogation reveals flow into the nodal hilum.



**e-Figure 84.5. Intussusception of the appendix.** Three-year-old girl with 3-day history of abdominal pain and bloody stools. (A) Transverse and (B) longitudinal image through right lower quadrant reveal the appendix *(short arrows)* within the intussusceptum complex *(long arrows)*. Air reduction was only partly successful; at surgery, reduction was completed and appendix removed, which showed gross lymphoid hyperplasia obliterating the lumen. *k*, Right kidney.

of the past. Current scanners with multidetector technology and volumetric acquisition permit very rapid examinations with isotropic reconstructions and new applications in areas such as angiography. Further developments in reconstruction techniques and temporal resolution have enabled subsecond examinations, with greatly reduced radiation dose and very limited need for sedation.[46–51]

These new capabilities are both an opportunity and a challenge,[52,53] with the need for newer protocols to accommodate more complex and sophisticated diagnostic demands. The timing and rate of contrast administration, with the ability to scan during a specific phase of intravascular contrast distribution, demand particular attention to technical details and new approaches to image interpretation. Dual energy examinations offer the ability to generate virtual precontrast images as well as iodine maps, and to perform tissue characterization.[54–57] The pediatric radiologist is further challenged by the need to balance image detail with radiation dose and implementation of the "as low as reasonably achievable" (ALARA) concept. The Image Gently Alliance sponsors the concept of justification and optimization, simply stated as the Right Study, for the Right Patient, at the Right Time, done the Right Way (www.imagegently.org).[58–61]

## Indications

Unlike US, CT images are sequential, standardized, and much less operator dependent. CT is particularly useful in patients with complex disease affecting multiple organ systems, such as malignancies, with reliable monitoring of change in extent of disease during therapy and follow-up (Box 84.2). CT is helpful as a problem-solving technique in patients with unusual multicompartment abnormalities (e-Fig. 84.6). Evaluation of solid organ pathology, such as hepatic portal hypertension, trauma, pancreatitis, and tumors, is rapidly accomplished with great anatomic detail and physiologic information. CT is also widely and successful applied to pathology of the hollow viscera and peritoneal cavity. The lack of operator dependence and high sensitivity and specificity of CT in the imaging diagnosis of appendicitis has led to its increasing use when this diagnosis is clinically equivocal, with documented reduction in negative appendectomy.[62] However, this success led to overuse in patients with abdominal pain; therefore physical examination, followed by US when the diagnosis is clinically uncertain, is recommended by most pediatric radiologists.[34,35] More recently, MRI has been shown to be an accurate substitute for CT scanning in many pediatric patients.[63–65] In the acute and chronic evaluation of inflammatory bowel disease, there is a role for US, contrast-enhanced US, CT, and particularly MR; MR is preferred for surveillance monitoring of disease activity and evaluation of perianal disease.[66,67]

## Protocols

Protocols for various pediatric abdominopelvic CT examinations vary and undergo change with the ongoing introduction of new applications and advances in equipment capability; generalizable protocols applicable to pediatric patients can be downloaded at www.imagegently.org. However, some underlying principles underscore most successful pediatric examinations. Administration of intravenous contrast is extremely important for diagnostic images, particularly in pediatric patients, in whom paucity of intraabdominal fat decreases intrinsic intraabdominal contrast.[56,68] CT angiography requires rapid contrast bolus injection, which in pediatrics can be challenging due to the caliber of possible intravenous access, but this limitation is countered by the smaller volume of contrast needed. Lowering kVp is important in patients in whom high contrast structures are of interest, such as those undergoing angiography or bone examinations. In neonates, the kVp can be decreased to as low as 80 or 70, with some adjustment of the mAs to produce acceptable image quality.[58] Precontrast images are rarely necessary, which decreases radiation dose. The use of oral contrast material is usually important when outlining intraperitoneal pathology, such as abscess or masses. In the evaluation of the bowel, its use is more controversial[69]; positive oral contrast material will mask mucosal enhancement, and water-density contrast may be more appropriate in such cases. We review images at 3 mm collimation in most patients and at 2 mm collimation in infants. Coronal and sagittal reformatted images are often diagnostically helpful.

CT is a life-saving, important modality in pediatric diagnosis. As with any imaging tool, it must be used judiciously, according to the principles of appropriateness, justification, and optimization.[70]

### BOX 84.2 Common Indications for Computed Tomography of the Gastrointestinal Tract

- Trauma
- Masses and malignancy
- Peritoneal disease: abscess, tumor, loculated collections
- Inflammatory conditions
- Liver disease: portal hypertension, liver transplantation
- Congenital anomalies: bowel rotation and fixation, duplication cysts, complications of Meckel/omphalomesenteric duct remnants

# MAGNETIC RESONANCE IMAGING

## Overview

MRI is increasingly used for pediatric GI applications. In this section, we review hepatic, biliary, pancreatic, and enteric MRI, including the most common indications and goals of MRI for these indications, followed by patient preparation concerns and a brief overview on preferred hardware. We also discuss the most commonly used sequences as well as combinations of these sequences to form protocols.

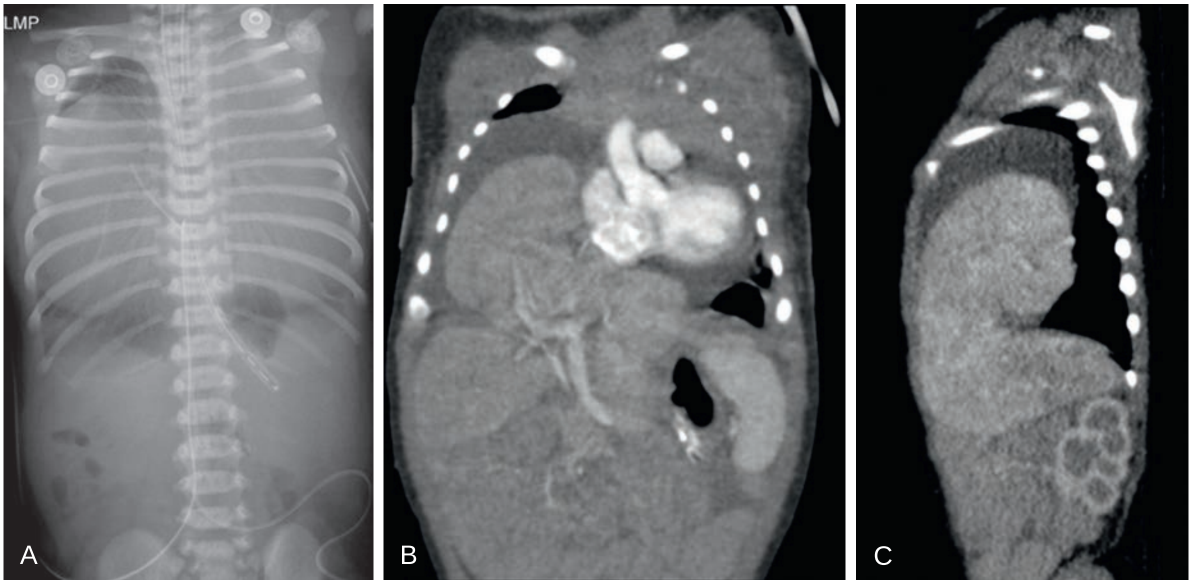
## Indications

### Hepatic Tumors

Hepatic tumors are well evaluated by MRI relative to CT in both adult and pediatric situations,[71] with the goal of imaging being tumor characterization, staging, and assessment of resectability. For characterization of these lesions, determination of T2 signal and enhancement characteristics is essential.[72] Tumor staging and determination of resectability requires delineation of anatomic boundaries, lymph node involvement, vascular invasion, and delineation of the biliary tree. In patients with hepatoblastoma, PRETEXT (PRETreatment tumor EXTension) staging dictates features that must be delineated, outlined by the International Childhood Liver Tumor Strategy Group (SIOPEL).[73,74] The same features are helpful in assessment of other malignant hepatic tumors.

### Biliary and Pancreatic Diseases

These are also well assessed by MRI.[75,76] Common indications include cholelithiasis, pancreatitis, sclerosing cholangitis,[77,78] ductal plate malformations, as well as choledochal cysts[79–81] and biliary complications of liver transplantation. Goals of imaging include (1) delineation of anatomy for strictures, stones, and anomalies; (2) assessment of inflammatory findings; and (3) assessment of obstruction. In the case of liver transplantation, assessment of vascular complications is often essential.



**e-Figure 84.6. Unusual presentation of Morgagni hernia.** (A) Abdominopelvic radiograph of newborn infant with prenatal diagnosis of hydrothorax. The radiographs suggest absence of most of the liver shadow from the right upper quadrant. The posterior costophrenic sulci are well outlined, indicating that chest density is not related to bilateral hydrothorax. (B) Coronal and (C) sagittal reformats of contrast-enhanced CT examination outline herniation of the liver into the pericardial sac with large pericardial effusion.

### Diffuse Liver Disease

These include conditions such as fibrosis, steatosis,[82–84] and iron deposition. Fibrosis can be assessed qualitatively[85] by T2-weighted imaging and delayed contrast enhancement.[86] More recently, MR elastography offers an accurate method to assess liver stiffness as a correlate to liver fibrosis. Other conditions that can lead to increased liver stiffness include acute liver inflammation and increased bloodflow in the postprandial state in patients with chronic liver disease; therefore the procedure should be performed with fasting.[87–91] Although steatosis can be assessed by spectroscopic methods,[92] more commonly steatosis, as well as iron deposition, are assessed by multiecho gradient echo imaging.[84,93–98]

### Enterography

MR enterography is most commonly performed for evaluation of inflammatory bowel disease.[99–101] The goals of MR include detection of bowel inflammation, distinction of active inflammation from chronic fibrosing disease, detection of fistulae and abscesses, characterization of disease, and response to therapy.[41,102–109]

### Fistulography

Fistulography, particularly for fistula in ano, is well performed by MRI.[104,110,111] The goals of the examination include detection of fistulae, classification (intersphincteric, transphincteric, suprasphincteric, or extrasphincteric), and abscess detection.

## Patient Preparation

### Sedation

Preparation begins with assessment of the needed sedation/anesthesia. Generally, children younger than 6 years of age who cannot perform a 20-second breath-hold will need sedation/anesthesia. This breath-holding requirement can be relaxed for MR cholangiopancreatography (MRCP), as will be detailed later, as well as in facilities with a distracting MRI-compatible goggle system. Sedation is avoided in patients undergoing enterography examinations due to the need for oral contrast. Finally, once the patient is on the MR table, a respiratory monitoring pillow or belt should be carefully placed. Often this is challenging and time-consuming in young children but is well worth the aggravation.

### Fasting Requirements

Patients should refrain from oral intake for 4 hours before the examination to minimize artifacts from bowel peristalsis as well as ensure full gallbladder distension in examinations of the biliary tree.

### Contrast

For all cases requiring vascular assessment, power injection of contrast is optimal, which requires adequate peripheral venous access. Oral contrast is essential for enterography examinations. A number of choices for oral contrast medium is acceptable, although most regimens consist of a biphasic agent (i.e., one that gives the bowel lumen a long T2 and T1 relaxation time). Agents include VoLumen (E-Z-Em, New York, NY), Breeza (Beekley Medical, Bristol, CT), mannitol solution, polyethylene glycol, locust bean gum solutions, and some fruit juices. The difference in efficacy of these choices is relatively small, though patient tolerance may vary.[112] The most important aspect of the regimen is rapid consumption of a large volume; 25 mL per kilogram of body weight over an hour is adequate. Placing the patient in right decubitus for the last 15 minutes before the start of imaging aids in emptying of the stomach.

### Antiperistaltic Agents

Spasmolytic agents that can be used during MR enterography include glucagon and hyoscine-N-butylbromide. Glucagon, the more commonly used intravenous agent, can be employed with either of two strategies: (1) half of the dose at the beginning of the examination and half just before intravenous contrast or (2) entire dose just before intravenous contrast. The dose varies between facilities from 0.5 mg to 1 mg. Although glucagon causes nausea and vomiting, it is well tolerated by the vast majority of patients if it is given as a slow intravenous push over 1 minute and if before administration the patient is instructed to expect a brief period of nausea.

## Hardware Requirements

Although the literature to date remains relatively sparse on pediatric abdominal imaging at 3 Tesla (T),[113–118] existing literature and experience suggest that most children will benefit from the higher signal provided by the higher field strength. In smaller patients, such as children younger than 8 years, the improvement in image quality is striking. Phased array surface coils are now standard, typically with 8 to 32 channels. For almost all children, cardiac arrays are optimal. For the largest patients, a torso array may be necessary. Situations in which 1.5 T often provides improved image quality over 3 T include very large patients, ascites, enterography examinations (fewer banding artifacts in steady-state imaging), and hepatic iron quantification in children with severe iron overload.

## Protocols

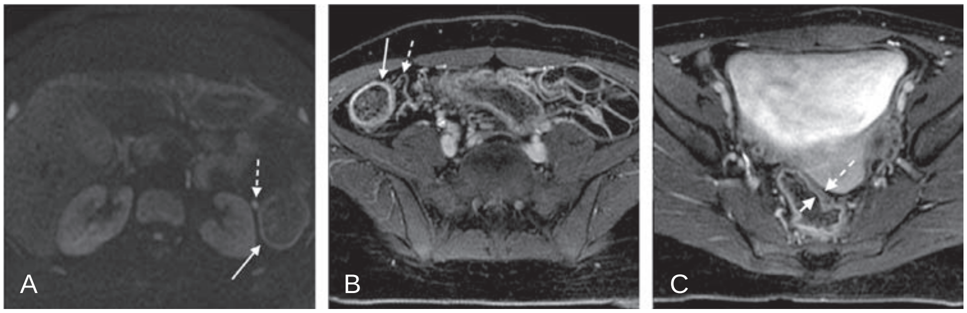
Suggested protocols are given in Table 84.2, with examples in Figs. 84.7 and 84.8 and e-Figs. 84.9 and 84.10, and details to follow. In general, matrix, field of view, and slice thickness should be adjusted to the patient size and are thus not emphasized in this chapter.

### Localizers

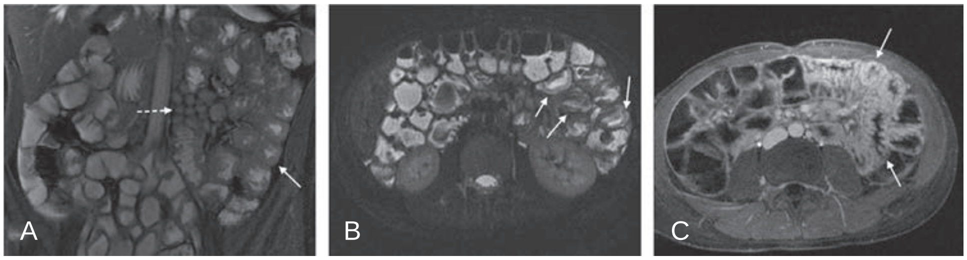
At 1.5 T, three-plane single-shot fast spin echo with low bandwidth (20 kHz), matrix, and repetition time (TR) are performed. If diagnostic single-shot images are required, the matrix (320 × 256), slice thickness (4–5 mm), and echo time (200 ms) can be adjusted appropriately and images acquired with respiratory triggering.[119] At 3 T, if diagnostic single-shot images are not required, localizers may be more efficiently achieved with balanced steady state imaging to conserve SAR (specific absorption rate), especially for small patients. All localizer sequences should employ parallel imaging.

### Conventional T2 Imaging

Conventional T2 imaging can be performed with fast spin echo in coronal and axial planes. In this instance, parallel imaging should not be employed, as the primary emphasis is on tissue characterization with high signal-noise ratio (SNR). Sequences should be respiratory-triggered or navigated, and performed at least in the axial plane.[120,121] Typical echo times are 80 to 90 msec at 1.5 T and 70 to 80 msec at 3 T. Fast recovery may be employed to improve SNR. As the literature is mixed on the ability of single-shot images with T2 weighting to provide an equivalent alternative to longer conventional T2 imaging,[122] our protocols almost always include conventional T2-weighted imaging.



**e-Figure 84.9. MR enterography of a 16-year-old girl with ulcerative colitis.** (A) Diffusion-weighted image highlights the colonic wall *(arrow)* as well as a small pericolonic lymph node *(dashed arrow)*. (B) Contrast-enhanced SPGR image shows cecal mucosal enhancement *(arrow)* and prominent adjacent vessels *(dashed arrow)*. (C) Enhancement is pancolonic and mucosal as seen by the signal intensity difference between the luminal *(arrow)* and serosal *(dashed arrow)* side of the bowel.



**e-Figure 84.10. MR enterography of a 14-year-old boy with Crohn disease and jejunitis.** (A) Coronal balanced steady state imaging shows jejunal wall thickening *(arrow)* and prominent mesenteric lymph nodes *(dashed arrow)*. (B) Axial single-shot T2-weighted image shows submucosal edema *(arrows)*. (C) Axial contrast-enhanced spoiled gradient echo with fat suppression immediately after intravenous glucagon administration shows hyperemic bowel and again demonstrates thickened folds *(arrows)*.

**TABLE 84.2** Common Pulse Sequences for Hepatobiliary and Bowel Magnetic Resonance Imaging

| | | Indication | | | | | |
|---|---|---|---|---|---|---|---|
| **Pulse Sequence** | **Scan Time** | **Tumors** | **MRCP** | **Transplant** | **Liver Iron/Fat** | **Enterography** | **Fistulography** |
| Localizer (1.5 T: SSFSE, HASTE, SSH-TSE; 3 T: FIESTA, TrueFISP, Balanced FFE) | 20 sec-3 min | x | x | x | x | x | x |
| Two dimensional T2 (FSE, TSE, TSE) | 3-4 min | x | x | x | Optional | | Two planes |
| Volumetric T2 (CUBE, SPACE, VISTA) | 4-5 min | Optional | x | x | | | x |
| Single-shot (SSFSE, HASTE, SSH-TSE) | 2-3 min | | x | x | | x | |
| Balanced steady state (FIESTA, True-FISP, balanced FFE) | | | | | | x | |
| Diffusion | 1-3 min | x | | Optional | | Optional | Optional |
| Dual echo (LAVA-Flex, VIBE-Dixon) | 30 sec | x | | x | x | | |
| Multi-echo gradient echo | 30 sec | | | | x | | |
| Noncontrast MRA | 4-5 min | | | x | | | |
| SPGR (LAVA, VIBE, THRIVE) | 30 sec | Full echo | Optional with gadoxetate | Partial echo | | x | x |

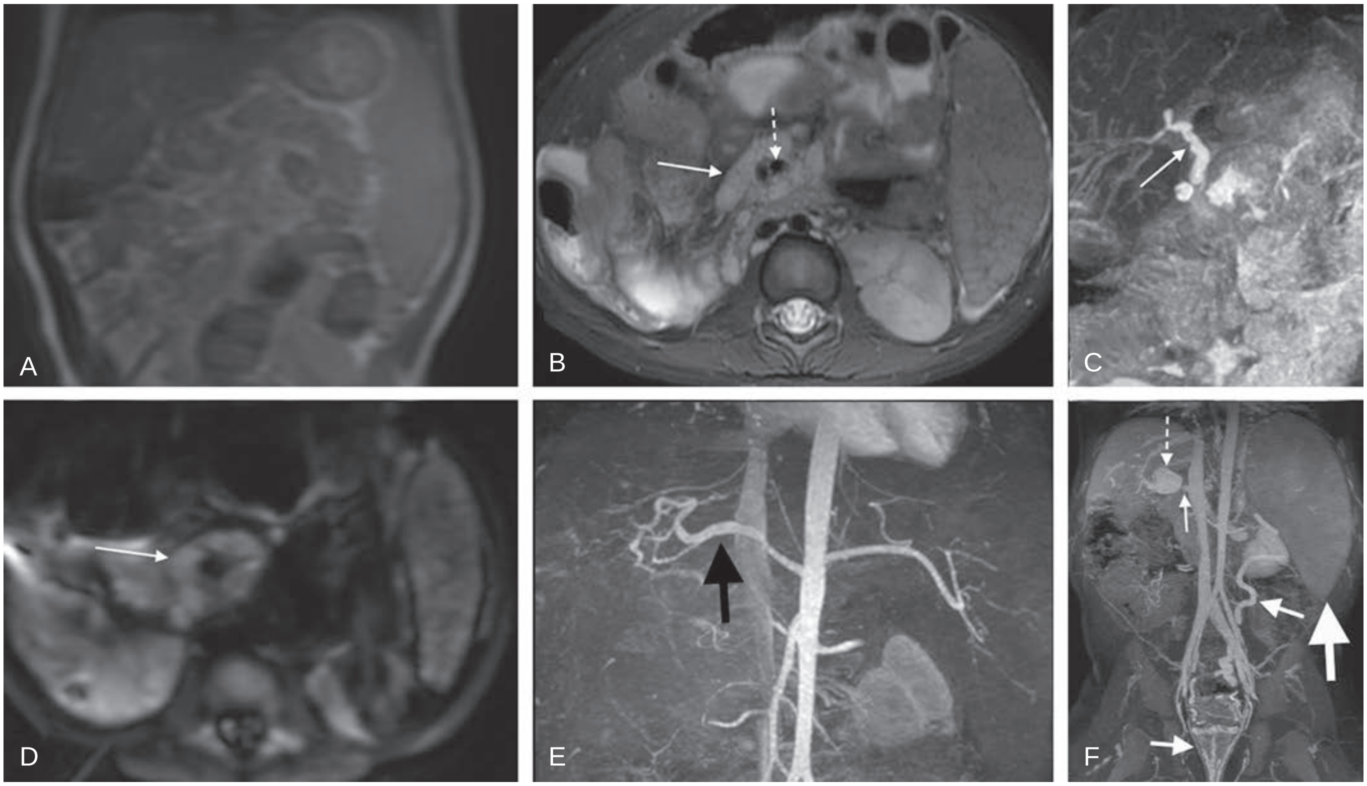


**Figure 84.7. MRI of a 1-year-old girl with a left lobe lateral segment liver transplant.** (A) Localizer is performed quickly. (B) Axial fat-suppressed T2-weighted image shows lymph nodes *(arrow)* surrounding mesenteric vessels *(dashed arrow)*, suggesting posttransplant lymphoproliferative disorder. (C) Maximum intensity projection of volumetric T2-weighted images showing patent bile ducts *(arrow)*. (D) Axial diffusion imaging again showing lymph nodes *(arrow)*. (E) Contrast-enhanced angiogram (SPGR with fat-suppression) showing patent hepatic artery *(black arrow)*. (F) Venous phase imaging shows proximal portal vein *(small arrow)*, poststenotic dilation of intrahepatic portal vein *(dashed arrow)*, hemorrhoidal varices *(medium arrow)*, and splenomegaly *(large arrow)*.

## Volumetric T2 Imaging

Volumetric T2-weighted sequences have been mostly described for musculoskeletal and neuroimaging.[123–125] These pulse sequences are similar to fast spin echo in that a 90-degree excitation is required, although it excites a slab rather than a slice. This excitation is followed by a train of refocusing pulses, and the flip angle is varied to maintain signal uniformity despite a long train (typically 60–100 echoes). This variation of the flip angle is set by the various vendors and does not require the user to prescribe it. These sequences

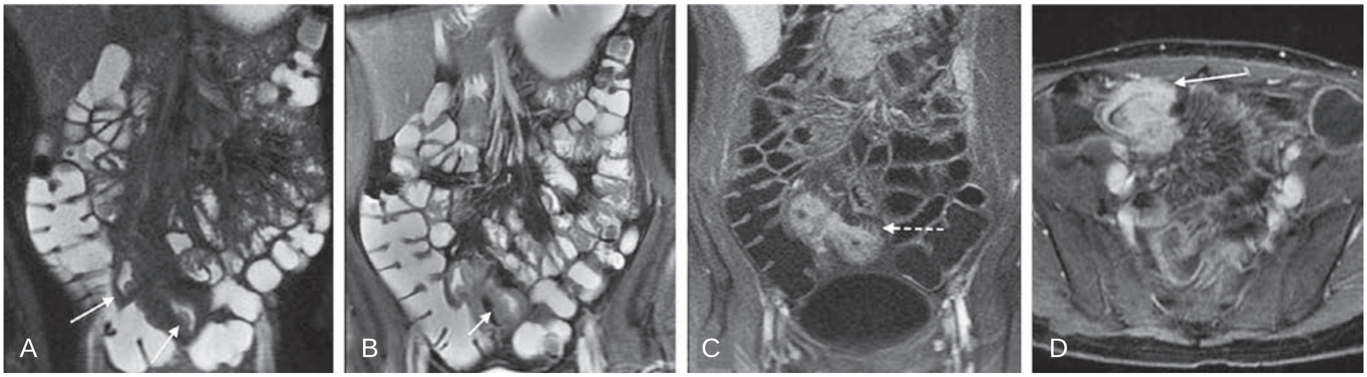

**Figure 84.8. MR enterography of a 20-year-old woman with typical manifestations of Crohn disease.** (A) Single-shot T2-weighted imaging shows thickened terminal ileum with submucosal edema *(arrows)*. (B) Balanced steady-state imaging shows wall thickening *(arrow)*. (C) Hyperemia and early transmural enhancement is seen after contrast administration *(dashed arrow)*. (D) Delayed imaging shows persistent enhancement of the terminal ileum *(arrow)*.

permit thin slices (1–2 mm) and reformatting in arbitrary planes. Parallel imaging is essential to maintain a reasonable scan time of 4 to 5 minutes. Navigation or respiratory triggering should be used along with a high bandwidth (e.g., 62 kHz). For dedicated MRCP examinations, a high TE (>500 msec) can be used to permit excellent maximum intensity reformation of the biliary tree and pancreatic duct. For other examinations, a TE of 70 to 90 msec can be used, which permits delineation of all anatomy, including a good assessment of the bile ducts on individual slices.

## Single-Shot Imaging

Although volumetric imaging usually displays the bile ducts well,[126] image quality will likely be suboptimal in patients with irregular breathing, peristalsis, and voluntary motion. Thus single-shot imaging is complementary[127] for biliary imaging and essential for bowel imaging.[116,128] In patients with irregular breathing, the user can hand-trigger acquisition of each slice by observing the respiratory belt tracing, enabling reasonable assessment of bile ducts in even the most challenging patients.

## T1-weighted Imaging

Dual echo imaging (SPGR with both in-phase and opposed-phase echoes) offers volumetric images at high spatial resolution along with fat-water separation. These sequences can be performed in a breath-hold, and data can be processed to yield four image sets from one acquisition: water, in-phase, opposed-phase, and fat. Typical parameters are high bandwidth (100 kHz), 4-mm slice thickness, and 12- to 15-degree flip angle.

## Contrast Agents

For assessment of contrast enhancement, several gadolinium-based agents are available. In the setting of renal insufficiency, macrocyclic agents have an enhanced safety profile.[129] If the primary clinical concern is evaluation of the vascular structures, gadobenate dimeglumine (MultiHance) is a reasonable option given its higher relaxivity and longer intravascular residence time. Gadofosveset trisodium (Ablavar) has been approved by the FDA for assessment of aortoiliac disease in adults and became an option in vascular evaluation; however, as of this writing, it is no longer available. More recently, ferumoxytol has become available for prolonged intravascular enhancement.[130–132] Finally, gadoxetate disodium (Eovist) is a good option in hepatic and biliary imaging.[133–141] This agent is taken up by hepatocytes and has 50% hepatobiliary excretion in the setting of normal hepatic and renal function and thus provides a functional as well as anatomic MRCP examination.[142] However, the user should note that gadoxetate dose is 0.025 mmol/kg (i.e., only a quarter of the gadolinium of other agents). As the T1 relaxivity of this agent is higher than that of conventional agents, adequate first-pass imaging of the liver can still be performed. For all agents, rate of single-dose administration at 1 mL/sec, followed by a saline flush is acceptable.

## Dynamic Gadolinium-Enhanced Imaging

In dynamic studies, a three-dimensional (3D) SPGR sequence with intermittent fat suppression can be used (minimum TR, 15-degree flip angle, 62 kHz bandwidth). Generally, if a patient can perform a breath-hold, the matrix and number of slices are adjusted to make the scan time match the patient's ability. If the patient cannot breath-hold sufficiently, quiet breathing can be used, along with motion-tolerant techniques, such as navigation,[143] radial,[144] or other noncartesian k-space trajectories.[145] Additionally, these techniques can be combined with parallel imaging,[146,147] view sharing,[148,149] and compressed sensing.[150,151]

There are two significant differences in technique of dynamic gadolinium studies, depending on the goal of the examination. If tumor characterization or detection of bowel wall enhancement is the primary goal, a scan delay should be set to ensure that the center of k-space is acquired at 30 seconds after half the contrast is administered: The scan delay to achieve this is calculated as follows: Scan delay = 30 seconds – (scan duration + bolus duration)/2. For example, with a 30-second scan and a 10-mL bolus infused at 1 mL/sec, the scan delay is 30 – (30+10)/2 = 10 sec. If vascular assessment is a primary goal, a timing run can be performed with fluoroscopic triggering and centric k-space acquisition, or sequential k-space acquisition and calculation of the scan delay substituting the time to abdominal aortic peak enhancement for 30 seconds in the previous equation.

The second difference in technique is the choice of echo time. For tumor characterization, the minimum full echo time should be chosen to maximize SNR. However, for vascular or bowel enhancement, the minimum echo time (i.e., a fractional echo) should be used to minimize spin dephasing artifacts from flowing blood, or field inhomogeneity near the bowel wall from enteric gas, as well as to minimize scan time.

## Noncontrast MRA and Alternatives to Gadolinium

Although contrast-enhanced MR angiography (MRA) has become the dominant MR method of vascular assessment, the administration of gadolinium contrast may be contraindicated in some patients with renal insufficiency. Additionally, the technique has little room for error as intravenous contrast can only be given once; an injection-scan timing mismatch or patient motion during the scan cannot be rectified. Thus noncontrast-enhanced techniques improve the reliability of MRI as a modality for assessment of abdominal vasculature.

Although time-of-flight-based approaches have been used, these sequences produce limited image quality in the abdomen. Noncontrast-enhanced techniques based on balanced-steady state approaches are useful, such as in the context of adult renal artery stenosis.[152] A variation of this method is based on a respiratory-triggered inversion pulse covering the imaged volume as well as a region inferior to it.[153] This is followed by a balanced steady-state echo train, similar to that used for noncontrast-enhanced coronary artery imaging but without cardiac gating. Thus blood flowing from superior to the inverted region is bright, producing an MR angiogram. These sequences have pitfalls similar to time-of-flight-based techniques, including flow-related dephasing, slow-flow related signal dropout, and intrinsically high T1 signal, but on the whole provide a nice complement to contrast-enhanced MR angiography.

Another option for vascular studies is the use of iron oxide–based contrast agents.[154,155] These agents have high relaxivity and prolonged residence time in the blood pool, which is particularly advantageous for pediatric applications.[156,157] However, these agents may have a higher rate of severe adverse reactions compared with gadolinium and thus should be administered with caution.[158–160]

### Iron/Fat Quantification

Although MRI methods of hepatic iron quantification based on T2 signal and a composite of signals (proton density, T2, T2*, and T1: see[161]) have been used, the most common approach is based solely on T2* measurement. T2* value depends on field strength, and measurement can be done on any scanner with a multiecho gradient-echo sequence. These examinations are generally done on 1.5 T scanners, but the calibration of iron concentration based on T2* has been reported at both 1.5 T[93] and 3 T.[162,163]

T2* may be calculated by running a gradient echo sequence multiple times at different TE values but with a fixed TR of approximately 150 msec. Typical normal values should range from approximately 1 to 20 msec, and the user should avoid prescanning between sequences (or the transmit and receiver gains may change). A region of interest can then be drawn in the same area of the liver on each of the resulting series of images. Thus mean signal at each echo time is known and will demonstrate an exponential decay relationship (Signal = $Ae^{-R_2^*TE} + B$, where $R_2^* = 1/T_2^*$). $R_2^*$ and hence $T_2^*$ can be determined by various software packages using logarithms and linear regression.

The previously described process for determining $T_2^*$ is time-consuming for data acquisition as a breath-hold for each echo time is required. Additionally, regression must be performed and is disruptive to workflow. An alternative is multiecho gradient echo sequences, in which a series of gradient echoes is obtained at various echo times after each excitation. The multiecho approach can be performed with two-dimensional (2D) acquisition of a single slice of the liver or a 3D volume acquisition. Whether 2D or 3D, the acquisition is a single breath-hold, which has the advantage of avoiding slice misregistration, is easier on the patient, and facilitates patient throughput. When coupled with an image reconstruction algorithm that performs a fit to determine $R_2^*$, image maps are obtained and workflow is improved. These pulse sequences and reconstruction programs are now widely available on all major MRI vendor platforms.

One of the challenges of pediatric hepatic iron determination is the wide range of $T_2^*$ values that are acquired in practice. Obtaining accurate $T_2^*$ over such a wide range can be challenging. A long series of echoes with long echo times in a patient with a short $T_2^*$ will have mean signal over region of interest dominated by noise, giving an overestimation of $T_2^*$. Conversely, a series of echoes with short echo times to address this situation will yield minimal signal decay in a patient with a long $T_2^*$, again resulting in poor estimation of $T_2^*$. Thus the longest echo time used to determine $T_2^*$ should be based in part on the $T_2^*$. One approach is to acquire two datasets (one with long echo times and one with short), and use the appropriate one.

For assessment of steatosis, qualitative evaluation may be performed by dual echo imaging (in phase/opposed phase gradient echo). For quantitative assessment, low flip angle multiecho imaging may be used to generate a proton density fat fraction map, or alternatively spectroscopy can be performed.[164–166] In general, the gradient echo methods are faster and easier, although considerable care has to be taken for quantitative accuracy to be maintained.

# NUCLEAR MEDICINE

## Overview

Nuclear scintigraphy plays an important role in the evaluation of hepatobiliary dysfunction and disorders of the GI tract in infants, children, and adolescents. The unique diagnostic information provided is often complementary to that obtained with other modalities. Radionuclide imaging of the GI system will be divided into two major categories: imaging of the hepatobiliary system and spleen (Table 84.3) and imaging of the GI tract (Table 84.4).

Hepatobiliary scintigraphy provides an anatomic and dynamic physiologic evaluation of biliary function. Splenic scintigraphy is useful in the evaluation of splenic sequestration, accessory spleens, posttraumatic splenosis, postsurgical residual splenic tissue, and wandering spleen with torsion. GI scintigraphy allows the dynamic assessment of swallowing, gastric emptying, GER,

esophageal transit, colonic transit, and tracheobronchial aspiration. Red blood cell labeling allows the anatomic localization of intestinal bleeding, and white blood cell (WBC) labeling can be used for the localization of sites of abdominal infection and inflammation. Finally, gastric mucosa scintigraphy is used for evaluation of suspected Meckel diverticulum. Tumor imaging will not be addressed in this chapter.

## Patient Preparation and Technical Aspects

Sedation usually is not required for GI radionuclide examinations. However, correct anatomic positioning beneath the camera is essential, and some type of restraint is usually required, even with cooperative children. Distraction techniques using videos or listening to music can be helpful in lengthy examinations, but rarely sedation may be necessary.

Many of the studies discussed in this section require a period of fasting before imaging. Prolonged fasting greater than 24 hours is not recommended. Medications can be used to enhance imaging in specific conditions. Standard imaging parameters vary, but imaging usually is performed with the child in the supine position with either a single-head or dual-head gamma camera, preferably using a low-energy high-resolution collimator. The photopeak and window settings should be predetermined for technetium-99m ($^{99m}$Tc) (140 keV, 20%). Imaging typically is performed using a dynamic acquisition framed at intervals for optimal viewing and interpretation depending on the study and institutional preference. Suggested protocols will be described. In our practice, we require that no barium studies be performed 24 to 48 hours before radionuclide imaging of the abdomen and pelvis.

## Radiopharmaceuticals

The radionuclide used for most of the indications discussed in this chapter is $^{99m}$Tc, which is administered either intravenously or orally, usually combined with a nonradioactive compound (pharmaceutical agent). The clinical information sought by the clinician dictates the specific radiopharmaceutical agent used, which is taken up by the target tissue and allows imaging. Ionizing radiation from the internalized radiopharmaceutical agent emanates in the form of gamma rays that deposit energy into the imaging detector.

The dose of a radiopharmaceutical agent used in a child should be determined by the minimal dose required to yield a high-quality diagnostic examination. Appropriate dose recommendations can be found in the recent publication *2016 Update of the North American Consensus Guidelines for Pediatric Administered Radiopharmaceutical Activities*.[167]

## Indications and Specific Examinations

### Hepatobiliary Scintigraphy

Hepatobiliary scintigraphy is a useful adjunct to sonography in the evaluation of infants with jaundice and cholestasis, as well as in children with hyperbilirubinemia and/or chronic abdominal pain. Its value in jaundiced neonates is the timely differentiation of neonatal hepatitis and biliary atresia, because surgical intervention with the Kasai procedure in patients with biliary atresia is most successful when performed in patients less than 3 months of age. Post-Kasai procedure, a hepatobiliary scan, can be used to confirm patency of the bilioenteric anastomosis. Imaging with sonography, CT, or MRI is frequently diagnostic for choledochal cysts. Hepatobiliary scintigraphy adds value in the diagnosis of the rare association of choledochal cyst with biliary atresia.[168] Similarly, the evaluation of Caroli disease is often facilitated with hepatobiliary imaging. Cystic duct patency can be assessed in children with suspected acute cholecystitis. Hepatobiliary scintigraphy remains the test of choice for detection of postoperative or posttraumatic biliary leaks, or for the identification of spontaneous neonatal bile duct perforation.[169] Other clinical indications are listed in Table 84.3.

Currently, $^{99m}$Tc mebrofenin is widely used for hepatobiliary imaging due to its high hepatic extraction. It is transported into the hepatocytes, then excreted into the bile ducts; $^{99m}$Tc Disofenin is also used. The radiopharmaceutical agent is administered intravenously, and an anterior dynamic acquisition is acquired at 5 minutes/frame during the first 60 minutes in the supine position. Static images are usually obtained at 60 minutes in the anterior, RAO, and right lateral views. Delayed images may be obtained at 2 to 4 hours and up to 24 hours, as necessary, to visualize the gallbladder and biliary tree and excretion into the duodenum. A normal scan demonstrates radiopharmaceutical uptake in the liver by 5 minutes, the biliary tree by 15 minutes, and the small bowel by 15 to 45 minutes. In patients with neonatal hepatitis, delayed and diminished uptake by the liver occurs, but the radiopharmaceutical agent eventually reaches the small bowel. In patients with biliary atresia, radiopharmaceutical uptake by the liver is usually adequate, but the radiotracer never reaches the small bowel, even on the 24-hour images (Fig. 84.11). When the differentiation between biliary atresia and neonatal hepatitis is required, premedication with phenobarbital (5 mg/kg per day for 3–5 days) can be considered due to improved hepatic extraction of radiotracer.[170] An alternative is ursodeoxycholic acid 20 mg/kg given every 12 hours over 2 to 3 days.[171] In addition, infants should fast for 2 to 4 hours. Diminished extraction of radiotracer can be seen in the setting of chronic cholestasis from long-term total parenteral nutrition administration, bile plug syndrome, Alagille syndrome, other forms of hepatocellular dysfunction, and delayed diagnosis of biliary atresia.

Acute cholecystitis is characterized by prompt hepatic extraction and excretion into the biliary system and bowel but lack of gallbladder visualization. Fasting of 4 to 6 hours is required, and the same imaging protocol is utilized with dynamic imaging acquired at 5 minutes/frame for 1 hour. When the gallbladder is visualized, an RAO and/or right lateral view is acquired. If the gallbladder is not visualized at 60 minutes delayed images at 4 hours may be necessary. Alternatively, if the gallbladder is not visualized at 45 to 60 minutes, in lieu of further delayed imaging, intravenous morphine sulfate (0.04 mg/kg) may be administered, followed by dynamic 1 minute imaging for 30 minutes. Morphine should not be given if the small intestine is not visualized or in setting of acute pancreatitis. If gallbladder dyskinesia is of concern, cholecystokinin (Sincalide or Kinevac) is administered (0.02 mcg/kg) as a slow infusion over 30 minutes after the gallbladder is visualized. A normal gallbladder ejection fraction is greater than 35%[172] (e-Fig.

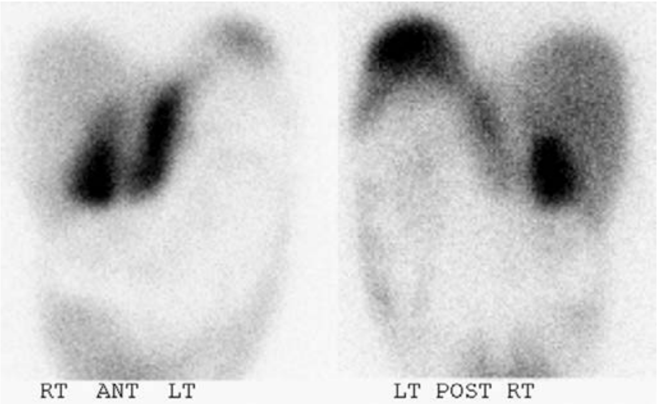
**e-Figure 84.12. Hepatobiliary scan with delayed gall bladder emptying.** Hepatobiliary study in a 15-year-old with right upper abdominal pain. (A) Anterior static images of the abdomen were obtained every 5 minutes for 60 minutes after the administration of $^{99m}$Tc disofenin. There is homogeneous radiotracer accumulation throughout the liver, with prompt visualization of the intrahepatic ducts and common bile duct by 10 minutes, small bowel by 15 minutes, and gallbladder by 30 minutes. These findings are normal. (B) Next, a Sincalide infusion was given over 30 minutes. Dynamic imaging revealed a decreased gallbladder ejection fraction of 8.65%.



**e-Figure 84.13. Hepatobiliary scan with bile leak.** A 12-year-old girl with persistent abdominal pain and jaundice after laparoscopic choledochal cyst resection and cholecystectomy. Images obtained in the anterior and posterior projection at 30 minutes show pooling of radiotracer in the midabdomen and the left subdiaphragmatic recess. Faint radiotracer activity is also seen in both paracolic gutters and in the upper pelvis consistent with radiotracer in the peritoneal cavity.

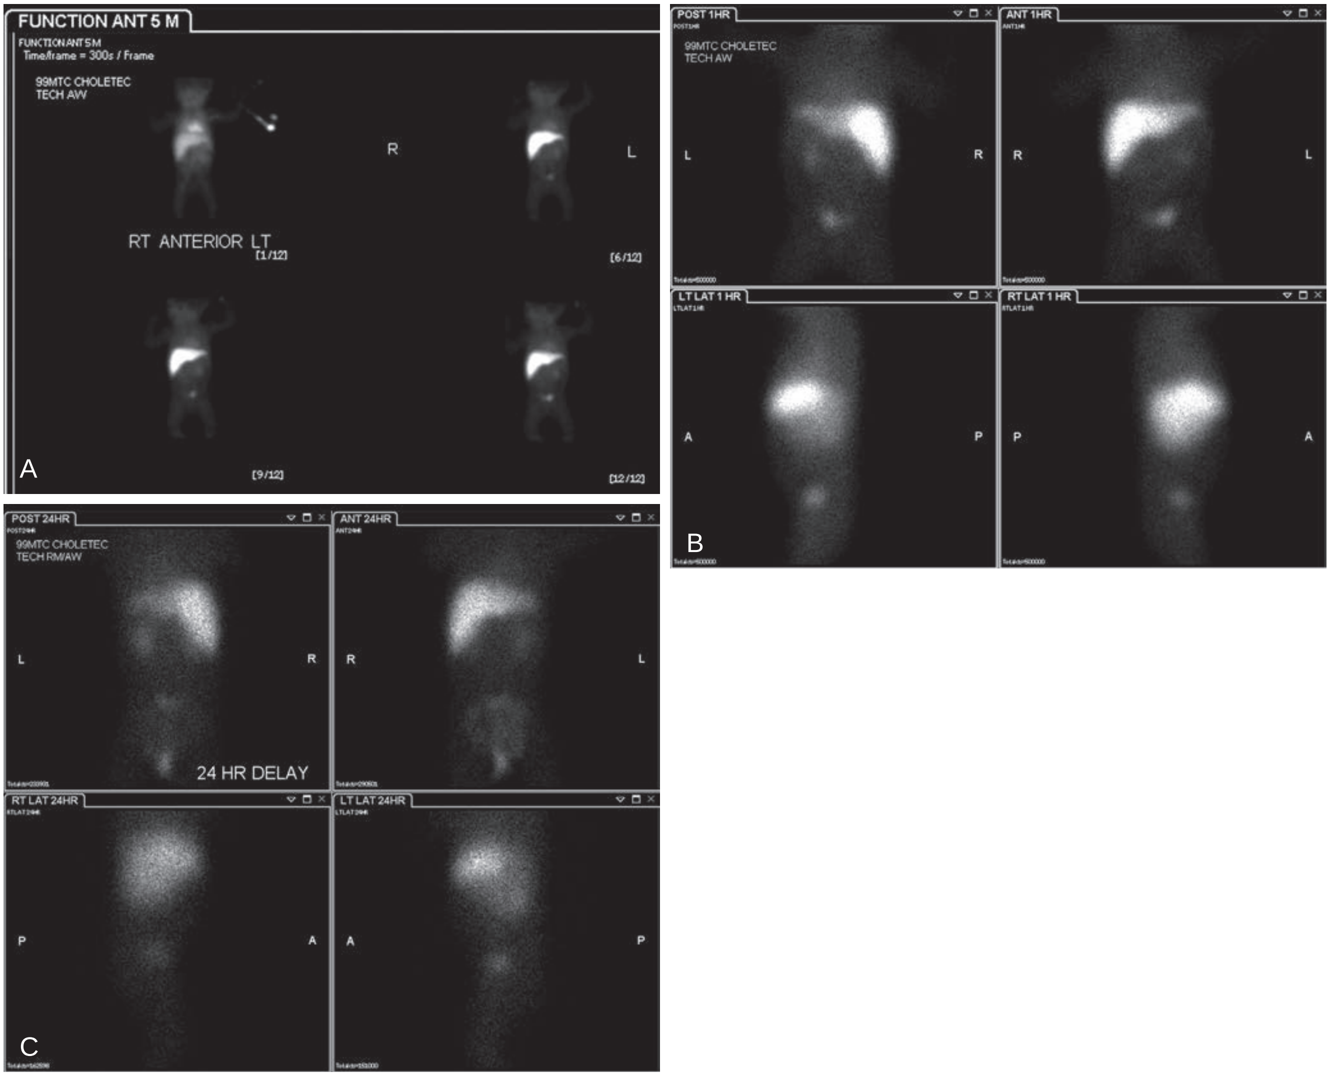


**Figure 84.11. Hepatobiliary scan in biliary atresia.** Eight-week-old infant presents with persistent jaundice and conjugated hyperbilirubinemia. $^{99m}$Tc mebrofenin biliary scintigraphy demonstrates good hepatic extraction of the radiotracer, nonvisualization of the biliary system, and no evidence of radiotracer passage into the bowel. (A) 0- to 60-minute, (B) 4-hour, and (C) 24-hour anterior projection images are shown. All images reveal normal, faint radiopharmaceutical accumulation in the urinary bladder.

84.12). Duodenal gastric reflux should be documented, as bile reflux gastritis may be the cause of symptoms. In patients in whom there is concern for bile leak, the cholecystitis protocol is utilized and fasting is not necessary. Delayed static images with patient in different positions may be helpful for detection or confirmation of a bile leak. A positive study demonstrates quite dramatic radiopharmaceutical accumulation around the liver, in the right paracolic gutter, and sometimes the pelvis (e-Fig. 84.13).

## Liver-Spleen Scintigraphy

The traditional liver spleen scan is seldom used today due to the advances in sonography, CT, and MRI, which provide far greater spatial and contrast resolution and provide more precise anatomic details. However, several important indications for the liver-spleen scan still exist, such as the location of accessory or ectopic spleens. The physiologic basis of the liver-spleen scan is the phagocytosis of radioactive colloid particles by the reticuloendothelial cells of the liver, spleen, and bone marrow. Normal images reveal homogeneous distribution of the radiopharmaceutical in the liver and spleen, which can be evaluated for size, position, configuration, and any focal areas of radiotracer deficit.

No patient preparation is necessary for the liver-spleen scan. The child receives an intravenous injection of $^{99m}$Tc sulfur colloid, and static images are obtained from multiple projections approximately 15 minutes after injection, with the child lying supine. Dynamic images may also be acquired, depending on the clinical indication. Single-photon emission computed tomography (SPECT) imaging can be performed to aid in the detection of small foci of splenic tissue.

In children with hepatitis, the liver-spleen scan may be normal. In the setting of severe hepatic disease, there is a redistribution of the colloidal radiotracer, with diminished uptake by the liver, greater than normal uptake by the spleen, and colloid shift with visualization of the bone marrow.

## Splenic Scintigraphy

Spleen scintigraphy can also be used to identify accessory spleens, posttraumatic “splenosis,” and to evaluate splenic uptake in a wandering spleen, as well as in splenic sequestration where there is acceleration of the sequestration and phagocytosis of abnormal erythrocytes, neutrophils, and platelets. Splenic function and functional asplenia is better documented with $^{99m}$Tc–labeled, heat-damaged red blood cell imaging. No patient preparation is necessary. Red blood cells are withdrawn from the patient, labeled with $^{99m}$Tc pertechnetate, and then denatured (in a warm temperature bath at 49.5°C for 12–15 min) to improve splenic localization. The child receives an intravenous injection of the $^{99m}$Tc–labeled, heat-damaged red blood cells, and static images are obtained from multiple projections approximately 15 minutes after injection. Images diagnostic of hypersplenism reveal rapid clearance of the radiolabeled red blood cells from the blood pool and greater than normal splenic uptake.

## Scintigraphy of the Gastrointestinal Tract

Radionuclide imaging of the GI tract is a sophisticated, systematic technique that allows anatomic and functional imaging of the esophagus and stomach, small bowel, and colon. Anatomic location of GI bleeding or infection can be accomplished with dynamic imaging of the entire GI tract.

These studies are usually more sensitive than conventional radiographic and fluoroscopic studies because dynamic, uninterrupted imaging can be performed for longer periods and with less radiation exposure. The physiologic information obtained with GI scintigraphy complements the anatomic information provided by other imaging studies.

## Gastroesophageal Reflux and Scintigraphy of Liquid Gastric Emptying

GER in infants and young children, when severe, manifests clinically with vomiting and failure to thrive; it can be associated with recurrent bronchitis and pneumonia, peripheral airway disease, esophagitis, and GI bleeding. Radionuclide imaging can detect GER and associated pulmonary aspiration as well as quantify gastric emptying. The sensitivity for detection of GER is greater than with conventional barium fluoroscopy because the chest and abdomen can be monitored continuously over a longer period of time without additional radiation exposure. The only disadvantage is the lack of resolution compared with conventional radiography. Patient preparation requires fasting for 2 to 4 hours. In neonates and infants, a liquid meal radiolabeled with $^{99m}$Tc sulfur colloid is administered with formula or saved breast milk to replace a scheduled feed. If the child is on continuous feeds, these should be stopped 2 to 4 hours before the examination. Older children should be fasted for 4 to 6 hours, and an age-appropriate volume up to 8 ounces of whole milk, whole chocolate milk, or Pediasure is administered. If the liquid meal is given via nasogastric tube, appropriate position of the tube should be verified with radiography. If the liquid meal is being introduced with a gastrostomy tube, the connector tubing should be removed before imaging, because residual activity in the tubing could skew gastric emptying calculations.

The meal should be introduced into the stomach quickly, preferably within 10 minutes. The radiolabeled meal should be followed with nonlabeled liquid; approximately two-thirds is labeled. Posterior images are acquired at 5 sec/frame for 60 minutes. If a longer frame rate of 30 sec/frame is used, up to 25% of GER episodes can be missed.[173] A radioactive marker is placed at the sternal notch or shoulders for anatomic localization. At the end of 1 hour, a 5-minute static image over the lungs is obtained to evaluate for possible aspiration. If gastric emptying is delayed, a 2-hour image can be performed for an additional time point to determine delayed vs. normal emptying.[173]

A study with normal findings shows the radiopharmaceutical agent in the stomach but no activity in the esophagus or lungs. If reflux is detected, the number of episodes and proximal extent is noted (e-Fig. 84.14). Quantification of gastric emptying is expressed as either the percent residual or the percent amount emptied at 1 hour. A study performed on normal infants who were fed radiolabeled milk demonstrated a T1/2 of 87 ± 29 minutes. Extrapolation of the data provides a normal 1-hour gastric residual range of 48% to 71%.[174] Feeds performed using a nasogastric tube bypasses the fundus and results in an increased rate of gastric emptying.[175] Gastric emptying data are particularly useful in the preoperative assessment of children with reflux undergoing fundoplication and gastrostomy tube placement.

## Gastric Emptying Scintigraphy of Solids

Gastric emptying imaging performed with a solid meal is useful in the evaluation of nausea, early satiety, bloating, or abdominal pain, and for evaluation of accelerated gastric emptying. The advantage of the gastric emptying study over fluoroscopic studies is that a real solid meal is used and it is quantitative. The disadvantages are that meal content and volume vary depending on the child's intake and food preference, imaging techniques vary, and precise normal pediatric gastric emptying standards are not established.

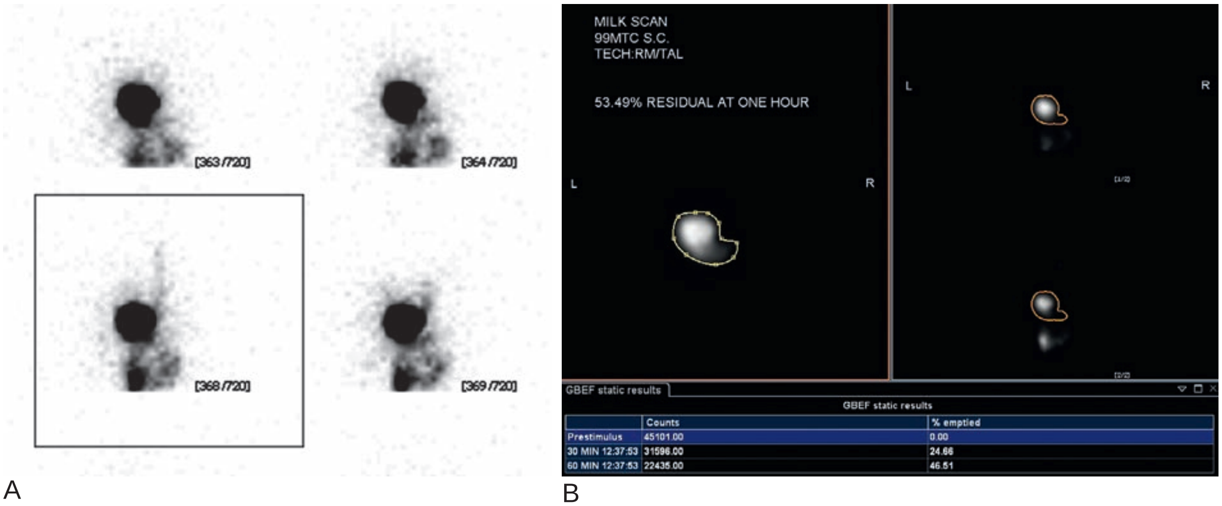
In children and adolescents, the typical standard solid meal-based $^{99m}$Tc sulfur colloid labeled egg whites followed by two pieces of toast, jam, and 8 ounces of radiopharmaceutical-free liquid, such as water, juice, or milk. Images are obtained with a dual-head camera in the anterior and posterior projections in the supine position for 30 seconds every 10 minutes for 120 minutes; delayed images at 3 and 4 hours can be performed. Patient preparation requires fasting for 4 hours. An ambulatory child can move between images, but walking about is discouraged. Fractional emptying is expressed in percent emptied or percent residual. In normal studies, the time-activity curve should exhibit a continuous decline in activity over time. Pediatric standards have not been developed.[173] Normal values for gastric retention in adults are 30% to 90% at 1 hour, less than 60% at 2 hours, less than 30% at 3 hours, and less than 10% at 4 hours.[176] Alternatives to the standard solid meal include $^{99m}$Tc labeled chocolate "Technecrispy cake," with a T1/2 of 107 minutes[174] or cheddar cheese on macaroni or pizza.[177,178]

## Esophageal Transit Scintigraphy

Esophageal transit scintigraphy may be used to evaluate esophageal motility disorders such as achalasia, diffuse esophageal spasm, and impaired motility from esophagitis and esophageal atresia/tracheoesophageal fistula. Patient preparation requires fasting for 2 to 4 hours. The child is placed in the supine position with the mouth and stomach in the field of view. A small radioactive marker may be placed over the cricoid cartilage to localize the upper esophagus. The child is instructed to swallow a $^{99m}$Tc sulfur colloid radiolabeled bolus of liquid (water or milk) as the computer acquisition begins. Posterior images are acquired dynamically at 0.25 to 1 sec/frame for 1 to 3 minutes. Regions of interest are drawn around the upper, middle, and lower thirds of the esophagus and stomach, and a time-activity curve is generated. Comparison of swallowing curves can be used to identify normal peristaltic waves, dysmotility, and functional obstruction. The normal transit time through the esophagus is generally less than 10 seconds.[179]

## Colonic Transit Scintigraphy

Colonic transit scintigraphy is useful in patients with chronic constipation to establish whether the cause is slow colonic transit or functional fecal retention, because the treatment strategy is different for each. Patient preparation requires discontinuation of laxatives for 5 days, and 4 hours of patient fasting is recommended.



MILK SCAN
99MTC S.C.

| 30 MIN 12:37:53 | 31596.00 | 24.66 |
| 60 MIN 12:37:53 | 22435.00 | 46.51 |

**e-Figure 84.14. Milk scan with gastroesophageal reflux and normal gastric emptying in a 6-month-old boy with persistent emesis.** (A) Dynamic images acquired at 5 seconds/frame reveal gastroesophageal reflux to the upper esophagus *(box)*. Other frames demonstrated 11 more episodes to the upper esophagus. (B) Quantitative analysis of gastric emptying reveals normal emptying with a residual of 53.5% at 1 hour, which is within the normal range at the institution where the study was performed.

A $^{99m}$Tc sulfur colloid radiolabeled liquid or solid meal is administered orally. Anterior and posterior static images are obtained in the supine position at 0 to 2, 6, 24, 30, and 48 hours. Radioactivity is measured in six regions (precolonic, ascending, transverse, descending, rectosigmoid colon, and evacuated feces). A normal examination shows radioactivity in the cecum by 6 hours and evacuation by 30 to 58 hours. Retention in the proximal colon at 48 hours indicates "slow colonic transit," while retention in the rectum at 48 hours indicates "functional fecal retention."[180–182]

## Salivagram

The salivagram allows the dynamic assessment of swallowing in patients suspected of having primary aspiration with feeding or in patients with neurologic deficits fed only by g-tube and suspected of aspirating saliva. Fasting is not required. A small dose of $^{99m}$Tc sulfur colloid mixed in 0.1 to 0.5 mL of water or saline is delivered as a drop under the tongue and allowed to mix with oral secretions. Dynamic images of the neck, chest, and upper abdomen are acquired for 1 hour. If there is no transit into the esophagus within 10 minutes, a small volume of water (1–2 cc) can be administered. At 1 hour, a posterior static image is acquired for 5 minutes. Detection of any radiopharmaceutical in the tracheobronchial tree is abnormal (Fig. 84.15).

## Meckel Scintigraphy

Meckel diverticulum is a congenital anomaly resulting from incomplete closure of the ileal attachment of the omphalomesenteric duct; it is present in approximately 2% of the population. Most of these diverticula are asymptomatic and lined by ileal mucosa. However, those that contain ectopic gastric mucosa are capable of producing hydrochloric acid and pepsin, thereby inducing ulceration of the gastric and adjacent ileal mucosa. Peptic ulceration causes acute GI hemorrhage in children, usually in the first 2 years of life. The Meckel scan is the study of choice for unexplained painless GI bleeding in children. Duplication cysts with ectopic gastric mucosa can also be detected with scintigraphy. Pharmacologic pretreatment is not considered a prerequisite to produce a high quality Meckel scan; however, histamine H2 blockers (cimetidine, ranitidine, famotidine) block secretions and increase gastric mucosa uptake that can increase diagnostic sensitivity.[183]

After the intravenous injection of $^{99m}$Tc pertechnetate, dynamic images are obtained at 1 to 5 sec/frame for 1 minute followed by 60 sec/frame for 30 minutes, and static images are obtained in anterior, posterior, right lateral, and left lateral projections. A normal study reveals radiotracer accumulation in the stomach as well as the urinary bladder and faint uptake by the kidneys due to excretion. An abnormal study demonstrates accumulation of radiotracer in ectopic tissue simultaneously with the appearance of gastric mucosa, usually between 6 and 10 minutes after injection (Fig. 84.16). SPECT imaging coregistered with simultaneously acquired low-dose CT (SPECT/CT) on a hybrid scanner has proven useful in discriminating between a Meckel diverticulum and artifact from the urinary tract or other visualized activity.[184,185]

## Gastrointestinal Bleeding Scintigraphy

Lower GI bleeding has many causes in infants and children, and the causes are largely age specific. When entities such as volvulus or intussusception are excluded, radionuclide imaging is useful for the localization of a bleeding source. Radiolabeled red blood cells are useful in patients who are bleeding slowly or intermittently.

No patient preparation is necessary. Simultaneously, intravenous injection of $^{99m}$Tc–labeled red blood cells and a dynamic flow study is performed for 1 minute, followed by a dynamic scan framed every 5 minutes for 30 minutes. If the images do not immediately reveal bleeding, delayed images are obtained at 45 minutes and 60 minutes and can be obtained up to 24 hours after injection. A positive study reveals activity in a location and configuration consistent with bowel, displays progressively increased intensity, and exhibits movement through the GI tract over time (Fig. 84.17). A cinematic display is often the most helpful method for localizing the abnormal bleeding site as determination of small bowel versus colon determines the next test (endoscopy, colonoscopy, or angiography).

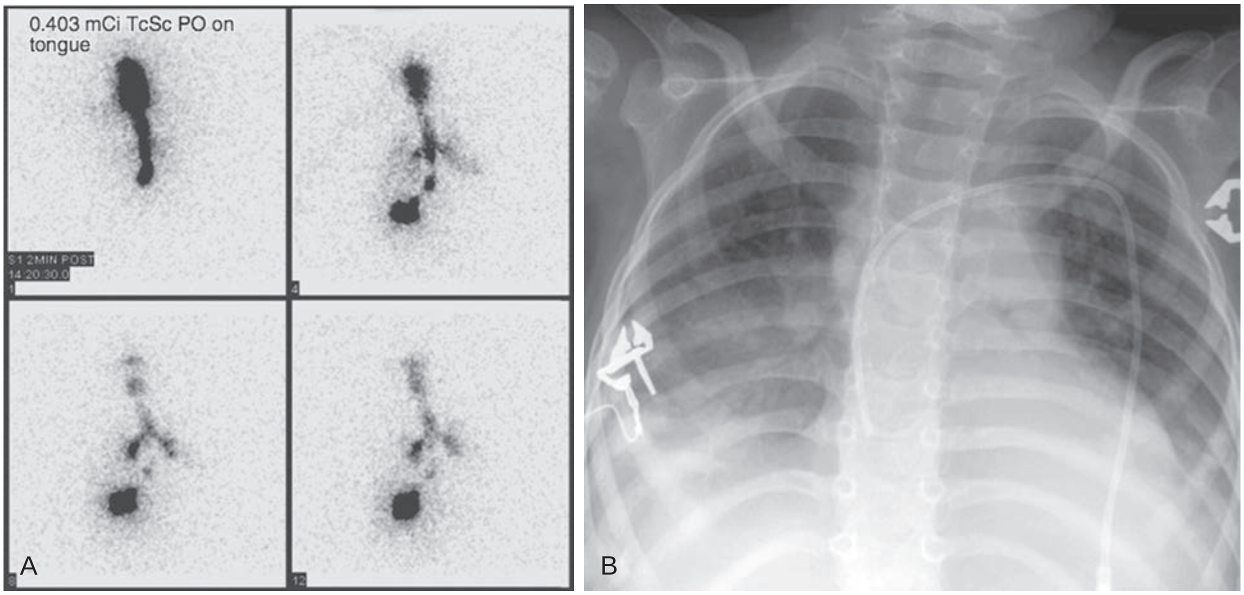

**Figure 84.15. Salivagram with pulmonary aspiration.** (A) Radionuclide salivagram (posterior images) obtained in a child with recurrent pneumonia and neuromuscular incoordination demonstrates $^{99m}$Tc sulfur colloid outlining the tracheobronchial tree. Some swallowed radiopharmaceutical is seen in the stomach. (B) Chest radiograph obtained the same day reveals bibasilar lung opacity, consistent with aspiration pneumonitis.

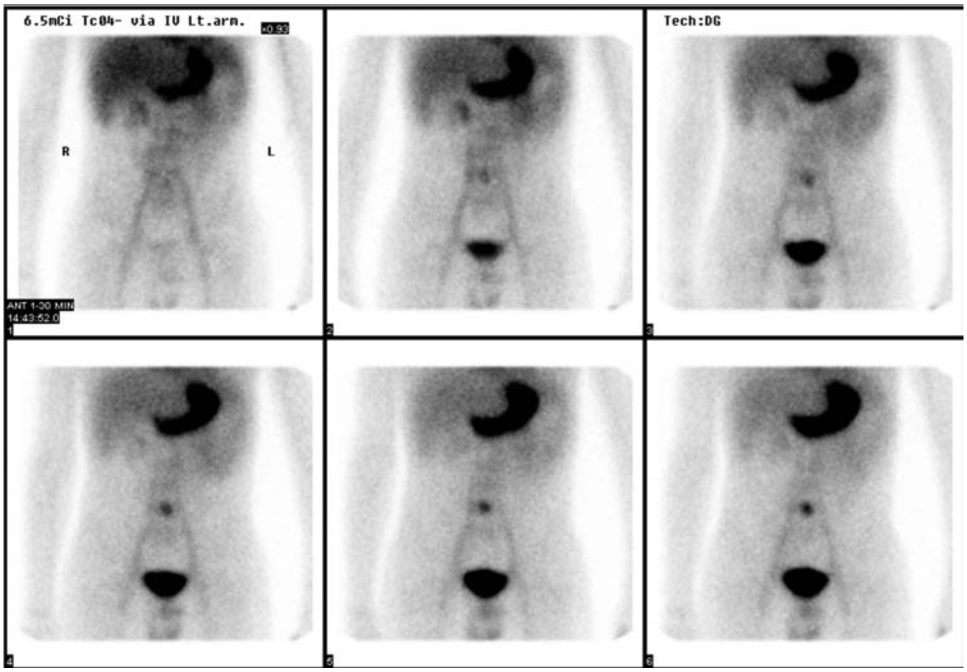

**Figure 84.16. Meckel scan with Meckel diverticulum.** Meckel scan in an 11-year-old with lower gastrointestinal bleeding reveals ectopic gastric mucosa in the midline of the lower abdomen. The timing coincides with the appearance of the stomach, with increasing conspicuity over time. Lateral views (not shown) revealed the abnormal uptake anteriorly in the lower abdomen.

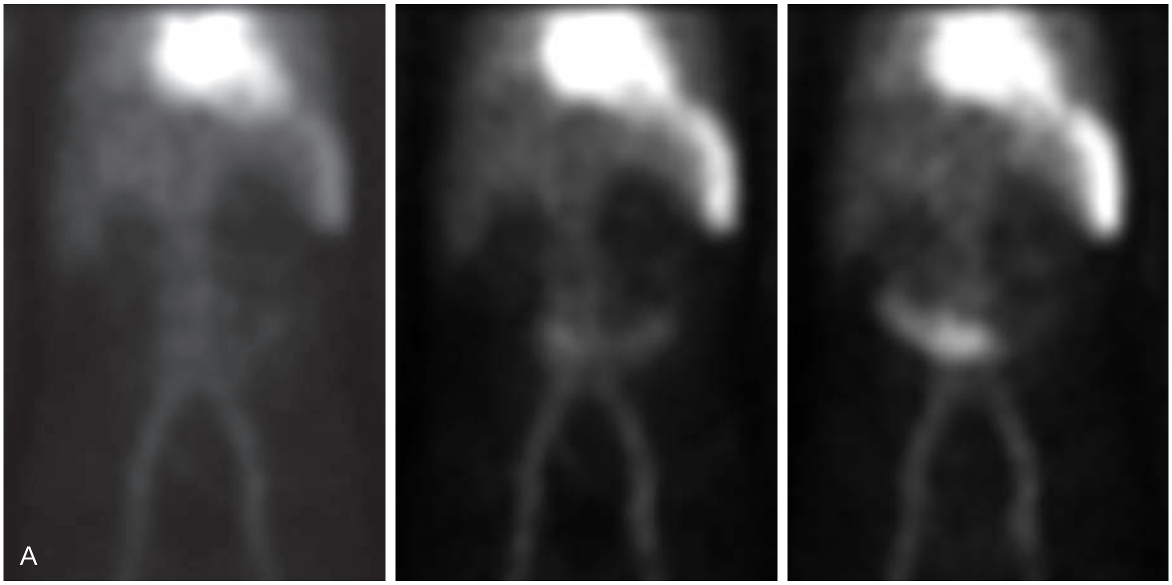

**Figure 84.17. Jejunal venous malformation in a 14-year-old with gastrointestinal bleeding.** (A) $^{99m}$Tc-labeled red blood cell scan performed dynamically at 1 minute per frame reveals an oblong region of radiotracer in the left upper quadrant. Selected successive frames at 1, 3, and 6 minutes show progression of radiotracer into the right lower quadrant.

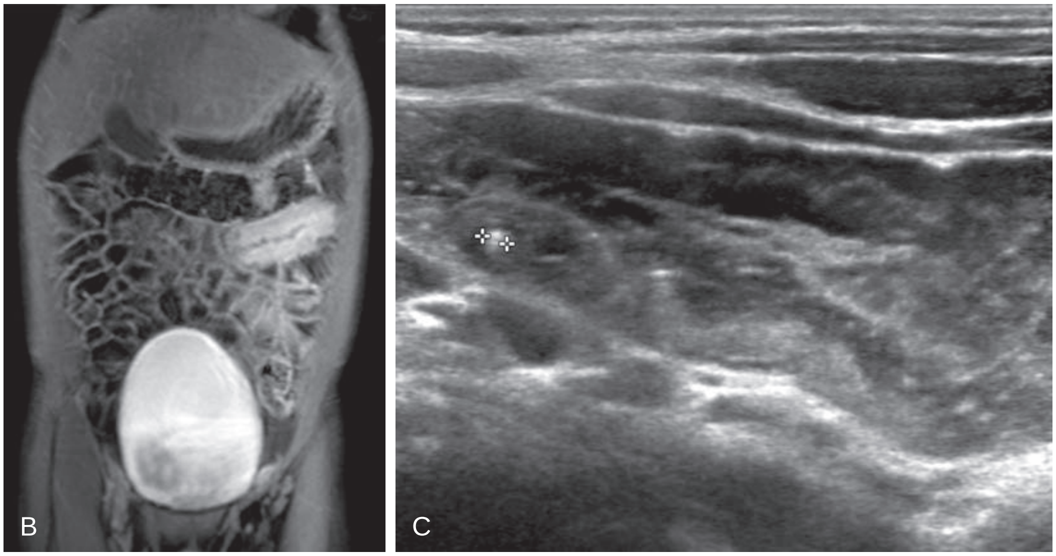

**Figure 84.17, cont'd.** (B) Coronal T1-weighted contrast-enhanced VIBE MR image shows an enhancing thick-walled loop of jejunum. (C) Ultrasound image reveals a hyperechoic focus (phlebolith) in the wall of a markedly thick-walled small bowel loop in the left upper quadrant. Superior mesenteric arteriogram (not shown) confirmed a low-flow jejunal venous malformation.

## Gastrointestinal Inflammation and Infection Scintigraphy

The radionuclide labeling of WBCs can be used for the localization of sites of abdominal infection, bowel inflammation,[186] and suspected intraabdominal abscess in critically ill patients with complex medical histories.

The radiopharmaceutical agent used is $^{99m}$Tc hexamethylpropyleneamine oxime (HMPAO). In children, the minimal amount of blood needed for labeling depends on the lab used and can range between 10 to 15 mL, depending on the child's size and circulating leukocyte count. Images are acquired at 30 minutes and 2 to 3 hours after the injection of the labeled WBCs. The patient should void before each image acquisition. A study with normal findings reveals uptake of the radiolabeled leukocytes by the liver, spleen, bone marrow, kidneys, and urinary bladder (e-Fig. 84.18). Normal bowel activity due to hepatobiliary excretion is seen in 20% to 30% of children by 1 hour. Abnormal bowel activity may be seen in 15 to 30 minutes and usually increases in intensity over the next 2 to 3 hours. Focal abdominal activity identified outside of the liver, spleen, and bowel may indicate focal infection or an abscess. SPECT imaging and SPECT/CT can be useful for localizing a collection.[187]

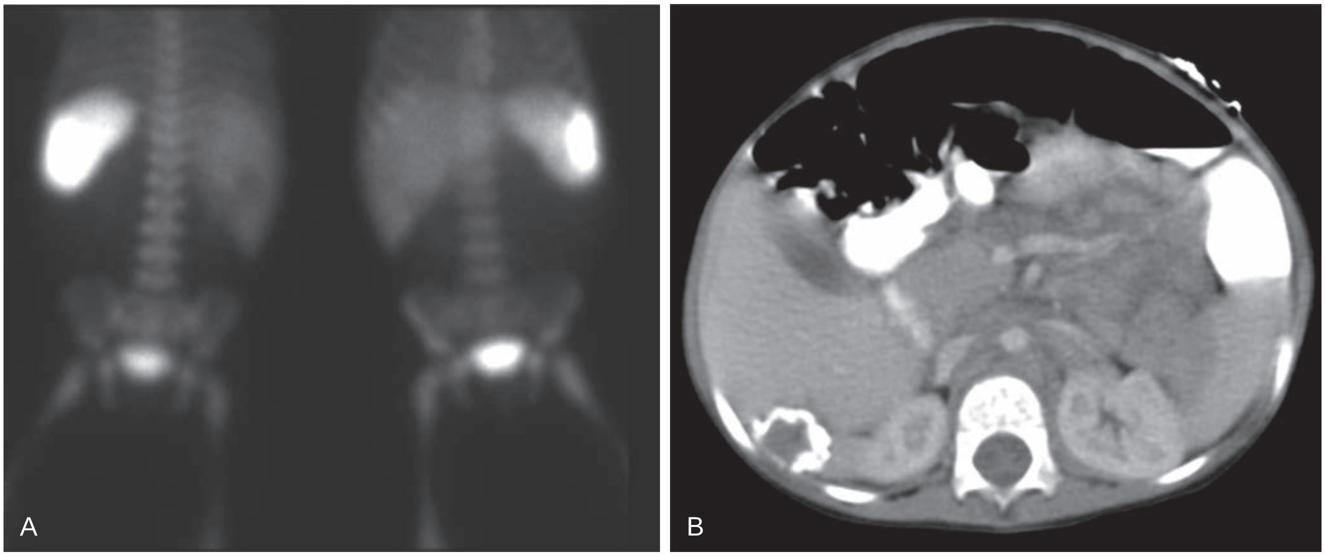
## Molecular Imaging

Positron emission tomography (PET) using $^{18}$F-fluorodeoxyglucose (FDG) is a sensitive alternative to conventional studies in the identification and localization of intestinal inflammatory and infectious processes in children. Specific inflammatory conditions described using $^{18}$F-FDG PET imaging include: inflammatory bowel disease,[188–190] chronic granulomatous disease, and fever of unknown origin.[191] PET/MR may have a role in the evaluation of inflammatory bowel disease, in the assessment of strictures, in determining the degree of active inflammation vs. fibrosis, and in detecting extraluminal disease.[192]

PET imaging using $^{18}$F-dihydroxyphenylalanine ($^{18}$F-DOPA, currently used under an investigational drug license supported by the FDA) is used to detect and localize the focal form of congenital hyperinsulinism in infants and neonates who are not responsive to medical therapy or have genetic defects associated with focal disease (Fig. 84.19). Histopathologic diagnosis is essential in the treatment of these infants. Diffuse disease is described as diffuse islet nuclear enlargement, and focal disease is described as focal beta cell adenomatosis. The term nesidioblastosis is no longer recommended for diffuse disease. Beta cell adenomatosis has a distinct histopathologic appearance different from insulinoma.[193] Resection of focal disease results in a greater than 95% cure rate. Patients found to have diffuse disease by biopsy may be treated with octreotide or undergo subtotal pancreatectomy, depending on the severity of the disease.

### KEY POINTS

- Hypertonic contrast media should not be used in the setting of possible aspiration.
- When hypertonic contrast media are used in contrast enema, fluid and electrolyte balance should be closely monitored and corrected.
- Pulsed fluoroscopy, removal of grid on small patients, and use of flurostore images can reduce radiation exposure by over 80%.
- Ultrasound should be performed with the highest frequency transducer that will penetrate to the area of interest.
- Protocols for pediatric CT imaging can be downloaded from the image gently website http://www.imagegently.org.
- Pediatric body MRI benefits from 3T fields strength and multi-channel receive arrays.
- Core pediatric MRI protocols consist of T2-weighted imaging, DWI, and contrast-enhanced T1-weighted imaging.
- Nuclear medicine studies provide a unique opportunity to utilize physiology in diagnosis.
- Most nuclear medicine studies can be performed with immobilization and distraction techniques, without sedation.



**e-Figure 84.18. White blood cell scan confirms successful treatment of liver abscess.** A 3-year-old with chronic granulomatous disease and liver abscess treated with interventional radiology drain placement and 6 week course of antibiotic therapy. (A) Coronal planar static images performed at 2 hours reveal a round, photopenic defect in the inferior right lobe. Nonuniform uptake is seen in the spleen. (B) Axial contrast-enhanced CT performed on the same day reveals a nonenhancing round focus in the right lobe with a rim of calcification that corresponds to the photopenic defect consistent with resolution of infection.

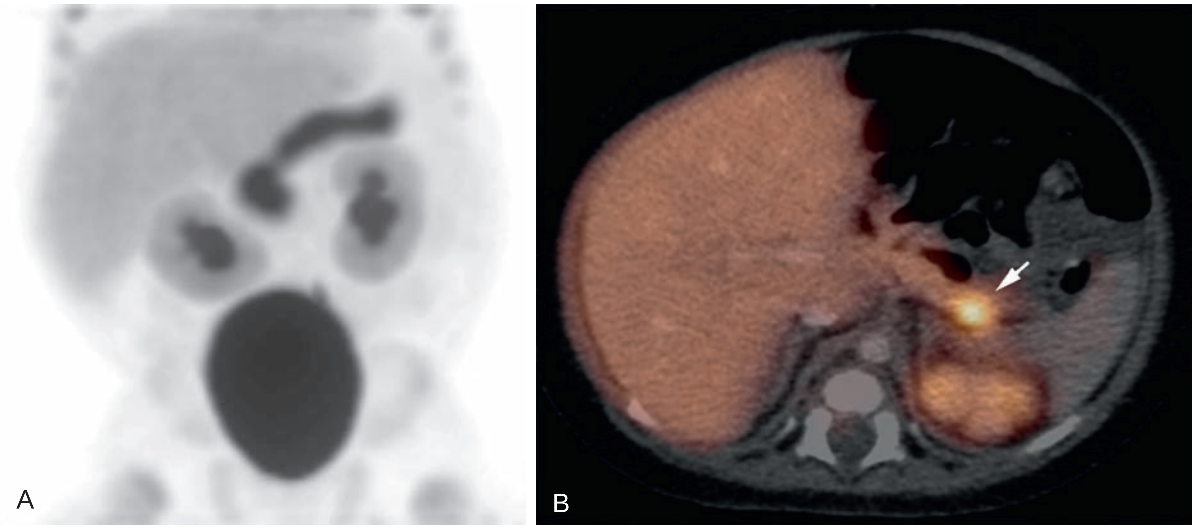


**Figure 84.19. PET/CT $^{18}$F-DOPA in congenital hyperinsulinism.** (A) Diffuse disease. Static MIP image in a 2-month-old reveals diffuse uptake throughout the pancreas. Note the normal uptake by the liver and kidneys and excretion into the urinary tract. Histopathology revealed diffuse islet cell nucleomegaly consistent with diffuse disease. The patient underwent a 98% subtotal pancreatectomy. (B) Focal disease. Fused axial CT and 18F-DOPA scan in a 5-week-old shows a round focus of increased radiotracer uptake in the pancreatic tail *(arrow)*. A 5% pancreatectomy was performed and confirmed a focal lesion of beta cell adenomatosis. Biopsies from the rest of the pancreas were normal.

## OVERVIEW

Fetal abdominal abnormalities evaluated on prenatal imaging can be grouped into one of several general categories: obstructions, ventral wall defects, echogenic bowel and peritoneal abnormalities, and finally masses and solid organ abnormalities.

In circumstances when ultrasound (US) cannot accurately determine the extent or nature of an abnormality, fetal magnetic resonance imaging (MRI) can be useful. Sequence selection includes standard single-shot fast spin echo (SSFSE) T2-weighted images at 3- to 5-mm slice thickness and steady-state free-precession (SSFP) imaging at overlapping intervals. Echo-time lengths range from 80 to 250 ms; longer lengths are advantageous for delineation of cystic abnormalities. T1-weighted fast gradient echo (GRE) sequences may be useful in the fetal abdomen, specifically for identification of the liver, which is mildly hyperintense, and very bright signal meconium.[1] Imaging modalities using ionizing radiation have no present role in the evaluation of a fetus with a gastrointestinal (GI) tract abnormality.

## INTESTINAL OBSTRUCTIONS

***Etiology.*** Interruption of the fetal GI tract can occur at any point from the esophagus to the anus, and the etiology for the loss of continuity is not the same at each site. The cause of esophageal atresia (EA) with or without a fistula to the trachea is not known but is believed to be a result of failure of the "system of folds" in the cranial and caudal ends of the tracheoesophageal space (see Chapter 96).[2–4] EA occurs in approximately 1 in 4,000 live births and can be associated with a number of additional abnormalities in the fetus. Most commonly, these abnormalities include those comprising the VACTERL complex (*V*ertebral, *A*nal, *C*ardiac, *T*racheo*E*sophageal, *R*enal, and *L*imb anomalies) and those seen in Down syndrome, such as common atrioventricular canal, absent or hypoplastic nasal bone, and nuchal thickening. EA occurs most commonly with a distal fistula (84%).[5]

Gastric atresia is the rarest atresia and is almost always pyloric with a distended proximal stomach. It likely results from vascular impairment during fetal development and is associated with epidermolysis bullosa, as well as multiple hereditary atresia and other conditions.[6]

In contrast to pyloric atresia, duodenal atresia (DA) is relatively common and, along with EA, is associated with Down syndrome. The etiology of DA has been thought to be related to failure of recanalization of the lumen of this segment of the proximal small bowel; more recent work implicates potential disruptions in fibroblast growth factor receptor 2 (FGFR2) and retinoic acid signaling pathways[7,8] (see Chapter 102).

Atresias distal to the duodenum are thought to be the result of ischemia or other focal insult to the bowel and may be multiple. Small bowel atresias are the most common cause of fetal and neonatal bowel obstructions, with colonic segments affected much more rarely (in 10% of all atresias).[9,10] Although most atresias are sporadic, some populations are prone to multiple atresia syndromes.[11,12] Meconium ileus in persons with cystic fibrosis also can have small bowel atresia, and colonic atresia can be seen in persons with Hirschsprung disease.[13,14] Anorectal atresia/malformation deserves special consideration because it often is seen in combination with other malformations, such as VACTERL, caudal regression, cloacal malformation, or the Currarino association (see Chapter 105).

***Imaging of the Esophagus.*** Despite the likelihood of a distal fistula that might allow for flow of fluid into the gut, the most consistent clues to the diagnosis of EA on US are a persistently small-volume stomach and polyhydramnios. Distension of a proximal esophageal pouch typically is intermittent and therefore unreliably witnessed either on US or MRI, although in the rare cases where it is vital to make a prenatal diagnosis, serial midline sagittal MRI with cine T2-weighted sequences may prove useful (Fig. 85.1).[15]

***Imaging of the Stomach.*** A lack of visualization of the stomach is most likely EA, with or without a distal fistula. Other considerations in the differential diagnosis of a small fetal stomach include congenital microgastria; oligohydramnios/anhydramnios; diminished swallowing function (e.g., in arthrogryposis, with little to no fetal movement); or obstruction to normal swallowing, including from increased intrathoracic pressure (Fig. 85.2). A markedly distended stomach, on the other hand, might raise concern for outlet obstruction, as with pyloric atresia. Gastric volvulus rarely has been reported in utero and is more of a risk when the stomach is not in its normal location.[16] A right-sided stomach in situs ambiguous or inversus should be evident as long as one is careful to establish the orientation of the fetus to the mother during the examination.

***Imaging of the Duodenum.*** DA appears on fetal imaging as the classic fluid-filled double bubble of dilated stomach and duodenal bulb (Fig. 85.3). Duodenal stenosis sometimes can be distinguished by hyperperistalsis of the dilated proximal duodenum as seen on US whereas, in DA, no peristalsis may exist at all. DA can be associated with malrotation of the bowel. Other causes for proximal obstruction include annular pancreas or an adhesive Ladd band in a patient with primary midgut malrotation. As with other obstructions to the GI tract, the more proximal the atresia, the earlier and the more frequent presentation with polyhydramnios; therefore polyhydramnios is typical in duodenal and proximal jejunal atresias.[17]

***Imaging of the Small Bowel.*** On T2-weighted sequences, high signal in liquid small bowel content should be evident on both sides of the abdomen; location of the small bowel primarily on the right may be an indication of a rotational abnormality (Fig. 85.4). The small bowel is considered to be dilated if it is larger than 7 mm; the colon is usually up to 15 mm in the third trimester, while the normal rectum, which should be the largest segment, can be larger[18–20] (Fig. 85.5). In proximal jejunal atresia, more loops will be dilated than just the double bubble seen with DA ("triple bubble" in very proximal jejunal atresia) (Fig. 85.6); distal jejunal atresia and ileal atresia, on the other hand, may be more difficult to distinguish prospectively because multiple dilated, fluid-filled loops are seen in both conditions, and typically a normal amniotic fluid volume is present.

The differential diagnosis for multiple dilated loops signifying a distal obstruction parallels that in newborn imaging and, in addition to atresia, includes meconium ileus, midgut volvulus, volvulus around a residual of the omphalomesenteric duct, and total colonic aganglionosis (Hirschsprung disease). One clue to the diagnosis of meconium ileus might be the presence of hyperechoic debris filling distended loops near the point of obstruction in the distal small bowel on US; MRI shows that the

## Abstract:

To detail the etiologies, imaging appearances, and treatment plan and follow up for gastrointestinal and hepatobiliary pathologies in the fetus. Fetal abdominal abnormalities evaluated on prenatal imaging can be grouped into one of several general categories: obstructions, ventral wall defects, echogenic bowel and peritoneal abnormalities, and masses and solid organ abnormalities. In circumstances when ultrasound (US) cannot accurately determine the extent or nature of an abnormality, fetal magnetic resonance imaging (MRI) can be useful.

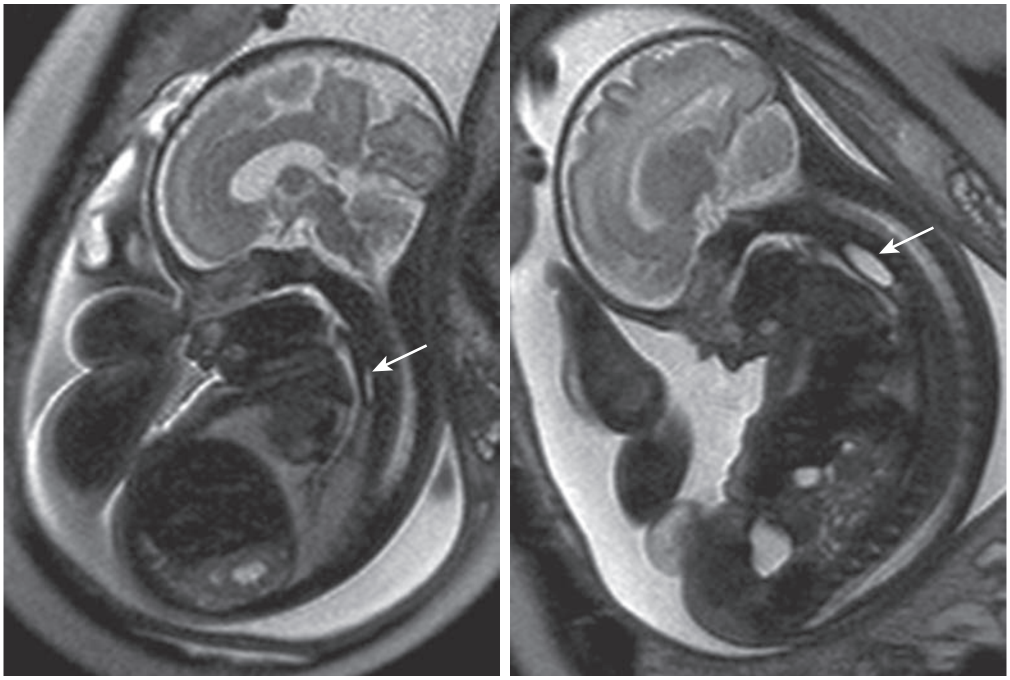

**Figure 85.1. Esophageal atresia.** Serial imaging may show intermittent phenomena: A sagittal SSFSE MR image in the neck and chest shows a small amount of fluid in the proximal esophagus that distends to a pouch on a later sequence *(arrows)*. Cine steady-state free-precession sequences are especially useful for serial imaging because of their fast acquisition times.

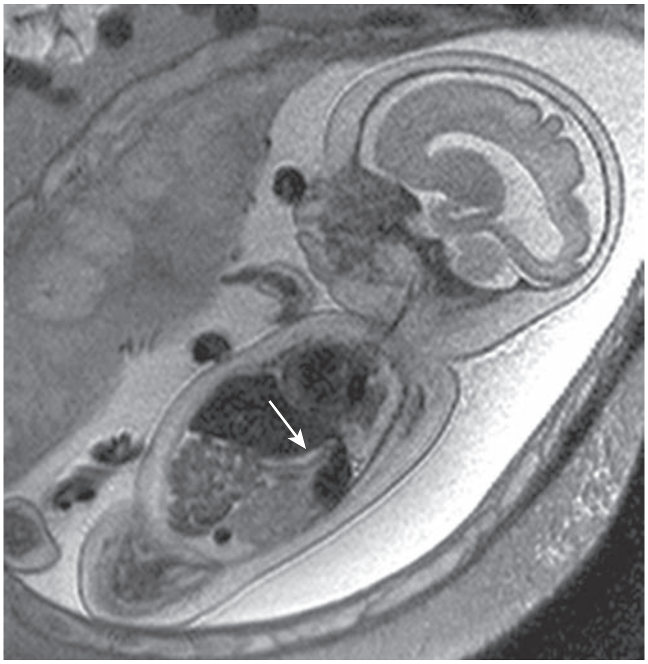

**Figure 85.2. Small stomach.** A small collapsed stomach *(arrow)* in a fetus with hydrops, hypotonia, and limited swallowing. Note the fetal edema, and the lack of any motion artifact in the amniotic fluid.

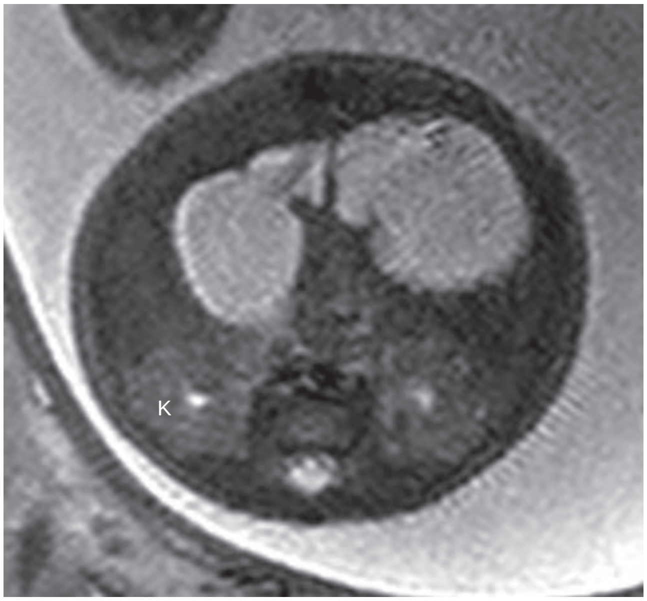

**Figure 85.3. Duodenal atresia.** Axial single-shot fast spin echo MR image of the stomach, pylorus, and dilated duodenum ("double bubble"). The right kidney is marked for reference *(K)*.

internal contents are hyperintense on T1-weighted images and intermediate on T2 imaging, consistent with meconium.[21–23] However, practically speaking, the MR pattern of dilated bowel containing meconium-typical signal characteristics is nonspecific, and both small bowel and colonic obstructions can show a pattern similar to that described for meconium ileus (Fig. 85.7). Vigorous hyperperistalsis of the bowel is indicative of obstruction (Fig. 85.8 and Video 85.1). Cases of in utero volvulus, although uncommon, have been prospectively identified either with a classic "whirlpool" twisting of the bowel or when the dilated ischemic segments are thick-walled, nonperistaltic, and have internal echogenicity from hemorrhage.[24,25] High-grade mechanical and functional obstructions of the distal small bowel are associated with congenitally small

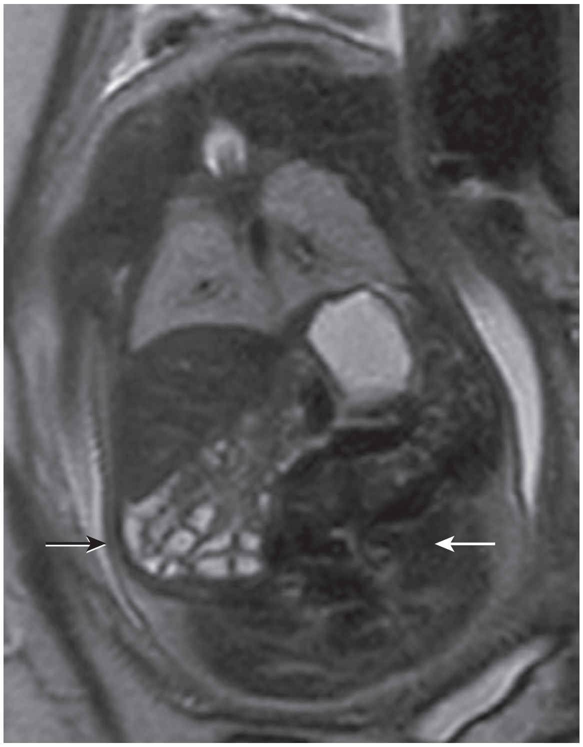

**Figure 85.4. Nonrotation.** All of the T2 high-signal small bowel is in the right abdomen *(black arrow),* and the low-signal meconium-filled distal ileum and colon are in the left abdomen *(white arrow)*.

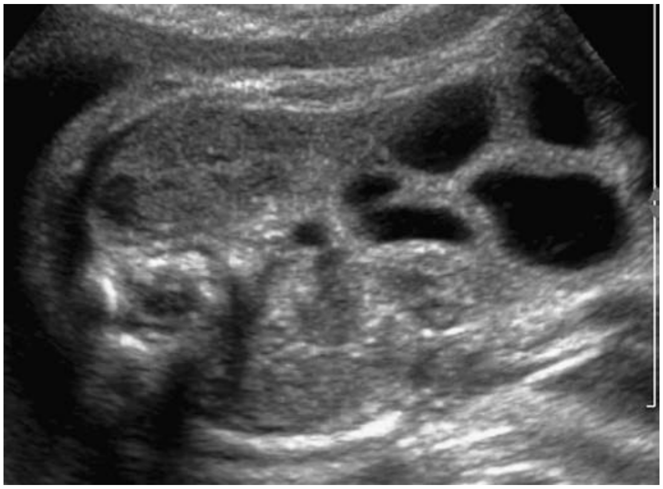

**Figure 85.5. Ileal atresia.** A coronal sonogram of the abdomen shows multiple dilated small bowel loops.

colons (“microcolon”), typically detectable on MR beginning in the late second trimester.

***Imaging of the Colon.*** Colonic atresias are difficult to diagnose specifically unless the obstructed segment can be identified with certainty in the expected location of the colon or interhaustral notches can be separated from valvulae conniventes on US. Meconium typically is seen in the rectum by 20 weeks’ gestation, in the left colon by 24 weeks’ gestation, and in the right colon by 31 weeks’ gestation, but this pattern may be altered by the pathology that is present.[26] On FSE T2-weighted sequences, meconium has a very low signal, whereas it shows a high signal on T1 weighting.

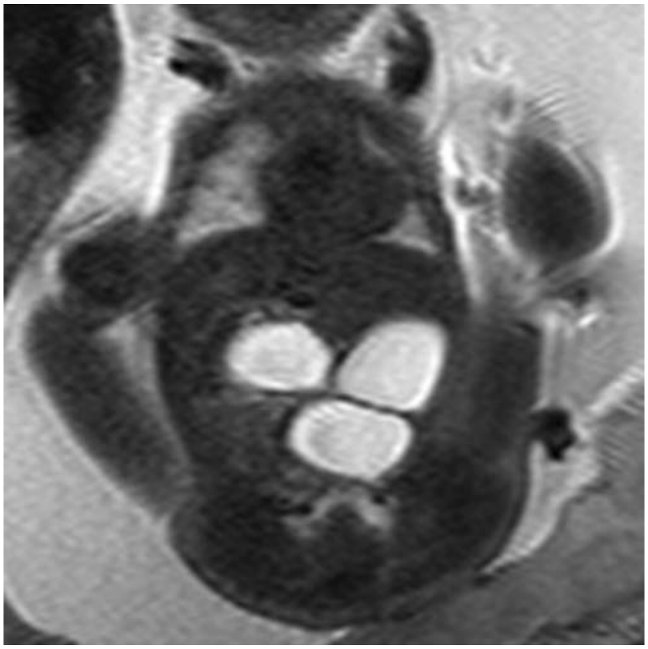

**Figure 85.6. Proximal jejunal atresia.** A single-shot fast spin echo coronal image with a dilated stomach, duodenal bulb, and proximal jejunum (“triple bubble”).

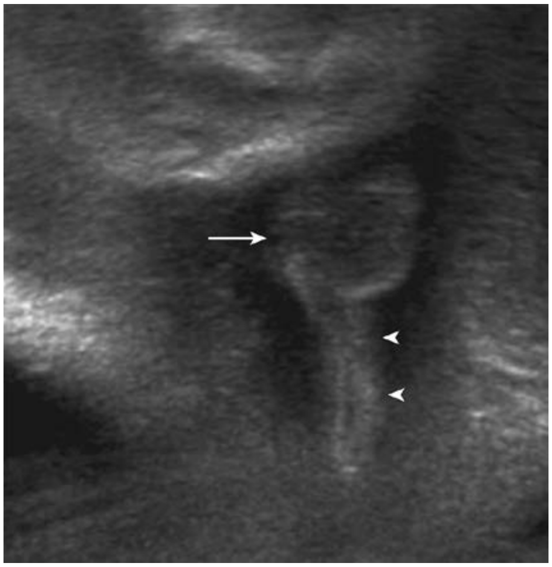
**BOX 85.1** Absent or Abnormal Signal in the Colon on Fetal Magnetic Resonance Imaging

Distal bowel obstruction
Bowel perforation (meconium peritonitis/pseudocyst)
Megacystis–microcolon–hypoperistalsis syndrome
Cloacal exstrophy
Cloacal malformation
Congenital diarrhea syndromes

In general, when dilated loops are discovered, US is sufficient to diagnose the level of obstruction as proximal versus distal and to generate a focused differential diagnosis. Fetal MRI is reserved for complex cases or for those in which other abnormalities are suspected and might be confirmed by additional imaging.[27] The advantage of MRI is in its larger field of view and reproducible multiplanar capability, showing the anatomy relative to other landmarks.[28] This advantage usually is demonstrated well with single-shot T2-weighted sequences in multiple planes, whereas the addition of GRE T1-weighted sequences to show the distribution of high-signal meconium can provide useful additional information (Fig. 85.9). It is crucial to understand that meconium is not exclusively restricted to the colon, can normally be seen in the distal ileum, and meconium signal may be present in dilated loops proximal to distal obstructions.[29] Box 85.1 lists causes of absent or abnormal meconium signal in the colon.

Although one might anticipate that bowel loops would be dilated in cases of anorectal atresia, such dilation is uncommon, and the diagnosis often is made on the basis of a high level of suspicion because of associated features.[30] On US, the diagnosis may be suspected if the characteristic hypoechoic configuration of the anal musculature with a central focus of echogenic mucosa (Fig. 85.10) is absent.[31,32] Also, a cord or ridge of abnormal fibrous tissue at the perineum may be imaged by US or MRI (e-Fig. 85.11). If a fistula between the colon and the urinary tract allows



**e-Figure 85.11. Typical configuration of the perineal cord (*arrowheads*) that may be seen from the genitalia toward the level of anal atresia.** The arrow indicates the scrotum in this male fetus.

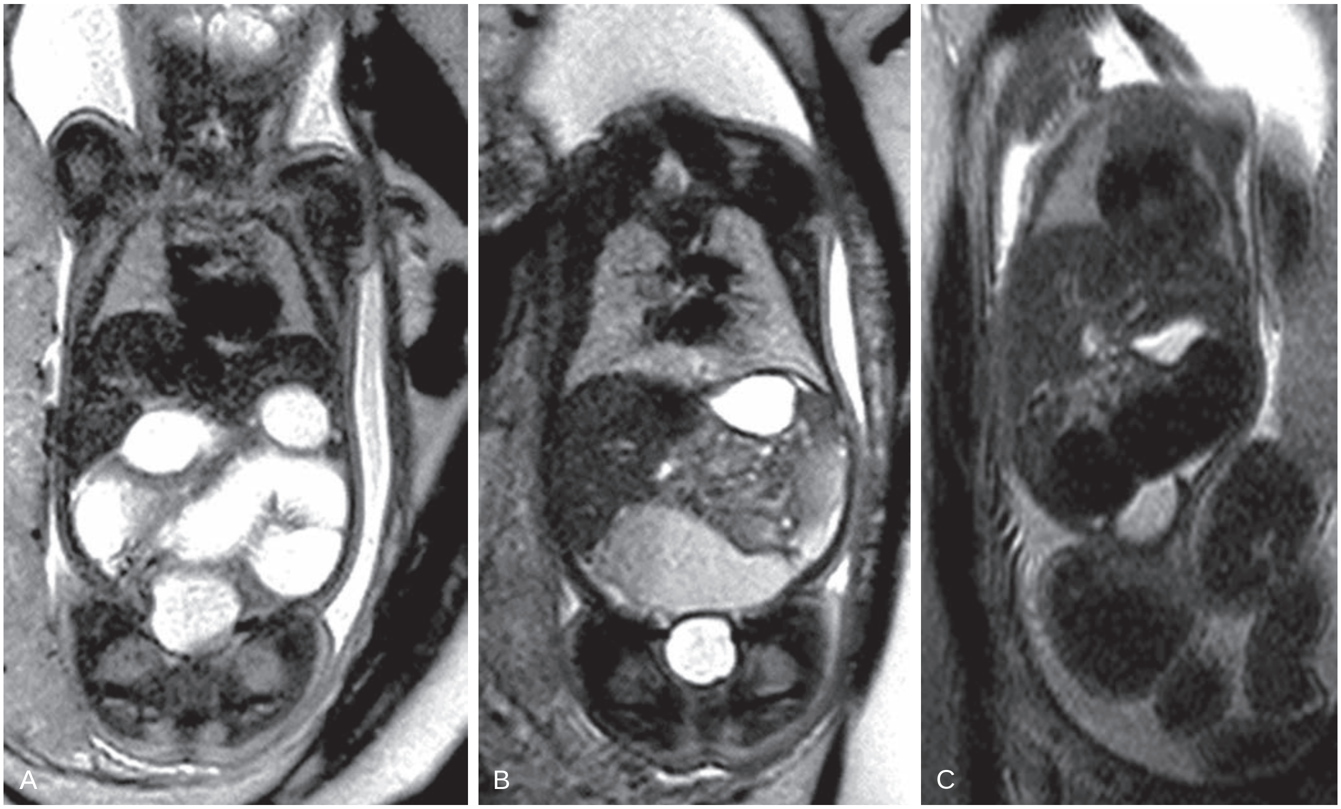


**Figure 85.7. Distal small bowel atresias, varying appearance.** Coronal MR imaging. On T2-weighted SSFSE imaging, these can have a variety of signal patterns. (A) Jejunal atresia with simple high signal in dilated loops. (B) Ileal atresia with medium intensity signal in focally dilated loops in the low abdomen. (C) Jejunal atresia with low signal from meconium in obstructed loops.

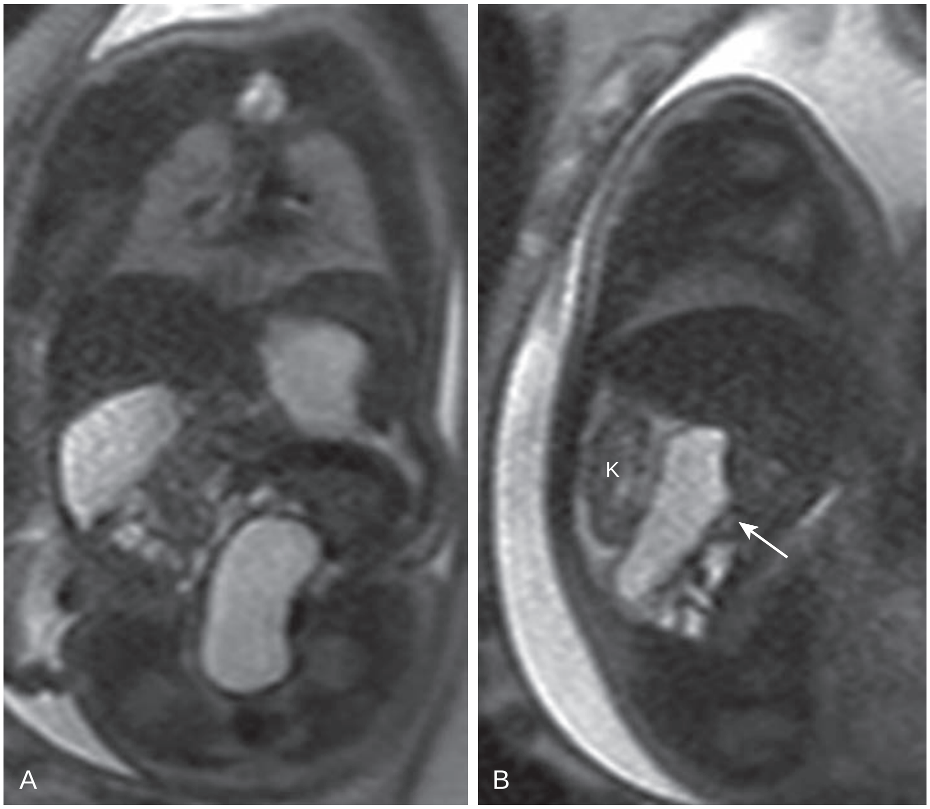

**Figure 85.8. Duodenal obstruction due to Ladd's band in malrotation.** (A) Coronal and (B) sagittal SSFSE MR images show the stomach in the left upper quadrant and a dilated segment of bowel in the right upper quadrant *(arrow)* ventral to the right kidney *(K),* representing the duodenum. The bladder is seen in the pelvis. The ultrasound clip shown in Video 85.1 is remarkable for hyperperistalsis of this segment.

mixing of meconium and urine, intraluminal precipitant calcifications may be detected (Fig. 85.12).

Hirschsprung aganglionosis only very rarely is identified by bowel dilatation antenatally in the third trimester, although it is among the most common causes of neonatal intestinal obstruction, and therefore this diagnosis is more often made postnatally.[33,34] Intestinal neuronal dysplasia type B, a malformation of the parasympathetic plexus, has been identified retrospectively in a fetus as a cause of bowel obstruction but is extraordinarily unusual.[35] Another rare form of functional obstruction that can be seen in the neonate, congenital segmental dilation of the bowel, has been described with both short segment or more extensive antenatal bowel enlargement, the latter indistinguishable from a pattern of mechanical obstruction.[36]

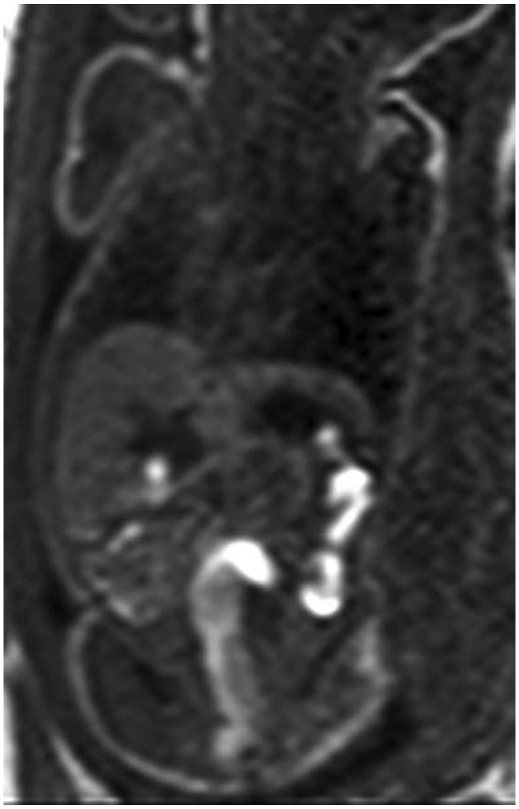

**Figure 85.9. Meconium.** A coronal T1-weighted gradient echo MR image showing T1 high-signal meconium in the colon.

Congenital diarrhea syndromes have been reported as showing dilation of the bowel to the rectum but without meconium signal on T1-weighted imaging, reflecting the loss of normal meconium.[37] Therefore lack of colonic meconium is not exclusive to mechanical small bowel obstructions. Differential considerations include secretory sodium or chloride diarrheas, megacystis-microcolon-hypoperistalsis syndrome, pseudoobstruction, and total colonic aganglionosis (Hirschsprung disease).[26,29,38,39]

***Treatment and Follow-up.*** At this time, no criteria have been established for intervention in the fetus based on bowel obstruction unrelated to ventral wall defects, aside from amnioreduction for polyhydramnios. Selected patients may have amniocentesis to evaluate for the possibility of chromosomal abnormalities or cystic fibrosis. Follow-up is performed with ultrasonography, with a plan to have the newborn evaluated at birth by the appropriate pediatric specialists.

## VENTRAL WALL DEFECTS

***Overview.*** Ventral wall defects include all abnormalities in which extrusion of internal anatomic structures to the outside of the fetal abdomen and/or pelvis occurs. The major abnormalities under this category include Pentalogy of Cantrell, omphalocele, bladder and cloacal exstrophy, and gastroschisis.

***Etiology.*** Normal herniation of the midgut into the proximal umbilical cord occurs in the eighth gestational week, and 270 degrees of midgut rotation, return of the bowel, and fixation are completed by the end of the twelfth week. Visualization of either the liver or bowel in the umbilical cord after 12 weeks is abnormal. In general, these abnormalities are thought to occur from a failure

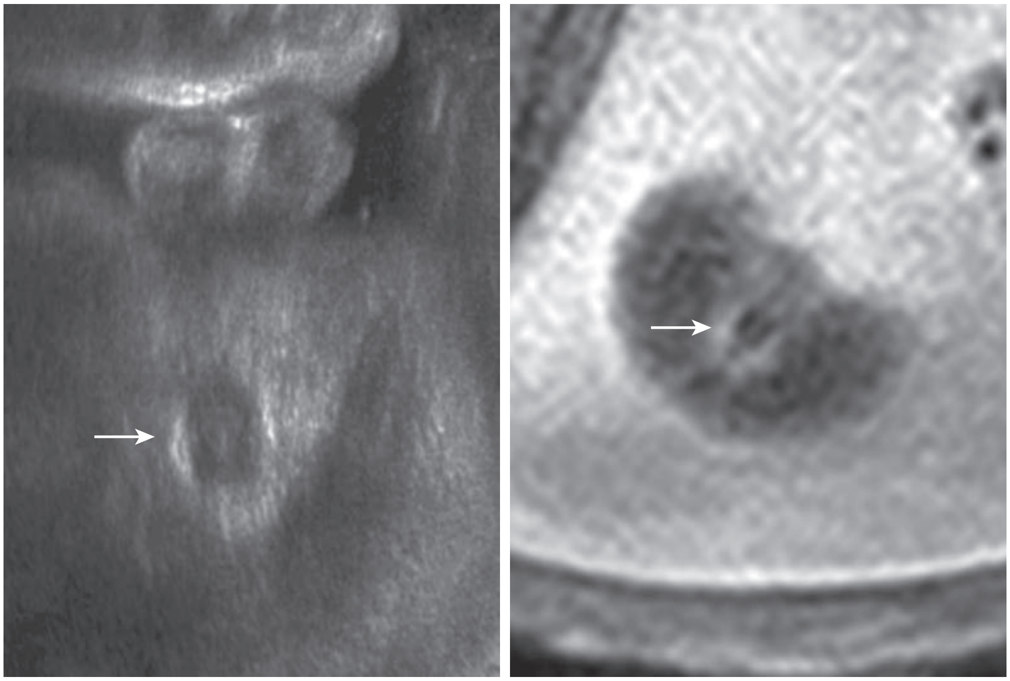

**Figure 85.10. Normal perineum.** The normal hypoechoic configuration of the anal musculature at the perineum *(arrows)* on ultrasound *(left)* and axial SSFSE T2-weighted MR *(right)*.

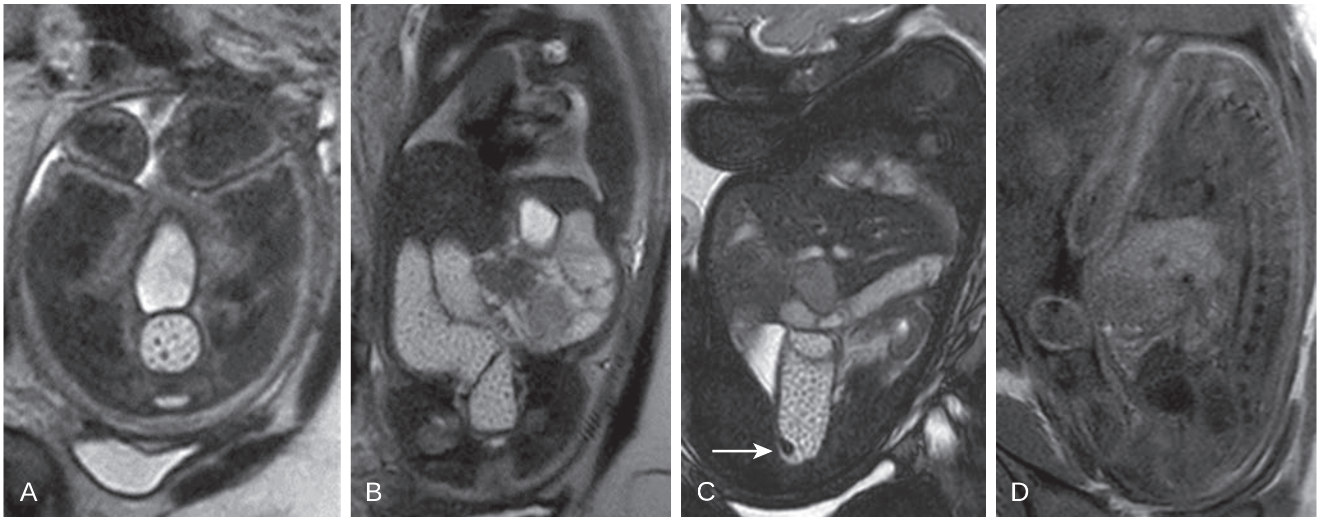

**Figure 85.12. Anal atresia with fistula.** (A) Axial, (B) coronal, and (C) sagittal SSFSE MR images demonstrate abnormal medium-high signal, containing multiple intraluminal punctate low-signal calcifications in the distal colon. (D) Sagittal T1-weighted GRE image confirms the lack of normal high signal meconium in the rectum. There is a fistula directed toward the expected level of the urethra on the sagittal image *(arrow)*.

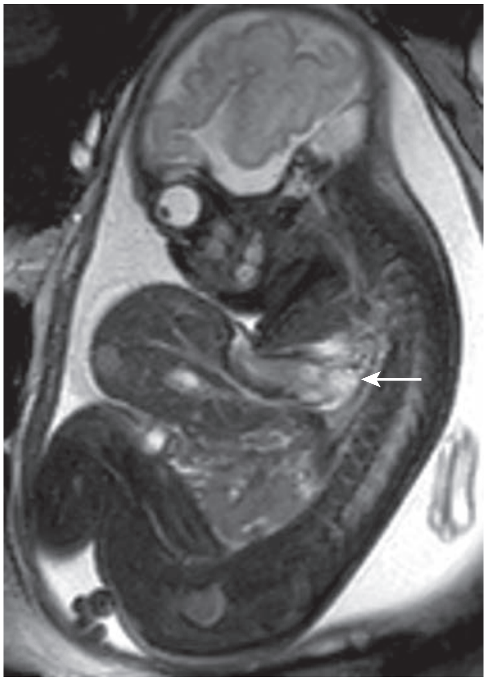

**Figure 85.13. Pentalogy of Cantrell.** Sagittal SSFP MR image through the chest shows herniation of low-signal liver and high-signal flowing blood within the heart *(arrow)* through a ventral wall defect.

of the normal infolding and fusion of the embryonic disc.[40] If craniad infolding fails, the resulting defect would be to the abdominal wall and lower chest, resulting in findings in the spectrum of the pentalogy of Cantrell (omphalocele, sternal defect, ventral mediastinal diaphragmatic hernia, pericardial defect, and ectopia cordis) (Fig. 85.13). Lateral fold defects lead to an omphalocele, which is the most common isolated ventral wall defect and is contained by a membrane (parietal peritoneum and amnion) unless ruptured (e-Fig. 85.14).[41] Caudal fold failure results in bladder or cloacal exstrophy, which primarily affects the genitourinary tract.

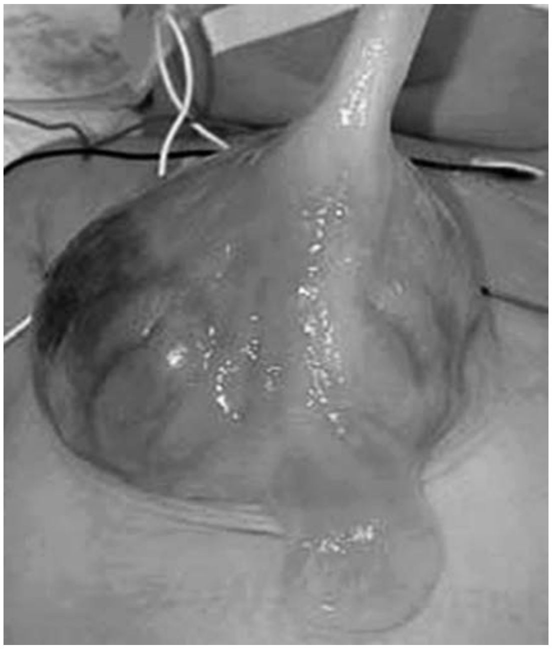
In bladder exstrophy, the ventral wall of the bladder, inferior rectus musculature, and skin are absent, and the residual dorsal wall of the bladder is continuous with the abdominal wall ("opened bladder") (e-Fig. 85.15). Imperforate anus with fistula is rarely associated. Cloacal exstrophy is more complex; persistence of the infraumbilical cloacal membrane is thought to prevent normal anterior abdominal wall closure and separation of the urogenital system from the rectum; as a result, two open hemibladders are separated by bowel. There is always an associated anorectal malformation. Both bladder and cloacal exstrophy include diastasis of the pubic symphysis and may have more complex pelvic bone deformities. OEIS complex describes the particular association of *O*mphalocele, bladder *E*xstrophy, *I*mperforate anus, and *S*pinal defect,[42] but this complex is believed by most to be a synonym for cloacal exstrophy.[43]

Limb-body wall complex is a severe form of ventral wall defect that results from failure of folding along multiple planes and is not compatible with extrauterine life (Fig. 85.16).[44]

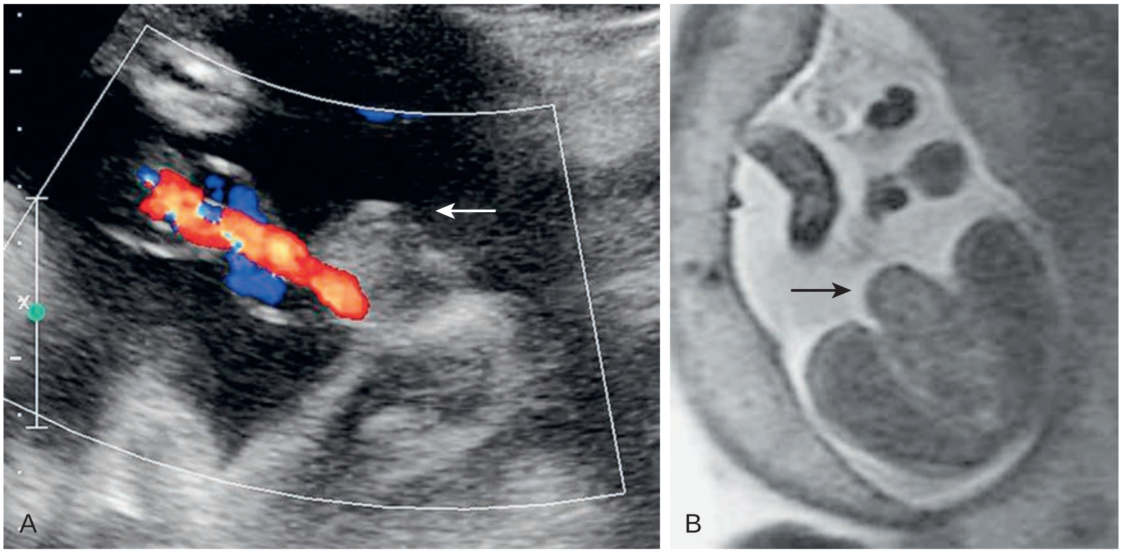
Gastroschisis is a type of ventral wall defect that may be unrelated to embryonic disc folding. It is possible that a vascular insult results in a through-and-through defect in the layers of the abdominal wall adjacent to the umbilicus, almost universally on the right, through which the bowel herniates without a covering membrane; other hypotheses have been proposed, but the cause is not yet known (e-Fig. 85.17).[45,46] The risk of bearing a fetus with gastroschisis is reportedly increased in young primigravida women and also has been associated with the use of agents that may cause vasoconstriction, such as tobacco and salicylates.[47,48]

Because of the lack of skin covering in this constellation of defects, the maternal alpha-fetoprotein levels can be elevated, and further subsequent screening with US leads to the prenatal diagnosis.

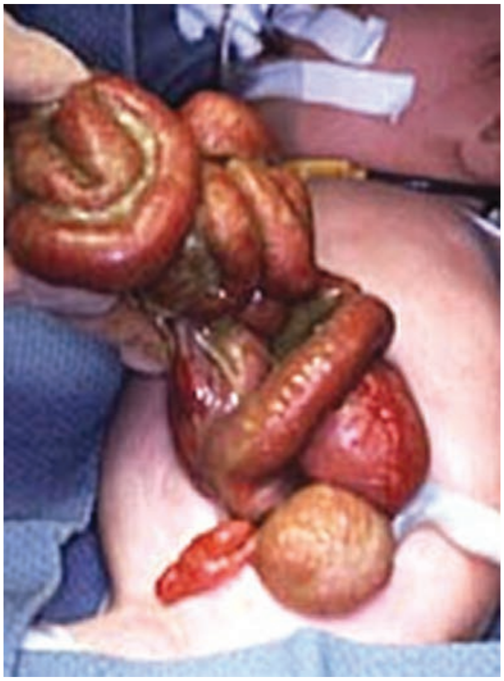
***Imaging.*** Visualization of liver or bowel within the umbilical cord beyond the twelfth week of gestation is evidence of an omphalocele. There is a spectrum, however: small lesions may just indicate an umbilical cord hernia, which has normal skin over it when the baby is born. Larger lesions should be considered likely true omphaloceles, and genetic evaluation should be strongly considered. A giant omphalocele is defined when more than 50% of the liver is extracorporeal or the defect is greater than 5 cm wide.[49,50] Wharton's jelly pseudocysts may be found in association with the defect, located near the cord insertion site on the omphalocele.[51]



**e-Figure 85.14. Omphalocele.** Photograph of a newborn shows a large anterior wall defect with a surrounding membrane. The umbilical cord is inserting at the apex.



**e-Figure 85.15. Bladder exstrophy.** (A) Longitudinal sonogram of the anterior pelvis shows a small outpouching just below the low-lying umbilical cord insertion *(arrow)*. No bladder is noted. (B) Axial SSFSE T2-weighted MR image of the pelvis confirms the presence of a soft tissue outpouching below the cord insertion *(arrow)*. No bladder is present.



**e-Figure 85.17. Gastroschisis.** This newborn has a large amount of dilated bowel protruding outside the abdominal cavity at the level of the umbilicus. No covering membrane is present.

Although, as noted earlier, the differentiation of a small, skin-covered umbilical hernia from omphalocele is difficult, US typically can diagnose these defects readily and accurately define the extruded anatomy (Fig. 85.18). When US fails to reveal the pertinent details, MRI can be useful and relies on standard single-shot FSE T2-weighted imaging; the liver tends to have a higher signal than other abdominal structures on T1-weighted sequences, which is useful for identification of the position of the liver in questionable cases. Characteristically, however, when fetal MRI is requested in cases of omphalocele, it is because of an interest in assessing for additional abnormalities or a need to calculate MR-derived lung volumes. Newborns with giant omphalocele have a tendency to need long-term ventilatory support and may have pulmonary hypoplasia.[50,52,53] Echocardiography is indicated, because 50% of fetuses with omphalocele have congenital heart disease. Ascites may be present but tends to decrease through gestation. Note that if a normal bladder is not seen over time or in repeated studies, exstrophy must be considered.

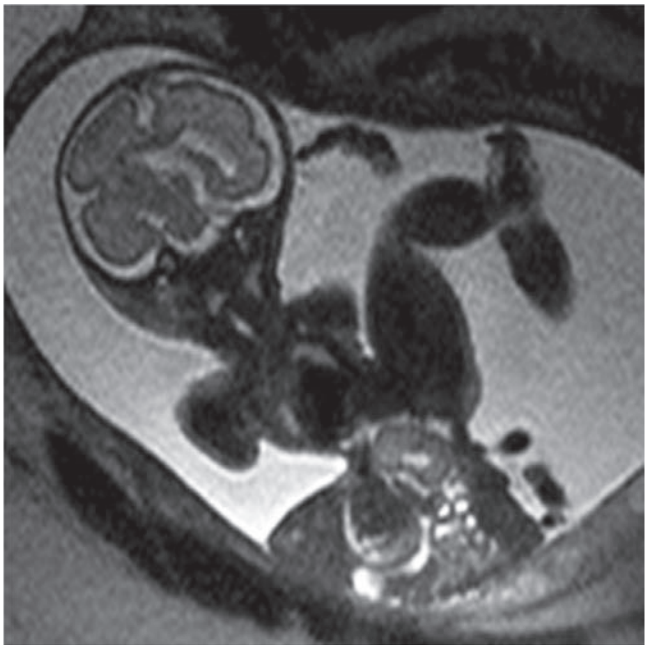


**Figure 85.16. Limb-body wall complex.** Extrusion of all abdominal contents in limb-body wall complex is seen on this T2-weighted MR image. Typically a very short umbilical cord and significant fetal contortion are present.

Gastroschisis is differentiated from omphalocele by the lack of a covering membrane of the herniated viscera and the normal insertion of the umbilical vessels at the abdominal wall (Fig. 85.19). MRI generally is not necessary for evaluation of this diagnosis because gastroschisis almost always is an isolated defect without additional fetal malformations or lung hypoplasia.[40] Closure of the abdominal wall defect in utero with subsequent severing of the extruded bowel, thus leading to extensive atresia/congenital short-gut syndrome, has been reported.[54] Additionally, on rare occasions, the membrane covering an omphalocele may rupture, thus simulating gastroschisis on imaging because of the free-floating appearance of the bowel. Differentiation is made by examining the relationship of the umbilical vessels to the extruded bowel and liver. Liver extrusion strongly favors ruptured omphalocele, though up to 6% of gastroschisis cases can have extracorporeal liver[55] (Fig. 85.20).

More complex ventral wall defects may benefit from combined US and MR evaluations, given their complementary attributes. MRI can provide a confident diagnosis of cloacal exstrophy in the appropriate setting.[56]

***Treatment and Follow-up.*** Fetuses in whom omphalocele is diagnosed are tested for chromosomal abnormalities because the incidence of aneuploidy is 40% to 60%, especially if only bowel is herniated.[57] The outcome for patients with omphalocele is usually dependent on the severity of other anomalies, including cardiac defects.[58] Repair of omphaloceles in the newborn period has a high rate of success, especially with surgical techniques emphasizing gradual reduction for larger lesions.[41,59,60]

Gastroschisis, unlike omphalocele, is not associated with chromosomal abnormalities, although the occurrence of extraintestinal abnormalities is approximately 6%.[61] Fetuses with gastroschisis experience complications that occur in the part of the bowel directly exposed to amniotic fluid during pregnancy; perforation or atresia occurs in up to 20% of cases.[61] Although dilation of the herniated loops is poorly correlated to worsened prognosis, sustained distension of intraabdominal bowel loops is of concern.[62] Postnatally, these patients may require resection of portions of their

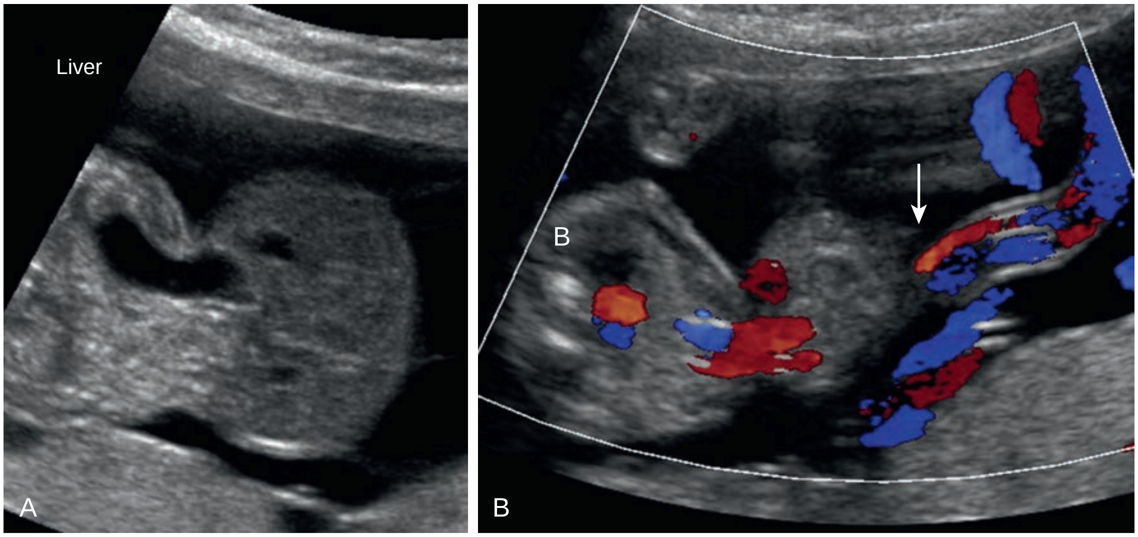

**Figure 85.18. Omphalocele containing liver and distal stomach.** (A) Gray-scale and (B) color Doppler sonogram shows the umbilical cord inserting into the omphalocele sac *(arrow);* see also Fig. 85.14. The spine is on the *left.*

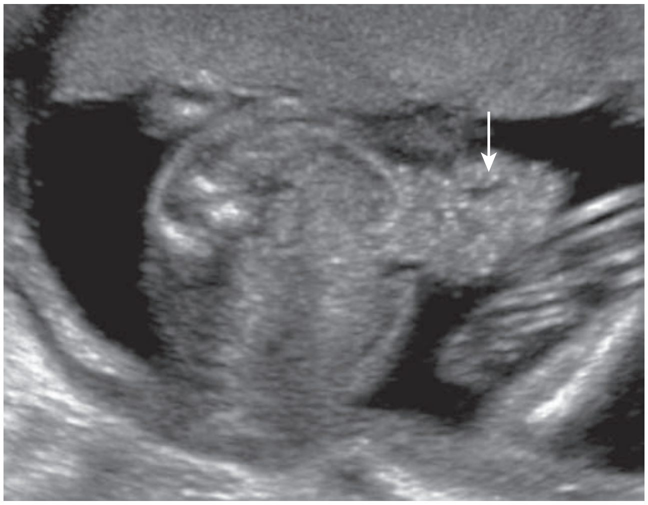

**Figure 85.19. Gastroschisis.** Transverse sonogram shows a right paraumbilical defect with herniation of small bowel loops *(arrow)* into the amniotic cavity with no surrounding membrane.

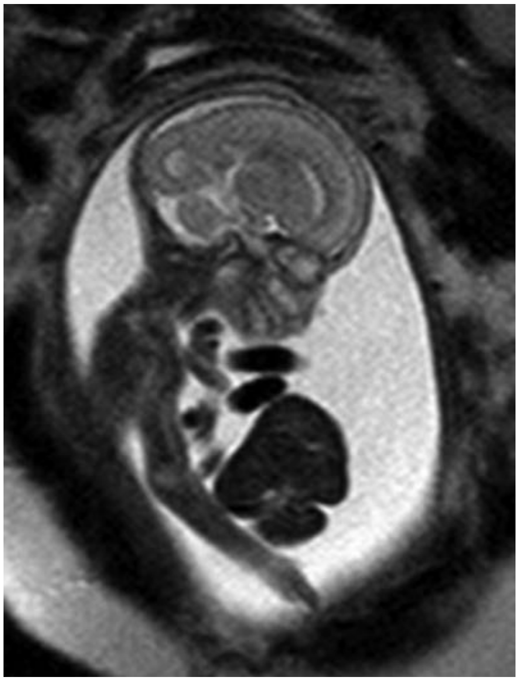

**Figure 85.20. Ruptured omphalocele.** Sagittal SSFSE MR image shows liver outside the fetal abdomen without a covering membrane.

bowel, and short-gut syndrome may develop. These children are at risk for presentation with necrotizing enterocolitis and perforation even months after undergoing repair.[63,64]

In fetuses with either omphalocele or gastroschisis, bowel rotation does not occur, and these patients, by definition, have malrotation of the midgut.

## ECHOGENIC BOWEL AND PERITONEAL ABNORMALITIES

***Overview.*** Echogenic bowel is a nonspecific US finding that should not be ignored, as it could be a marker for an underlying abnormality, although, in most cases, no subsequent fetal or neonatal problem develops.[65] Abnormalities of the peritoneum in the fetus include ascites and calcifications.

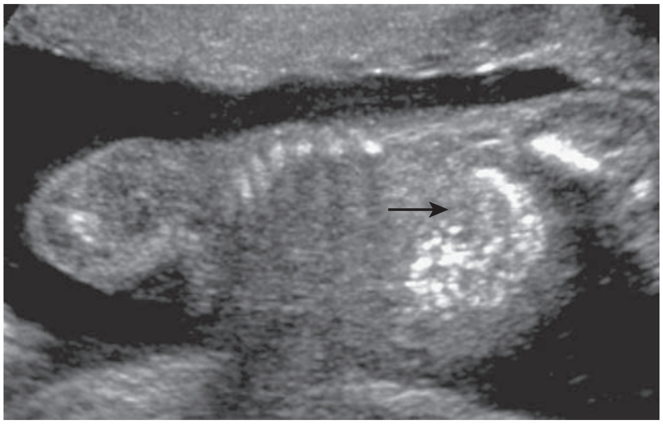

**Figure 85.21. Echogenic bowel.** Longitudinal sonogram of a 20-week fetus with echogenic bowel *(arrow)* that is as hyperechoic as the adjacent bone. Intrauterine growth retardation was present.

**BOX 85.2** Causes of Fetal Ascites

**SEROUS**

Bowel perforation (fluid may be complex)
Hydrops: immune and nonimmune (most common cause)
Ruptured or torted ovarian cyst
Cardiac decompensation
Hypoproteinemia
Hepatic dysfunction (storage disorders, mass, infection)

**BILIOUS**

Perforation of a choledochal cyst

**CHYLOUS**

Thoracic duct obstruction, increased intrathoracic pressure
Lymphatic malformation (e.g., Klippel–Trenaunay syndrome)
Mesenteric lymphangiomatosis

**HEMORRHAGIC**

Rupture of a vascular tumor
Trauma

**URINIFEROUS**

Perforation of the collecting system or bladder
Cloacal malformation, urogenital sinus

***Etiology.*** The underlying conditions in fetuses with echogenic bowel are as varied in etiology as infection (e.g., cytomegalovirus or parvovirus), intrauterine growth retardation, or aneuploidy (e.g., trisomy 21); alternatively, the direct cause of the increased conspicuity of the bowel might remain unclear. In other cases, the etiology may be more obvious; for example, in persons with cystic fibrosis, the meconium is more viscous and may present as hyperechoic contents within the bowel lumen. If bleeding has occurred into either the amniotic fluid or GI tract, intraluminal fluid can appear bright on US.

The etiology of fetal ascites can be classified under five general categories, ranging from serous through chylous, hemorrhagic, bilious, and related to the urinary tract (Box 85.2).[66–75]

***Imaging.*** When the echogenicity of the fetal bowel equals that of the fetal skeleton, it is considered abnormal (Fig. 85.21).[76] It has been recommended that transducer frequencies of 5 MHz or less be used for confirmation, because higher frequencies may make the bowel appear unnecessarily bright.[77] Although most of these patients are healthy, the finding of abnormally bright bowel in the fetus should prompt a careful US search for additional abnormalities, with consideration of further imaging by MRI for evaluation of the neural axis if infection is suspected.

Imaging of fetal ascites should be directed toward determining whether the fluid can be related to a particular organ system. Anatomy should be examined carefully, whether on US or MRI, for abnormalities of the urinary or reproductive tracts, biliary system, chest, and bowel. The presence of septations or loculations might suggest protein contamination from blood products, bowel pathology, or abdominal lymphangiomatosis. In some cases, ascites may be a physiologic consequence of a condition (e.g., hypoproteinemia, hydrops, or infection) not directly related to an anatomic abnormality. It is important to look for any evidence of calcifications in the peritoneum, especially along the liver capsule, that would indicate meconium peritonitis and the implied disruption of bowel integrity, as from perforations secondary to obstruction or ischemia. Calcifications in the parenchyma of the liver or spleen might be a clue to the presence of aneuploidy or infection, or rarely may be related to portal emboli.[78,79] Calcification inside the bowel lumen is an indication of GI-genitourinary fistula (see Fig. 85.12).[80]

***Treatment and Follow-up.*** Treatment and follow-up are directed toward the cause of the finding and could include in utero intervention (e.g., intrauterine transfusion) and postnatal surgery, depending on the etiology. Fetuses who have isolated fetal ascites with a normal karyotype and a negative infection screen have a good prognosis.[81,82]

## MASSES AND OTHER VISCERAL ABNORMALITIES

***Overview.*** The category of fetal abdominal mass includes visceral enlargement and neoplasia. Cystic and solid mass lesions can also occur in the peritoneal cavity. Moreover, absence of structures, such as the spleen, should also be considered.

***Etiology.*** Visceromegaly includes hepatosplenomegaly, which may be the result of viral infection, fetal hydrops, glycogen or lysosomal storage disorders, Beckwith–Wiedemann syndrome, or the presentation in utero of anemia or hematologic malignancy (particularly for trisomy 21), and amniotic fluid testing may be necessary.[67,69,83–85] Isolated hepatomegaly may be secondary to increased right heart pressure; the liver also might appear enlarged if it lies transversely across the abdomen, as in heterotaxy. Neoplasia also may present with visceromegaly, with the organ being either a repository for metastatic disease, such as neuroblastoma diffusely metastatic to the liver,[86,87] or the site of a primary intraperitoneal mass, most frequently in the fetal liver, such as a hemangioma or hepatoblastoma (Fig. 85.22). Intrauterine torsion also can present with visceromegaly secondary to edema.[88–90] A special note should be made of megacystis-microcolon-hypoperistalsis syndrome, which can be considered in patients, more commonly female, with gross bladder enlargement and no colonic meconium on T1-weighted MRI (Fig. 85.23).[26,91]

The category of abnormal structures presenting as mass lesions includes intraperitoneal cysts or fluid collections, such as meconium cyst as a result of perforation of the bowel and meconium peritonitis (Figs. 85.24 and 85.25), or, as recently reported, as a result of reflux of meconium into the peritoneum through the uterus in a fetus with cloacal malformation.[92] Box 85.3 lists the origins of cystic masses in the abdomen and pelvis, and Box 85.4 describes solid masses that have been reported. Occasionally, a “pseudomass” is described inside of a bowel lumen, such as the stomach; in this particular case, it is thought to represent debris such as blood products and may be seen after a history of intervention (e.g., amniocentesis).[93] Note that, most commonly, masses in the fetal abdomen are related to the genitourinary tract.

Some abnormalities are related to the absence of expected structures. For example, the spleen may be absent, and the gallbladder may be in abnormal position or absent; these findings suggest heterotaxy, which would mandate careful evaluation of the cardiac axis and configuration and other viscerovascular structures. The gallbladder usually can be detected on serial US[94] and is identified consistently on MRI.[95] Its absence would suggest biliary atresia and polysplenia if found within the heterotaxy complex. A gallbladder also may be indistinguishable in a fetus with cystic fibrosis.

Calcifications and/or debris in the gallbladder can be a sign of fetal hemolysis, but most are incidental and do not cause

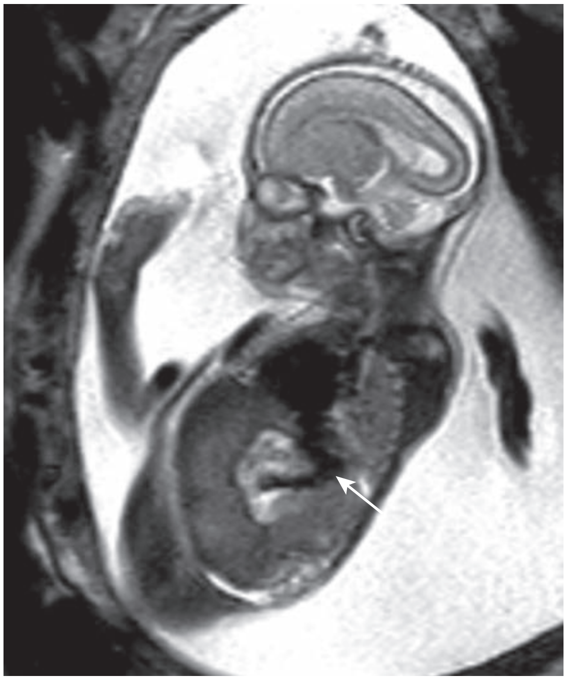

**Figure 85.22. Rapidly involuting congenital hemangioma (RICH).** Sagittal T2-weighted MR image of a high-signal mass lesion in the liver with large flow-void draining vein *(arrow)*.

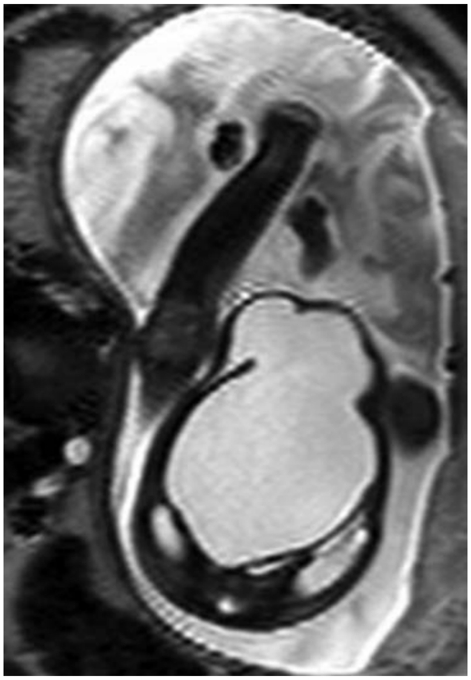

**Figure 85.23. Megacystis-microcolon-hypoperistalsis syndrome.** Axial SSFSE MR image in a female fetus with hydronephrosis and marked bladder distension. Normal amniotic fluid volume was present. No meconium could be identified in the bowel on T1-weighted imaging.

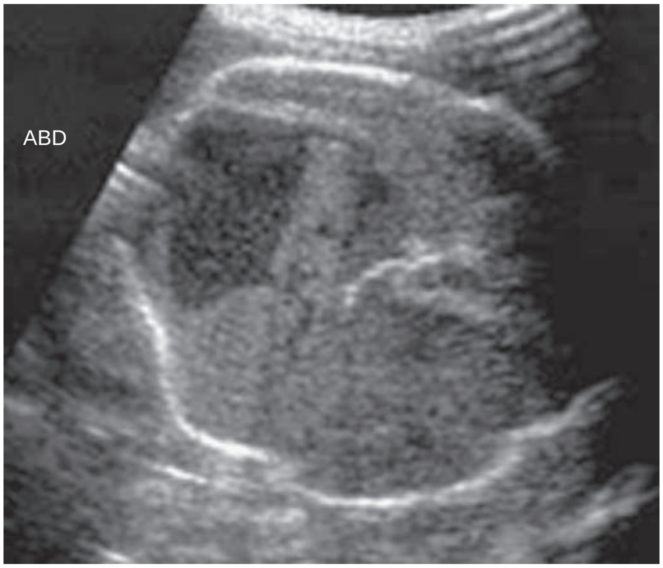

**Figure 85.24. Meconium pseudocyst.** Transverse sonogram shows a large loculated heterogeneous collection with a calcified rim within the abdomen. A sigmoid perforation was identified after delivery.

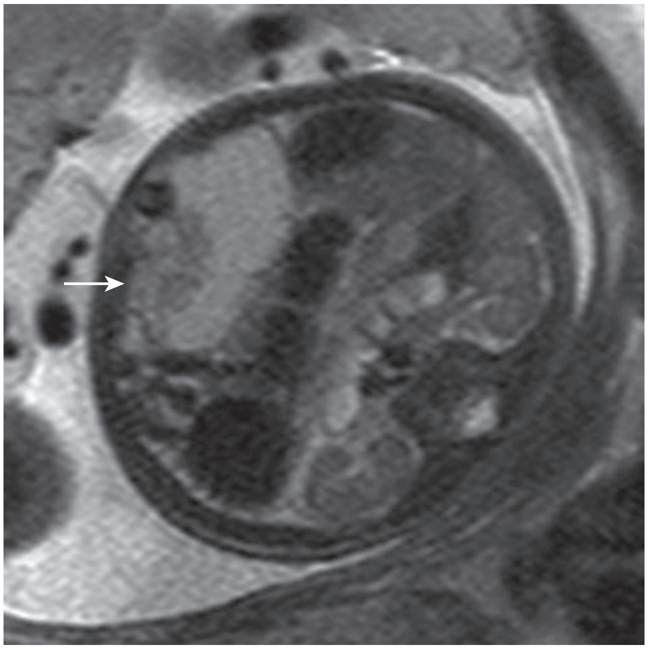

**Figure 85.25. Meconium pseudocyst.** T2-weighted MR image shows a medium to moderately high signal collection containing debris *(arrow),* consistent with meconium mixing.

### BOX 85.3 Intraperitoneal Cystic Masses in the Fetus*

Gastrointestinal tract: duplication, meconium pseudocyst, segmental dilatation of the ileum (ileal dysgenesis)
Biliary: choledochal cyst
Hepatic: epithelial cyst, mesenchymal hamartoma, vascular malformation
Splenic: congenital epithelial cyst, epidermoid
Lymphatic: mesenteric cyst, mesenteric lymphangiomatosis
Ovarian†: follicular cyst, torsion (late), teratoma

*Most cystic masses in the fetal abdomen are related to the genitourinary tract.

†Technically retroperitoneal, but may seem to present as an intraperitoneal mass. Note that other retroperitoneal masses, such as cystic neuroblastoma in the adrenal, may seem to be intraperitoneal depending on size.

### BOX 85.4 Intraperitoneal Solid Masses in the Fetus

Hepatic: hepatoblastoma, leukemic infiltration, rapidly involuting congenital hemangioma, torsion of accessory lobe, mesenchymal hamartoma, infarction
Splenic: torsion, leukemic infiltration
Gonadal*: torsion (early), teratoma, endometrioma
Pulmonary*: infradiaphragmatic sequestration

*Technically retroperitoneal, but may seem to present as an intraperitoneal mass.

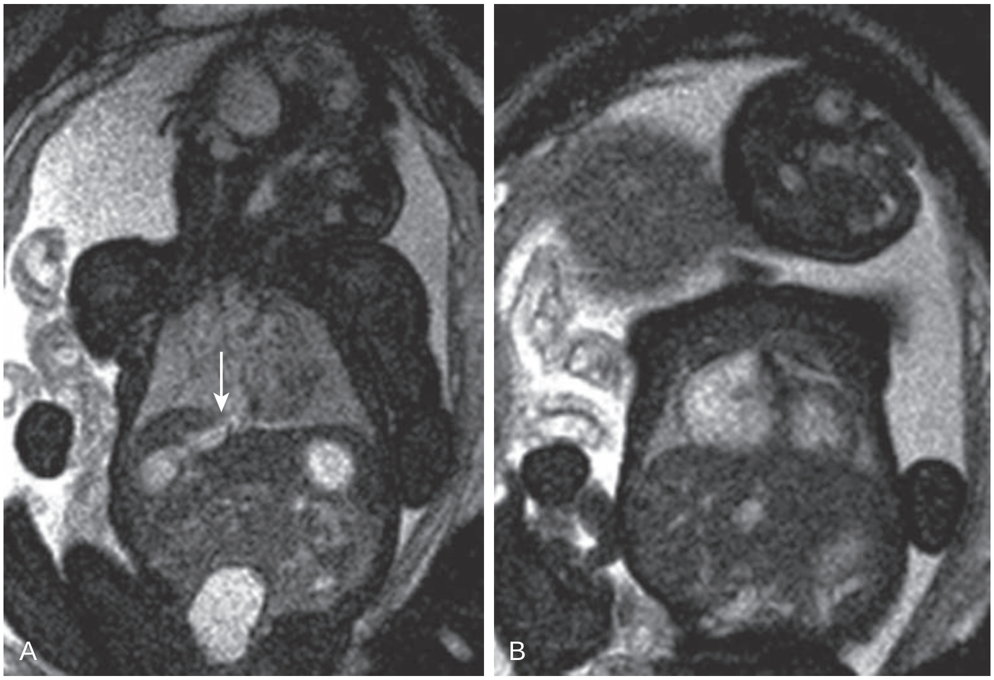
complications.[96] Small stones typically resolve without intervention. Finally, organs may be displaced from their normal position in persons with splenogonadal fusion, the so-called *wandering spleen* or *liver*, and of course with diaphragmatic hernias and ventral wall defects.

***Imaging.*** Careful delineation of the organ of involvement and of the pertinent anatomy can suggest the correct diagnosis (Fig. 85.26). When calcifications are identified, infection should be considered, as discussed earlier.[97] The use of a high-resolution linear transducer in the appropriate patient can be extremely advantageous in delineating fine detail, such as subtle calcifications, the presence of a daughter cyst within a large cyst, indicative of ovarian origin, or the characteristic bowel signature of a duplication cyst. For all abnormalities, in addition to identifying the organ of origin, Doppler evaluation will help to understand whether a primary vascular lesion (increased flow) or torsion/ischemia (decreased flow) should be advanced in the differential diagnosis (Fig. 85.27).

US generally delineates well the origin of fetal abdominal masses from solid organs. Masses are investigated by MRI when the organ of origin or the extent of involvement is imprecisely detailed by ultrasonography. In addition to the use of GRE T1-weighted and FSE T2-weighted sequences, SSFP T2-weighted sequences are useful because of their ability to delineate adjacent structures and high-signal blood flow. This effect can be very helpful in identifying primary vascular lesions (e-Fig. 85.28) or enlarged vessels supplying tumors. In addition, fetal MRI may be indicated in the evaluation of the liver in conditions of potential iron overload, in which the signal from the liver is abnormally low.[98,99]

Umbilical venous varix is a vascular lesion that is variably associated with in utero complications.[100] Other vascular anomalies of the venous system, such as absence of the ductus venosus or agenesis of the portal vein, have been described and require meticulous delineation of the associated portosystemic shunt pathway by US Doppler or bright-blood (SSFP) MRI for accurate diagnosis.[101,102]

***Treatment and Follow-up.*** Depending on the diagnosis, alterations in planning and timing of delivery may be indicated; amniocentesis and in utero therapies may be considered (e.g., intrauterine transfusion for fetal anemia). In general, therapy is targeted at providing the safest environment in which appropriate treatment can be directed for the fetus or neonate. To date, there are no clear indications for fetal surgery for GI anomalies, although imaging evaluation can alter both the timing and mode of delivery. Open fetal surgery has been reserved for conditions determined to be terminal without intervention in a previable fetus, and has been limited to excisions of malformations and tumors of the chest, head and neck, and coccyx (e.g., sacrococcygeal teratoma).[103–105]



**e-Figure 85.28. Hepatic vascular malformation.** Balanced coronal SSFP MR images show an enlarged draining vein *(arrow*, (A)*)* and enlarged right atrium (B) as a result of congenital vascular malformation in the liver.

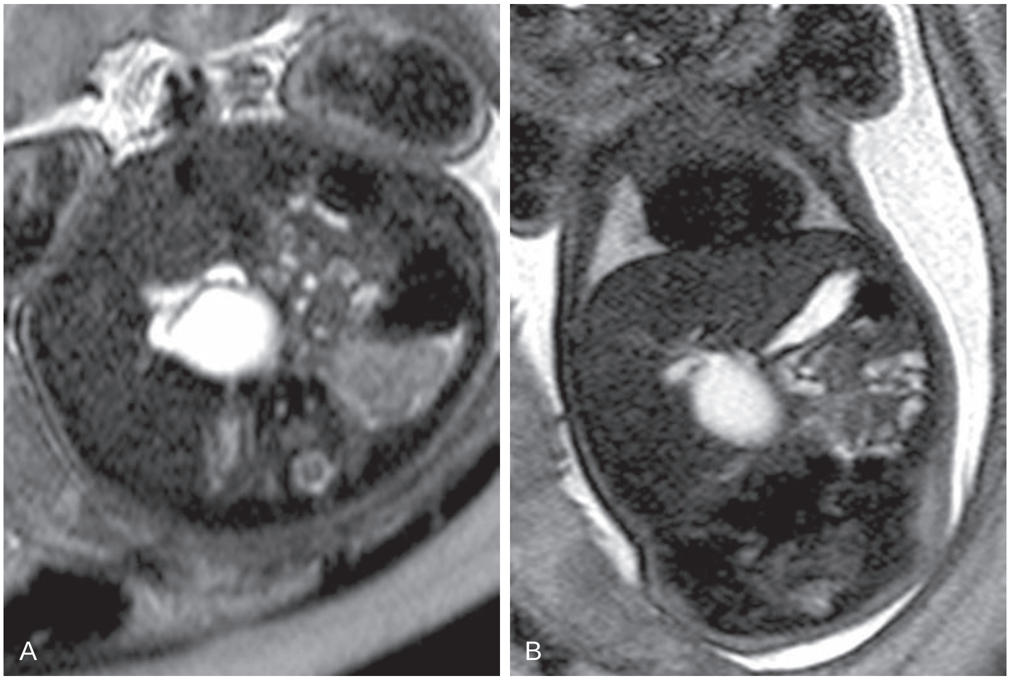


**Figure 85.26. Choledochal cyst.** (A) Axial and (B) coronal T2-weighted SSFSE MR images of a cystic mass at the margin of the liver demonstrate a connection to the biliary system.

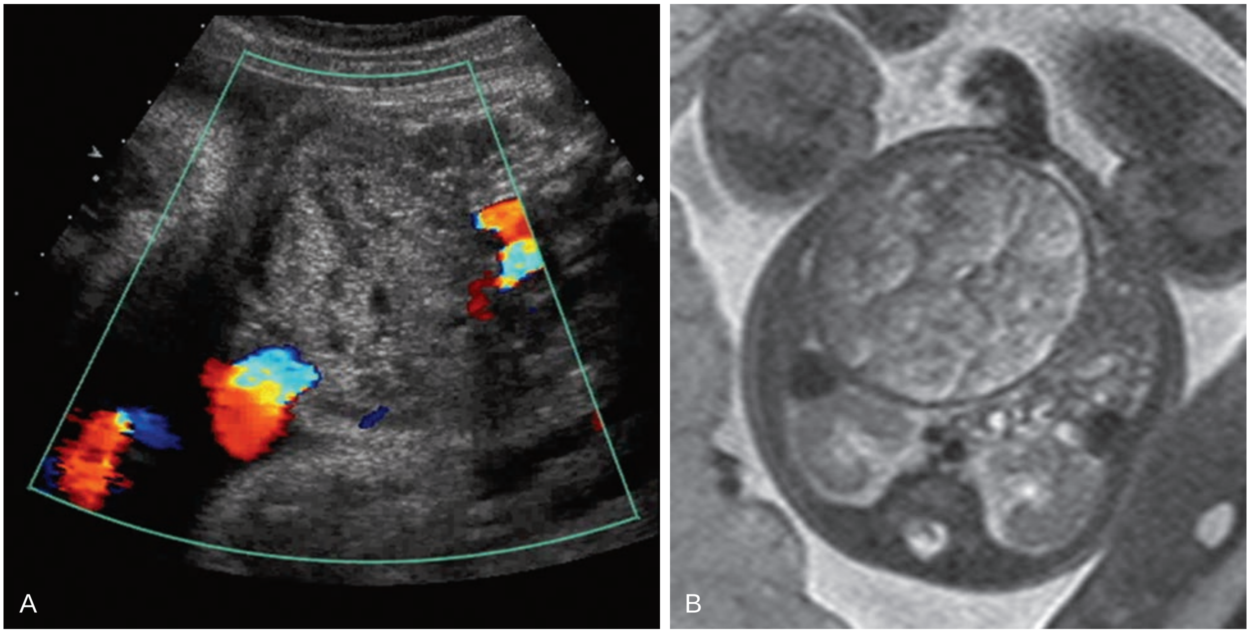

**Figure 85.27. Ovarian torsion.** A solid-appearing but avascular mass is delineated in this female fetus with both color Doppler ultrasound (A) and MRI (B).

## KEY POINTS

- US is for screening of fetal bowel abnormalities and will answer almost all questions. MRI can be useful for targeted questions unanswered by ultrasonography, including evaluation of microcolon and abnormal meconium signal distribution.
- Ventral wall defects are distinguished by what is herniated from the fetal abdomen, the presence of a covering membrane, and the relationship of the umbilical vessels to the herniated viscera.
- When fetal ascites are encountered, a careful search for an anatomic abnormality to the cardiac, pulmonary, biliary, genitourinary, and GI systems is indicated.
- Precise identification of the organ(s) of origin will determine an appropriate differential diagnosis for fetal abdominal masses.

# The Abdominal Wall and Peritoneal Cavity

*Katrina F. Chu and Michael S. Gee*

## PERITONEAL CAVITY

***Overview.*** The peritoneum is a thin serosal membrane of mesodermal origin that comprises a single layer of mesothelial cells resting on a basement membrane.[1] It is divided into visceral and parietal components, and the space between the two components constitutes the peritoneal cavity. The layer covering the abdominal viscera, omentum, and the mesenteries is designated *visceral*, whereas the layer covering the abdominal walls, undersurface of the diaphragm, anterior surface of the retroperitoneal viscera, and the pelvis is designated as *parietal*. The peritoneum is continuous in males, whereas in females it is discontinuous at the ostia of the oviducts to allow communication between the peritoneal cavity and extraperitoneal pelvis.

The layers of peritoneum that invest blood vessels, lymphatics, nerves, adipose tissue, and connective tissue within the abdomen and the pelvis form the various peritoneal ligaments, omentum, and mesenteries. A ligament usually supports a structure within the cavity, whereas a mesentery usually suspends the structure to the retroperitoneum. Omentum is a specialized ligament that connects the stomach to another structure. These ligaments and mesenteries not only serve to suspend and support the visceral organs but also divide the peritoneal cavity into multiple compartments that dictate the location and routes of spread of malignancies and infection.

The mesothelial cells produce a small amount of sterile fluid within the peritoneal cavity that is continuously circulated by the movement of the diaphragm and peristalsis of bowel, and the fluid provides a frictionless surface over which the viscera can move, a site for fluid transport, and local bacterial defense.[1] Peritoneal fluid predominantly flows up the right paracolic gutter into the right supramesocolic compartment, and 90% of the fluid is cleared by the subphrenic lymphatics to the supradiaphragmatic nodes.[2] Areas of relative stasis include (1) the rectouterine pouch or cul-de-sac (pouch of Douglas) in females, (2) the rectovesical region in males, (3) the right lower abdomen at the end of the small bowel mesentery, (4) the left lower abdomen along the sigmoid mesocolon, (5) the right paracolic gutter, and (6) the right subhepatic/subdiaphragmatic space (Morison pouch).[2]

## ENTITIES AFFECTING THE PERITONEUM

### Pneumoperitoneum

***Overview.*** The term *pneumoperitoneum* refers to the presence of air within the peritoneal cavity. Benign postoperative pneumoperitoneum is a separate entity that results from accumulation of free air after abdominal surgery. Usually, free intraperitoneal air clears more rapidly in children than in adults, but the timing can be variable. Timing of clearance usually depends upon the amount of air initially trapped after surgery, which in most cases is related to patient body habitus; obese patients trap less air than thin patients.[3] Several studies have demonstrated clearing of free air in 68% to 90% of children postoperatively by 24 hours, but free air can be seen for as long as 6 to 7 days postoperatively in 2% to 3% of cases.[3]

***Etiology.*** Free intraperitoneal air is most commonly a consequence of gastrointestinal (GI) tract perforation.[4] In the neonate, this usually results from intestinal obstruction, necrotizing enterocolitis, or spontaneous gastric or bowel perforation, usually at the ileocecal region (Box 86.1).[5] Necrotizing enterocolitis is the most common cause of pneumoperitoneum in the neonatal intensive care unit.[6]

Free intraperitoneal air sometimes results from mediastinal extension in newborns supported by mechanical ventilation. Rarely, nasogastric or nasoduodenal tubes may perforate the bowel. The position of the tube is often a clue to the perforation (e-Fig. 86.1).

In children beyond the neonatal period, perforated peptic ulcers and inflammatory bowel disease (IBD) are other causes of pneumoperitoneum; it should be noted that pneumoperitoneum is rarely found with appendiceal perforation, because the omentum usually seals off the perforation very quickly.[7] Trauma, both accidental and nonaccidental, may also result in pneumoperitoneum.

***Clinical Presentation.*** Pneumoperitoneum may be suspected clinically because of the history of an underlying condition that predisposes to bowel perforation, detection of acute abdominal distension with increased tympany on physical examination, and clinical deterioration of the patient. Occasionally it is incidentally discovered on imaging of the chest or abdomen.

***Imaging.*** A single supine abdominal radiograph is usually the most common imaging study requested for patients with suspected abdominal pathology. The cited overall detection rate of free intraperitoneal air on supine imaging ranges from 56% to 59%; detection rates as high as 80% have been quoted on supine abdominal radiographs and 78.7% on supine chest radiographs.[4] It is important to be familiar with the various signs of intraperitoneal free air on supine radiographs, because this may be the only initial study requested by the patient's primary caregiver.

Once suspected, the diagnosis can be confirmed on upright or decubitus films. Upright radiographs will show air collecting between the diaphragm and the liver on the right and between

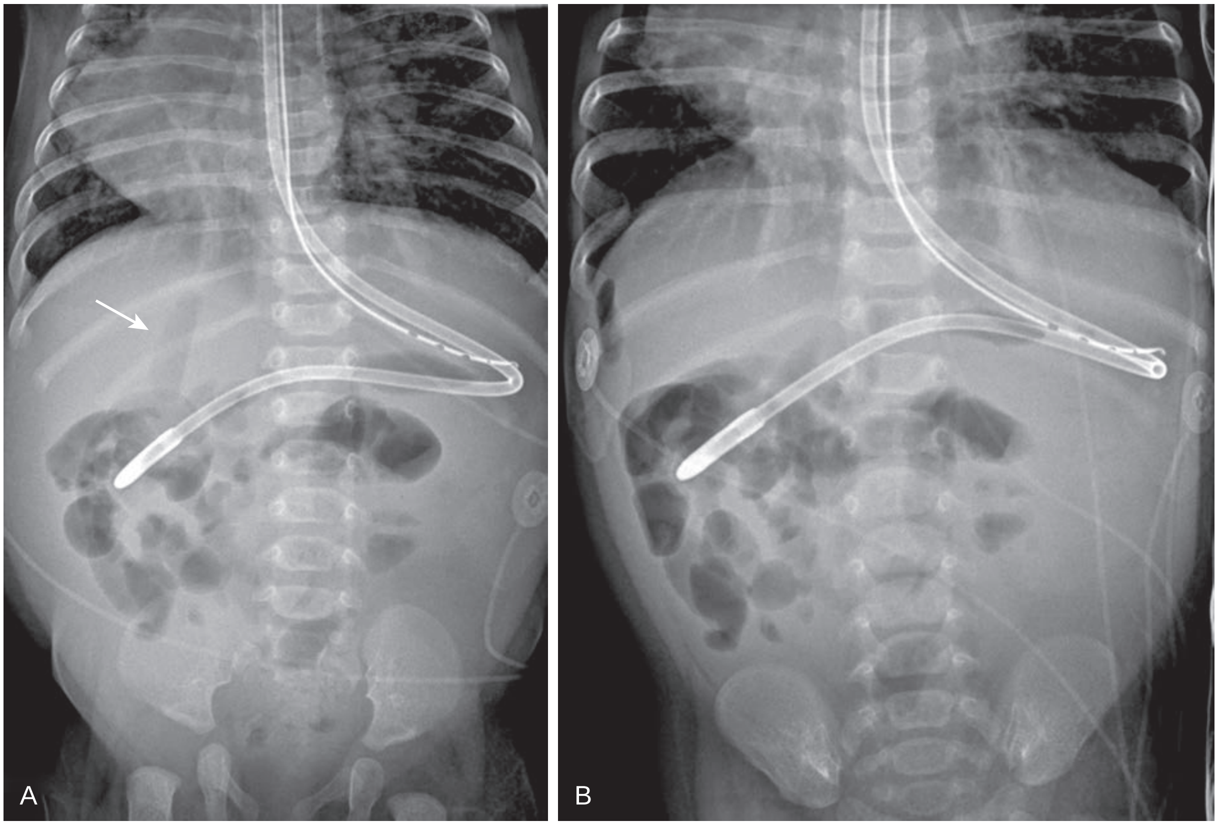
**BOX 86.1** Causes of Pneumoperitoneum in Newborns

**WITH PERFORATION OF THE GASTROINTESTINAL TRACT**

- Gastric perforation, spontaneous or iatrogenic (nasogastric tubes)
- Duodenal ulcer with perforation
- Isolated perforation of the small bowel or colon in the absence of associated abnormality
- Perforation of Meckel diverticulum (ectopic gastric mucosa with ulceration)
- Necrotizing enterocolitis
- Colonic perforation (secondary to instrumentation, enema tip, thermometer)
- Perforation secondary to intestinal obstruction (atresia, meconium ileus, Hirschsprung disease, neonatal small left colon)
- Secondary to postsurgical anastomotic leak

**WITHOUT PERFORATION OF THE GASTROINTESTINAL TRACT**

- Pulmonary air leaks (pneumomediastinum) with or without other manifestations of alveolar leaks
- Idiopathic (extremely rare)



**e-Figure 86.1. Perforation by enteric tube.** (A) This 3-month-old infant with dextrocardia and heterotaxy underwent imaging for abdominal distension. The feeding tube is more lateral than expected, and a concerning lucency overlies the liver (*arrow*). (B) The left-side-down decubitus view shows gas collecting adjacent to the liver. The patient was found to have a duodenal perforation at surgery.

the diaphragm and the liver, spleen, stomach, or colon on the left (Figs. 86.2 and 86.3). Young children and those too ill to sit or stand can be examined in the decubitus position. The decubitus view should be obtained with the right side up to allow the liver to fall away from the wall of the peritoneal cavity to allow visualization of free air between the liver and the abdominal wall. Both techniques are considered equally effective.[4]

If decubitus or upright imaging is difficult to obtain, a supine view using a horizontal-beam technique can be utilized. On the horizontal-beam supine radiograph, free peritoneal air may collect between the anterior surface of the liver and the anterior abdominal wall (Fig. 86.4), but small amounts of free air may be more difficult to detect, particularly if located over loops of bowel.

Multiple signs related to pneumoperitoneum are described on plain radiographs (Table 86.1) based on the location and volume of air and its relationship to adjacent structures. The lucency caused by the free air rising to an anterior position in the abdomen

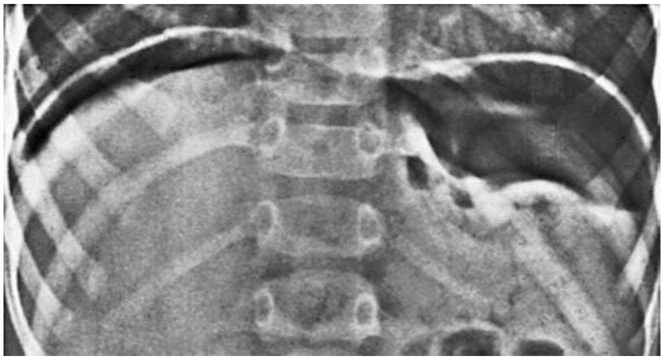


**Figure 86.2. Free intraperitoneal air.** Upright abdominal radiograph in a 2-year-old boy with perforated gastric ulcer. Air is easily demonstrated between the diaphragm and the liver on the right side and between the diaphragm and the spleen and stomach on the left.

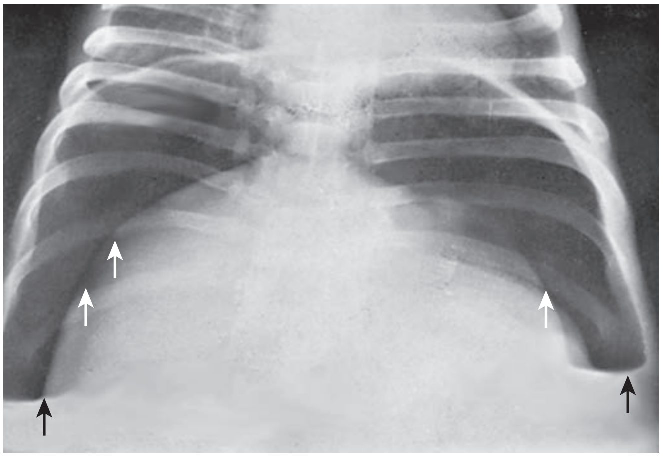

**Figure 86.3. Hydropneumoperitoneum.** Upright abdominal radiograph shows a massive amount of free air below the diaphragm *(white arrows)* with air-fluid levels *(black arrows)*.

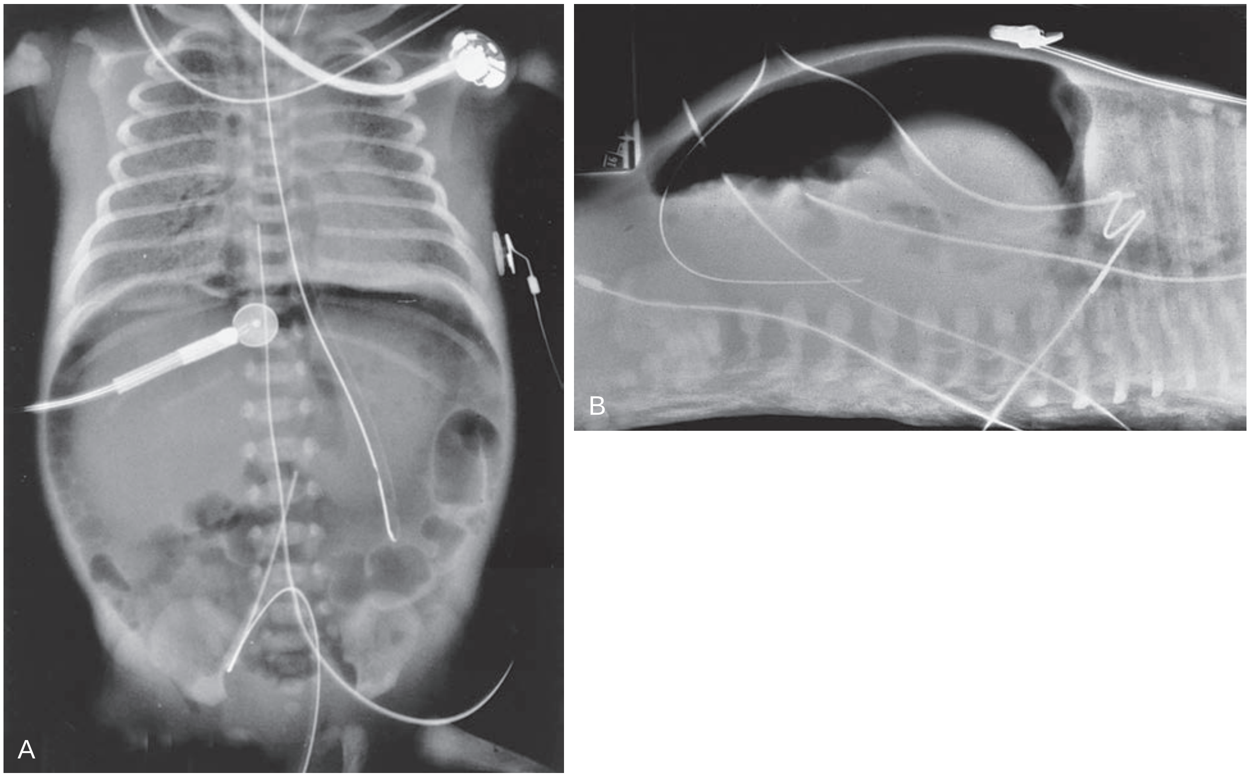

**Figure 86.4. Pneumoperitoneum.** (A) Anteroposterior view of the chest and abdomen in a newborn with pulmonary interstitial emphysema, pneumomediastinum, and pneumoperitoneum. A large amount of gas is in the peritoneal cavity, there is a Rigler sign and the density of the liver is decreased compared with the extraperitoneal soft tissues. The falciform ligament per se is not visualized because of the obscuring umbilical venous catheter. (B) Cross-table lateral view of the same patient demonstrates large pneumoperitoneum without air-fluid levels, suggesting that the air has dissected into the peritoneum from the chest.

is most easily detected when it projects over the liver, thus many right upper quadrant signs of free air are described.[8] The normal density of liver is uniform and typically denser than the heart. Air overlying the liver on a supine radiograph decreases the radiodensity of that portion of the liver.

Small amounts of free air may appear as subtle, localized collections in the right upper quadrant. Linear accumulation of air in the right subhepatic space is known as the *hepatic edge sign*, whereas triangular collections seen with air in the Morison pouch is known as the *Doge cap sign*, because it resembles the cap worn by the Venetian Doge.[9,10] A linear collection of air may also be located in the fissure of the ligamentum teres.[11]

*Rigler sign* refers to visualization of the bowel wall caused by the presence of air on both sides of the wall (e-Fig. 86.5). The telltale *triangle sign* is a triangular focus of extraluminal air seen on the cross-table lateral view of the abdomen, created by the external surface walls of adjacent bowel loops and the anterior abdominal wall, as the air collects at the highest point in the peritoneal space.[12]

**TABLE 86.1** Radiographic Signs of Pneumoperitoneum

| Bowel-Related Signs | Right Upper Quadrant Signs | Peritoneal Ligament–Related Signs | Miscellaneous Signs |
|---|---|---|---|
| Rigler sign | Hyperlucent liver sign | Falciform ligament sign | Football sign |
| Triangle sign | Anterior-superior oval sign | Inverted V sign | Cupola sign |
| | Fissure for ligamentum teres sign | Urachus sign | Left-sided anterior-superior oval sign |
| | Doge cap sign | | Subphrenic radiolucency |
| | Hepatic edge sign | | Focal radiolucency |
| | Dolphin sign | | |

A sufficiently large amount of free air can be seen as a large, ovoid lucency overlying the abdominal contents (Fig. 86.6). In the supine position, the liver falls away from the anterior peritoneal surface and free air can dissect along both sides of the falciform ligament, which attaches the liver to the anterior abdominal wall. When outlined by free air, the ligament appears as a thin, vertical, opaque line. The distension of the flanks caused by the free intraperitoneal air and the outline of the falciform ligament centrally are the elements of the well-known *football sign*, so termed because of its similarity to an American football; the falciform ligament represents the central thread in the ball (see Fig. 86.6). A less commonly encountered sign of pneumoperitoneum is the *inverted V sign*, caused by air outlining the medial umbilical folds in the pelvis.[13]

Causes of pneumoperitoneum can sometimes be inferred by certain signs. For example, a ruptured viscus permits both air and fluid to escape into the peritoneal cavity, causing abnormal extraluminal air-fluid levels (compare Figs. 86.3 and 86.4). On the other hand, tension pneumomediastinum is an entity in which air dissects along the retroperitoneum and subadventitial layer of the mesenteric vessels and sometimes ruptures into the peritoneal cavity; this will not demonstrate significant extraluminal air-fluid levels unless the patient has underlying ascites from an unrelated cause. The latter is also usually suspected from a history of assisted ventilation and the presence of pneumomediastinum on the chest radiograph.

Apart from plain radiographs, ultrasound (US) can also be used in the detection of pneumoperitoneum by detecting gas over the liver, with a reported sensitivity of 93%, specificity of 64%, and accuracy of 90%.[14] However, US should not be considered definitive

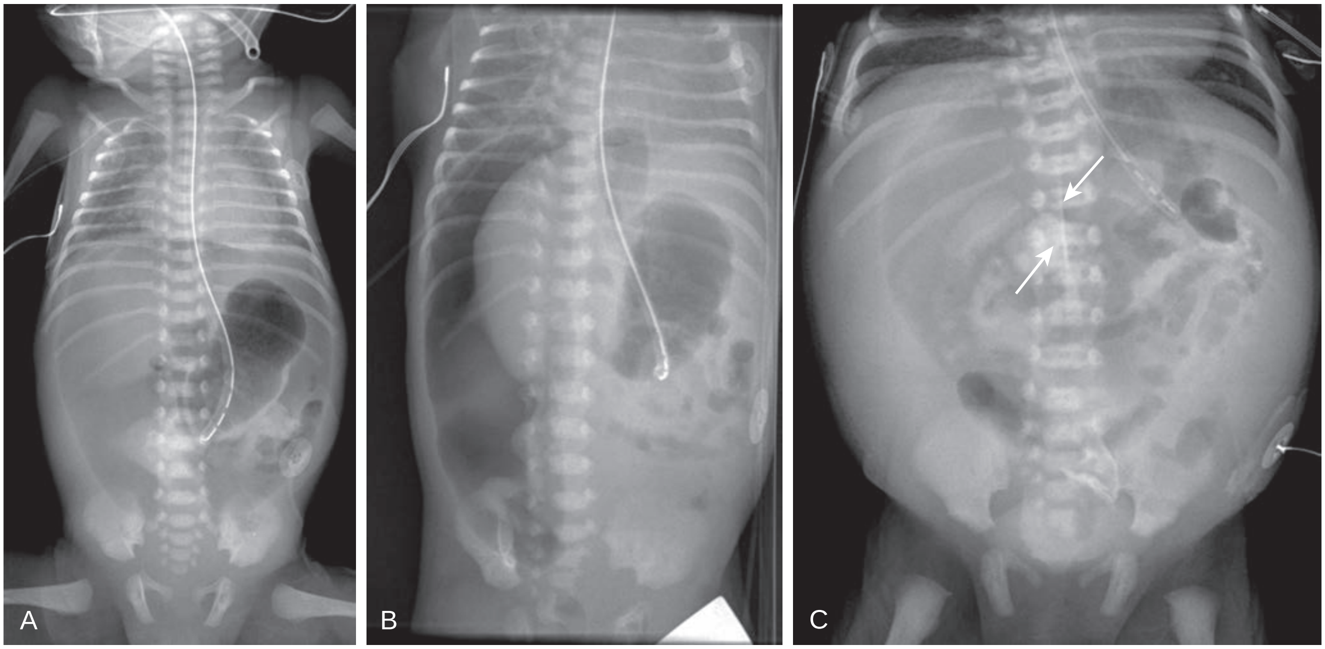

**Figure 86.6. Pneumoperitoneum with "football sign."** (A) Supine radiograph in a 5-day-old, 30-week-gestation premature infant shows a large lucency over the entire abdomen. (B) Decubitus view in the same infant confirms the large pneumoperitoneum. Multiple intestinal perforations were found at surgery. (C) Another patient with pneumoperitoneum demonstrates the classic football sign on abdominal imaging. Gas outlines the falciform ligament *(arrows),* and a large lucency overlies the upper abdomen centrally as the gas accumulates anteriorly. At surgery, this patient was found to have a colonic perforation.

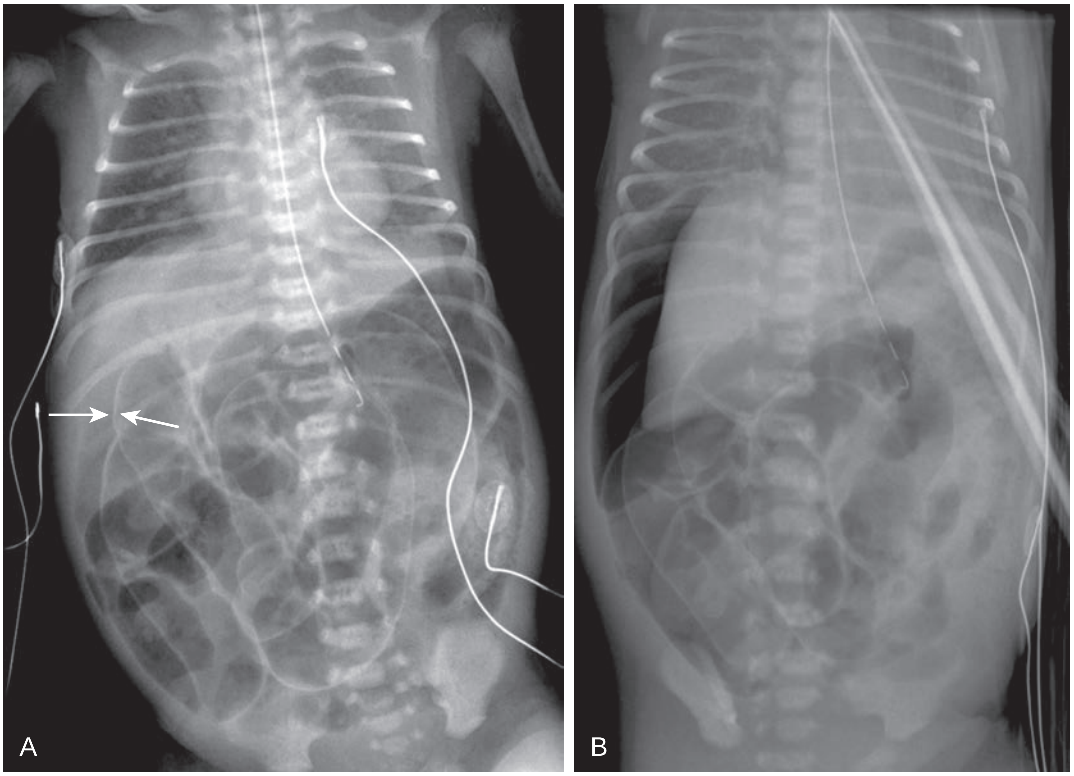

**e-Figure 86.5. Pneumoperitoneum with Rigler sign.** (A) Supine radiograph in a 6-day-old, 33-week-gestation premature infant shows a large amount of free intraperitoneal gas with right upper quadrant lucency. Rigler sign is present, and air outlines both sides of the bowel loops *(arrows);* subtle signs of portal venous gas are also present. (B) Left-side-down decubitus view of the same infant shows a large amount of free intraperitoneal gas rising to outline the liver. Rigler sign is again evident.

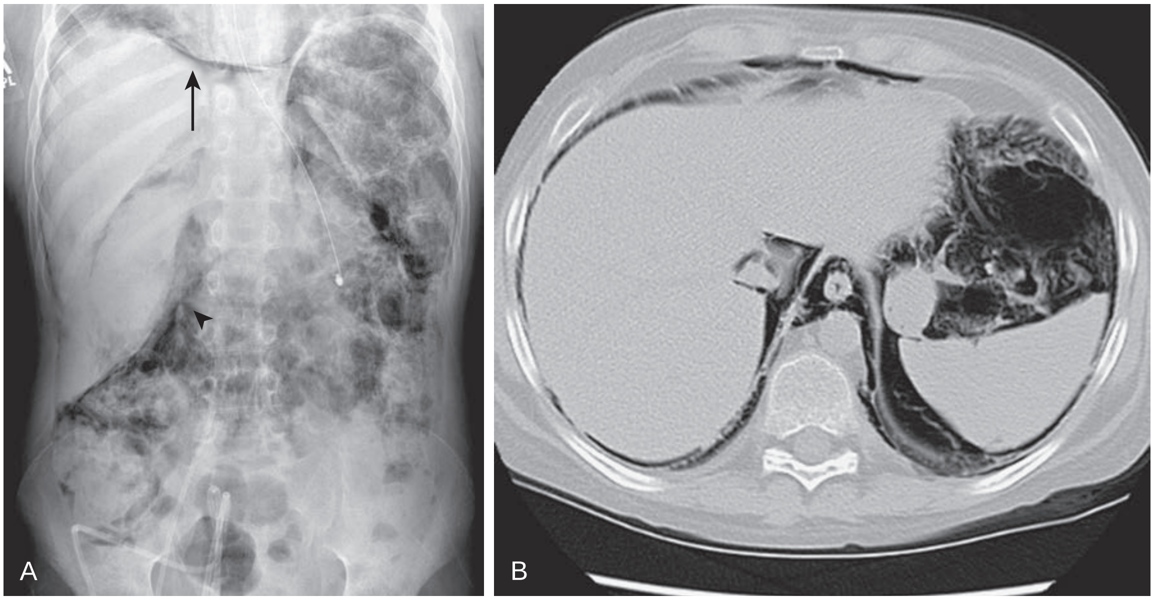

**Figure 86.8. Pneumatosis intestinalis.** (A) Radiograph of the abdomen and pelvis in a patient who underwent bone marrow transplantation for refractory recurrent neuroblastoma. Abundant pneumatosis intestinalis has resulted in pneumoperitoneum *(arrow)* and pneumoretroperitoneum *(arrowhead)*. (B) CT image through the upper abdomen viewed with lung windows confirms the pneumoperitoneum, pneumoretroperitoneum, and pneumomediastinum. Note absence of air-fluid levels.

in diagnosing or excluding a pneumoperitoneum without extensive expertise and experience, and US findings should be confirmed by appropriate radiographic evaluation.

Although not typically performed for assessment of pneumoperitoneum, computed tomography (CT) is an extremely sensitive method to identify small amounts of intra- or retroperitoneal air, intraperitoneal air-fluid levels, and often the underlying cause of pneumoperitoneum.[15] It can be optimized by reviewing abdominal images using lung-window parameters (e-Fig. 86.7 and Fig. 86.8).

## Mimics and Potential Pitfalls

A *pseudo-Rigler sign* occurs when two loops of dilated air-filled bowel lie adjacent to one another. The line seen in the pseudo-Rigler sign is thicker than with free peritoneal air, because it represents a double thickness of bowel wall (from the two adjacent bowel loops), whereas the line in patients with free peritoneal air—a true Rigler sign—represents a single bowel wall. However, this is not always a reliable differentiation, because the underlying disease-causing perforation may lead to a thickened bowel wall. In equivocal cases, a left lateral decubitus radiograph can be obtained for clarification.[16]

## Ascites

***Overview.*** A small amount of fluid in the peritoneal cavity is normal. This is more common in females and is often seen incidentally on cross-sectional imaging. *Ascites* refers to abnormal or pathologic accumulation of fluid within the peritoneal cavity.

***Etiology.*** Pathologic intraperitoneal fluid collections stem from a variety of causes and most commonly result from sequestration of fluid from the splanchnic vascular bed. Other causes of pathologic intraperitoneal fluid include hemoperitoneum, urinary ascites, bile, pancreatic juices, chylous fluid, and cerebrospinal fluid (CSF). *Transudative ascites* is most commonly found in patients with hepatobiliary disease, especially cirrhosis; heart failure; hyponatremia; renal failure; peritonitis; and Budd-Chiari syndrome. *Exudative ascites* can occur secondary to peritoneal infections and peritoneal metastases. Perforation of the GI tract results in the escape of both air and fluid into the peritoneal cavity. In children, the most common causes for ascites are hepatic, renal, and cardiac disease.[17]

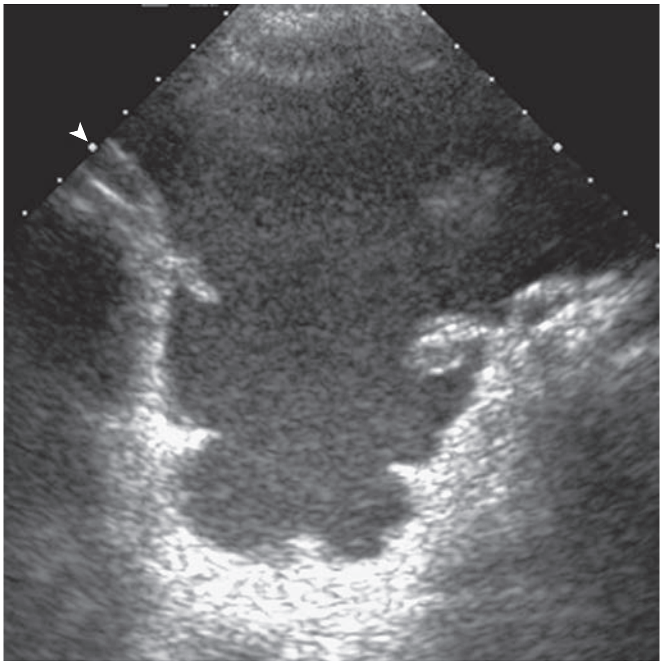

**Figure 86.9. Complex ascites.** Transverse ultrasound image through the deep pelvis in a 6-year-old patient with epithelioid sarcoma demonstrates abundant complex ascites. The thickening of the lateral peritoneal surface indicates peritoneal disease.

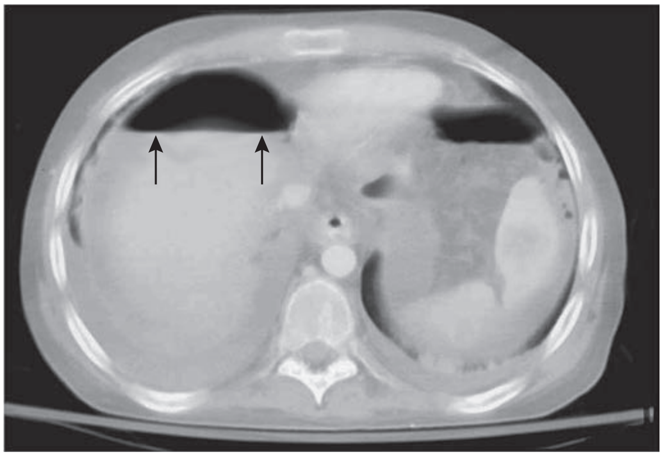
The lesser sac, Morison pouch, paracolic gutters, pelvis, and recesses formed by many of the peritoneal ligaments are all sites where fluid can collect (Fig. 86.9). Typically, small amounts of



**e-Figure 86.7. Hydropneumoperitoneum.** Axial contrast-enhanced CT image at lung-window settings shows hydropneumoperitoneum in a 19-year-old man with relapsed Hodgkin disease who presented with severe abdominal pain. Note air-fluid levels *(arrows)*.

ascites collect in the pelvis when the patient is supine. As the amount of fluid increases, it moves cephalad along the paracolic gutters into the subhepatic spaces and Morison pouch, and it can sometimes be identified in the fossa of the ligamentum teres (e-Fig. 86.10). Ascites eventually spreads through the peritoneal cavity and into the mesenteric recesses (e-Fig. 86.11); in cases of inflammation, loculations may occur. Encysted collections of CSF may be seen adjacent to the tip of a ventriculoperitoneal shunt tube ("CSF pseudocyst"), usually as a result of an inflammatory response around the shunt tube tip entrapping fluid (Fig. 86.12).

***Clinical Presentation.*** The clinical hallmark of ascites is abdominal distension, which in itself is a nonspecific sign. The clinical findings are in part governed by the underlying etiology. Early satiety and dyspnea can be seen with increasing accumulation of fluid within the abdominal cavity.[17]

*Abdominal compartment syndrome* is an uncommon sequela of acute accumulation of large-volume ascites or other material that leads to intraabdominal hypertension. Increased pressure in a confined space leads to progressive organ failure with significant associated mortality. It is most commonly described after trauma but can also be seen in the setting of surgery and other entities, such as pancreatitis. The diagnosis is usually made at the bedside with measurement of intravesical pressure.[18] The criteria for diagnosis of abdominal compartment syndrome include elevation of intraabdominal pressure to 20 mm Hg or higher, coupled with impaired function of at least one organ; typically, it affects respiratory or renal function.[19]

***Imaging.*** Diagnosis of ascites is usually made based on clinical history, physical examination, and aspirated fluid analysis. Imaging is usually performed to confirm clinical ascites; estimate its volume; identify loculations, septations, or internal echoes; or to assist in sampling or draining of ascitic fluid.

Abdominal radiographs are only sensitive to large amounts of intraperitoneal fluid. In such cases, the gas-filled bowel loops will appear centrally located within the abdomen (Fig. 86.13). Separation of bowel loops may also occur as a result of ascites, but this appearance can be simulated by large amounts of intraluminal fluid or thick-walled bowel loops (e-Fig. 86.14).[20]

US is an extremely sensitive imaging modality for ascites.[21] Simple ascites appears as anechoic fluid and can be seen in the various peritoneal recesses.[22,23] Septations, loculations, and internal echoes usually suggest complex fluid, which can be seen in the setting of blood, chyle, inflammatory cells, or peritoneal metastases (see e-Fig. 86.14). Ascites occasionally will pass through the esophageal hiatus or patent pleuroperitoneal canals to present as intrathoracic fluid.[24]

CT is equally sensitive to detect ascites, although it does not visualize internal septations, which are easily seen on US. Because of radiation exposure, CT is not the first-line modality in the evaluation of ascites.

*Abdominal compartment syndrome* is suggested on CT by a ratio of anteroposterior to transverse diameters of the abdomen exceeding 0.81 (e-Fig. 86.15).[19] However, abdominal measurements on a single CT scan may be nonspecific, because an increased anteroposterior abdominal dimension may be seen with chronic ascites. Other telling findings include an elevated diaphragm, the presence of hemoperitoneum, increasing girth on serial examinations, attenuated inferior vena cava or renal veins, and shock bowel. Although not specific, a combination of these findings in the appropriate clinical setting or worsening on sequential imaging studies should raise the possibility of abdominal compartment syndrome.[18]

***Treatment.*** The course, prognosis, and treatment of ascites depend entirely on the cause. Drainage of the ascitic fluid can usually provide symptomatic relief; however, in most cases treatment is aimed at the underlying disorder. The treatment for abdominal compartment syndrome includes emergent drainage or decompressive laparotomy. The mortality rate in abdominal compartment syndrome remains high, at approximately 60% to 70%.[18]

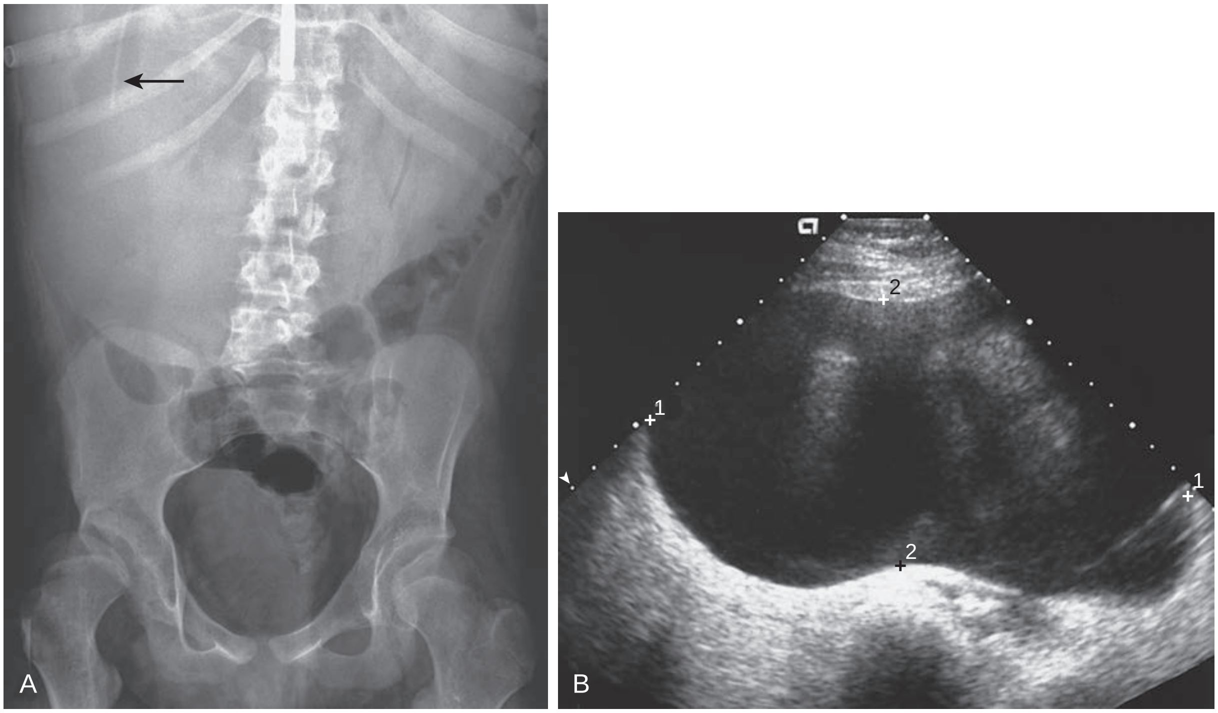


**Figure 86.12. Cerebrospinal fluid pseudocyst.** (A) Abdominal radiograph demonstrates a large soft tissue mass that occupies the entire upper abdomen, especially the right abdomen. The tip of a ventriculoperitoneal shunt is seen in the right upper quadrant *(arrow).* (B) Transverse sonogram through the upper abdomen confirms a large cystic mass surrounding the tip of the shunt.

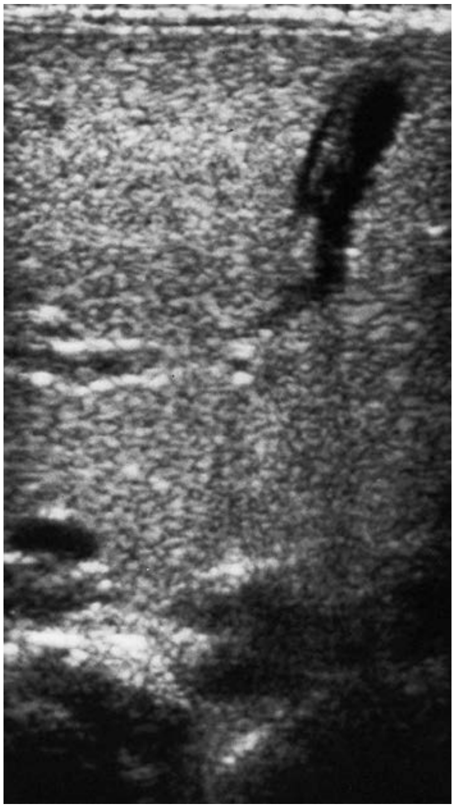
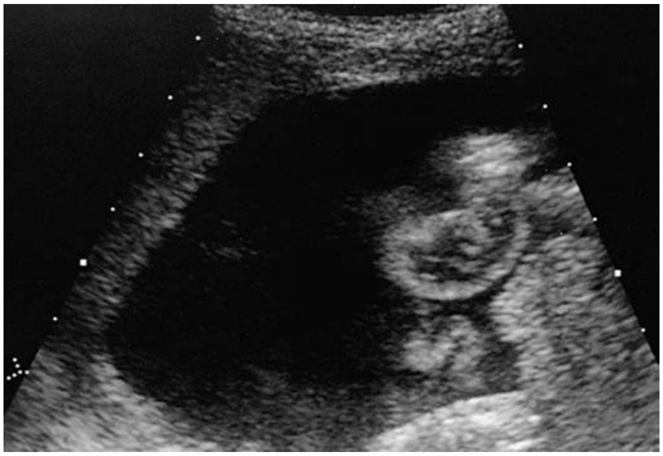
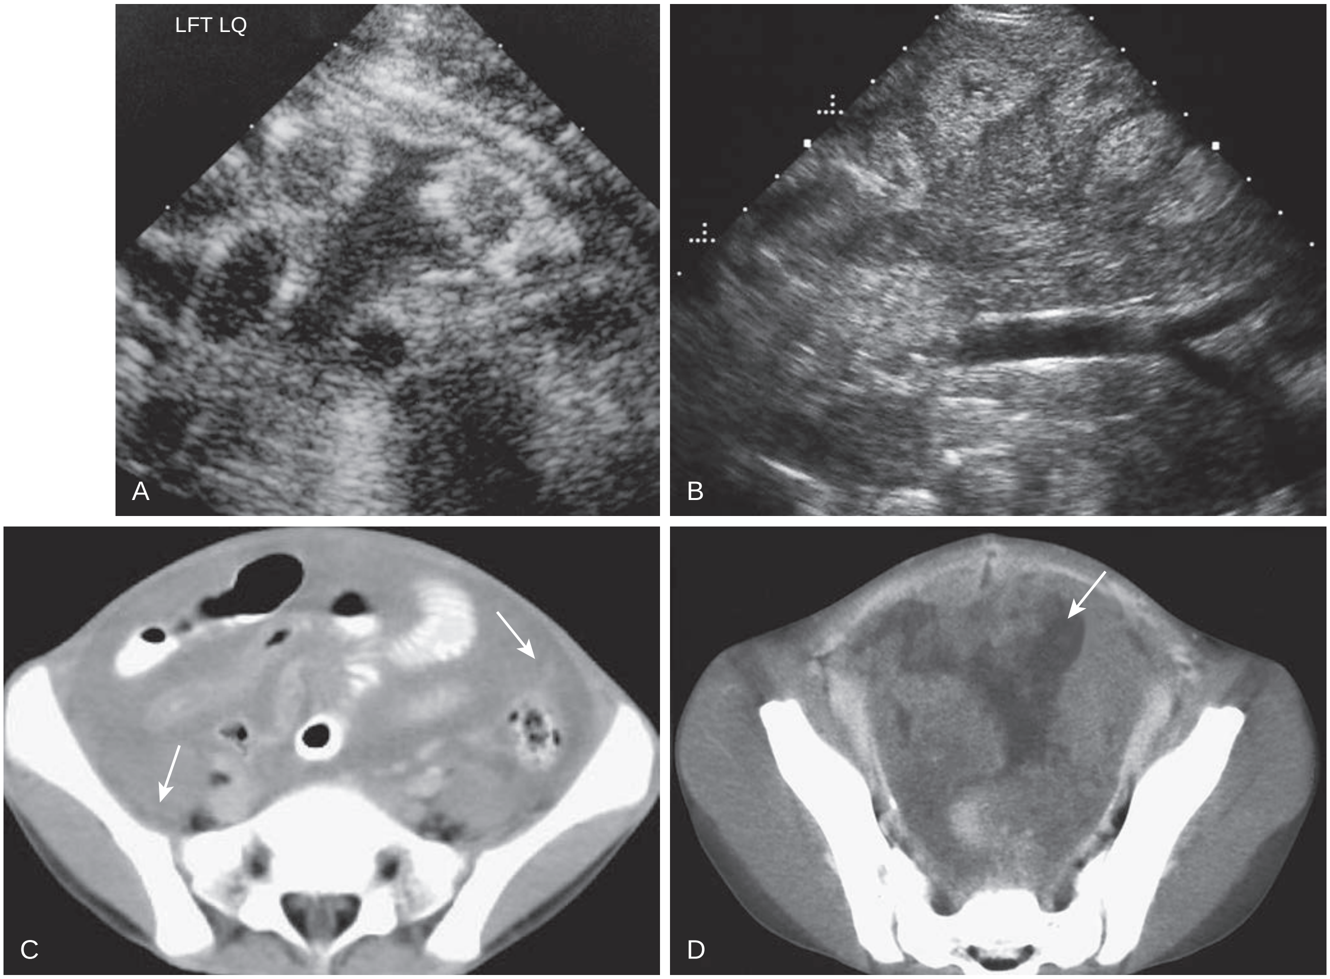


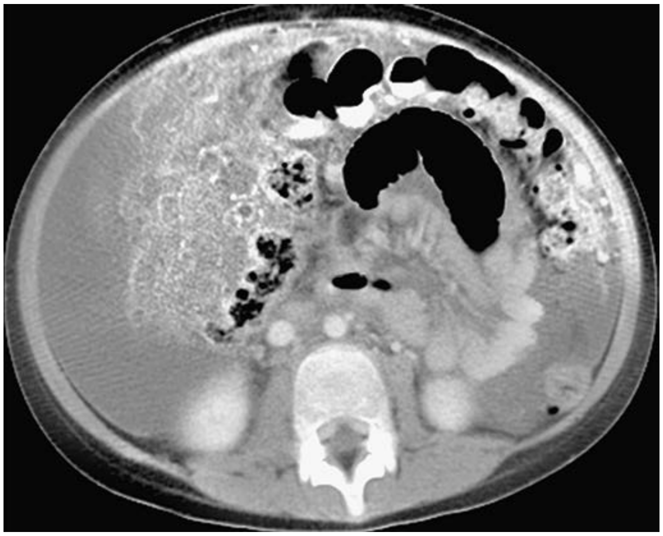
**e-Figure 86.10. Ascites.** Oblique sonogram through the liver demonstrates ascitic fluid in the fissure of the ligamentum teres. The ligament and the obliterated umbilical vein can be seen within the fluid collection.



**e-Figure 86.11. Ascites.** Transverse sonogram through the left lower quadrant demonstrates anechoic ascitic fluid that outlines thick-walled loops of intestine in a patient with graft-versus-host disease after bone marrow transplantation.



**e-Figure 86.14. Complex peritoneal fluid.** (A) Transverse sonogram through the left lower quadrant of a 1-year-old boy with disseminated intravascular coagulation and thrombocytopenia after surgery for congenital heart disease. Fluid separates multiple loops of bowel and is not completely anechoic as in simple ascites. Rather, it contains some internal echoes. Paracentesis confirmed hemorrhage. (B) Peritoneal mesothelioma in a 7-year-old boy who had been treated with whole-abdomen radiation therapy at age 3 for non-Hodgkin lymphoma. Coronal ultrasound through the midabdomen shows echogenic material surrounding and displacing small bowel loops, which are also hyperechoic. (C) Axial contrast-enhanced CT image through the same area shows ascites and peritoneal soft tissue densities and masses *(arrows)*. (D) Axial contrast-enhanced CT through the pelvis shows intense peritoneal enhancement and numerous soft tissue masses *(arrow)*.



**e-Figure 86.15. Abdominal compartment syndrome.** Axial contrast-enhanced CT image in a 6-year-old with abdominal epithelioid sarcoma has an increased ratio of the anteroposterior to transverse diameters of the midabdomen measuring 0.84, consistent with abdominal compartment syndrome.

## Peritonitis

***Overview.*** Peritonitis is a generalized or localized inflammatory process that affects the peritoneum. Acute generalized peritonitis is usually of infectious etiology and can be further subclassified as primary and secondary. *Primary peritonitis*, also called *spontaneous bacterial peritonitis*, is a primary infection of the peritoneal cavity that does not result from spread from the visceral organs. *Secondary peritonitis* results from secondary infection of the peritoneum, usually from urogenital or GI sources, particularly perforation.[25] Abscesses may develop locally and at sites where fluid is likely to accumulate. The subhepatic and subphrenic spaces are common distant sites for abscess formation.

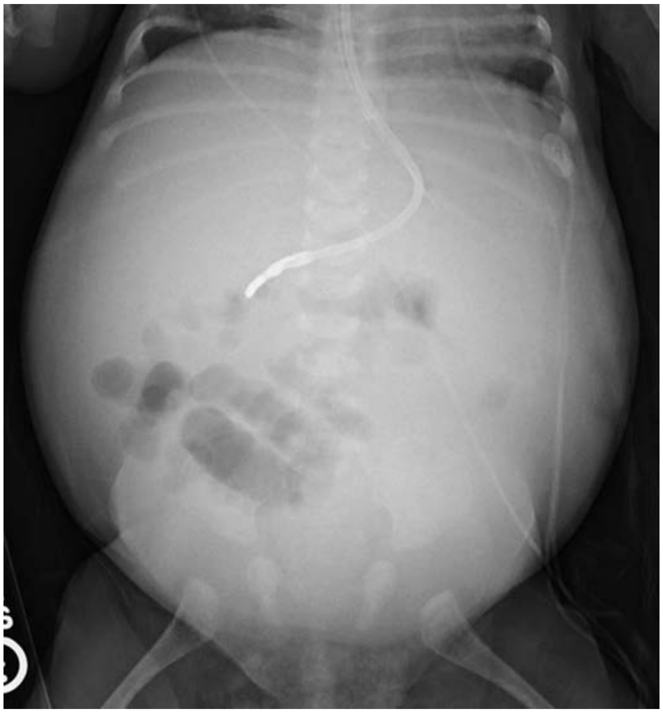


**Figure 86.13. Ascites on plain radiograph.** Anteroposterior views of the abdomen in a neonate with severe nephrotic syndrome. Abdominal distension is noted with bulging flanks, and loops of gas-containing intestine are seen floating in the center of the abdomen.

***Etiology.*** *Primary peritonitis* may occur spontaneously in patients without underlying pathology, and it is usually seen in association with postnecrotic cirrhosis and nephrotic syndrome.[25] Access of organisms to the peritoneal cavity through the fallopian tubes is another putative cause of this condition, supported by the increased occurrence in patients with intrauterine contraceptive devices.[25]

*Secondary peritonitis* in children is most commonly caused by a perforated appendix. Other causes of bowel perforation that could potentially result in secondary peritonitis include IBD, incarcerated hernias, complications of Meckel diverticulum, midgut volvulus, intussusception, hemolytic uremic syndrome, necrotizing enterocolitis, typhlitis, and traumatic perforation.[17] Peritoneal dialysis is another cause of peritonitis in children and is the most common cause of dialysis failure.[26]

*Granulomatous peritonitis* is usually associated with infectious etiologies such as tuberculosis, histoplasmosis, or pneumocystosis, most often in immunocompromised hosts. Involvement of the peritoneum occurs in approximately 4% of patients with tuberculosis[27] but is reported to occur in 10% of children aged less than 10 years.[28] Noninfectious causes for granulomatous peritonitis include foreign material, such as talc and barium, meconium, bowel contents, bile, or gallstones.[2] *Meconium peritonitis* is a sterile peritonitis that results from prenatal perforation of the bowel; this is discussed in Chapter 102.

***Clinical Presentation.*** Patients usually come to medical attention with fever (≥39.5°C), diffuse abdominal pain, nausea, and vomiting. Signs of peritoneal inflammation on physical examination include rebound tenderness, abdominal wall rigidity, and decreased or absent bowel sounds from a paralytic ileus.[17] Patients with infectious granulomatous peritonitis secondary to histoplasmosis or pneumocystosis are nearly always immunocompromised.[2]

***Imaging.*** Abdominal radiographs in patients with peritonitis often show a nonspecific, adynamic ileus pattern with dilated bowel, multiple intraluminal air-fluid levels, and evidence of ascites; in addition, the properitoneal fat plane may be obliterated (e-Fig. 86.16). US may demonstrate intraperitoneal fluid with internal echoes and septations, and abscesses are identified as focal collections of mixed echogenicity.

CT demonstrates enhancement of the peritoneal lining with associated dense ascites (Fig. 86.17). Abscesses appear as focal fluid collections with relatively high attenuation values and densely enhancing walls (Fig. 86.18). On magnetic resonance imaging

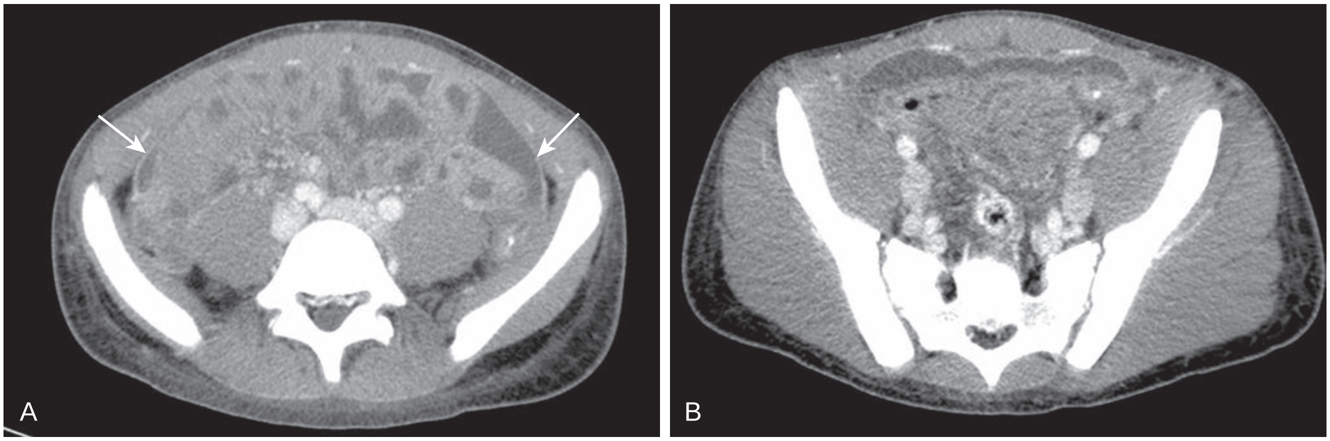

**Figure 86.17. Peritonitis.** (A) Axial contrast-enhanced CT image in a 14-year-old boy with perforation occurring after severe retching after a Heller myotomy shows low-attenuation fluid within the pelvis and between bowel loops. The peritoneal lining is enhancing *(arrows)* consistent with a clinical diagnosis of peritonitis. (B) Image caudal to (A) shows similar findings.

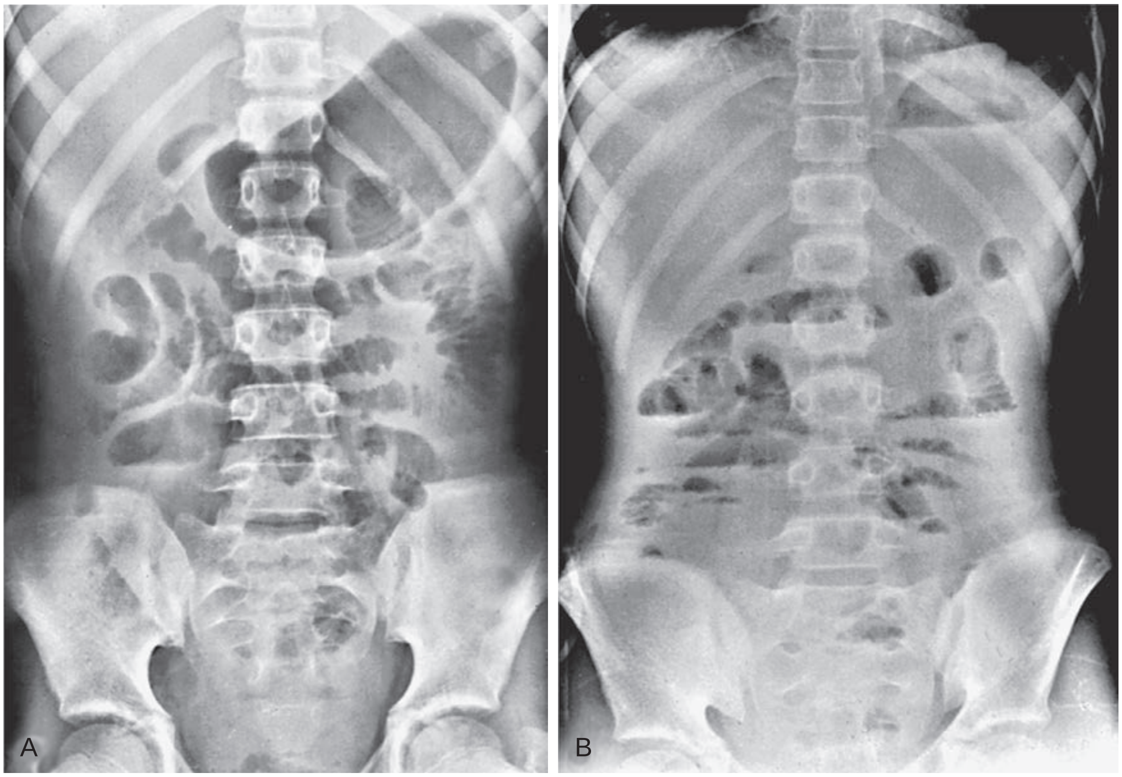

**e-Figure 86.16. Peritonitis.** (A) Supine abdominal radiograph in a teenage patient with purulent peritonitis shows gas-filled loops of small intestine that are mildly dilated and separated from one another, suggestive of ascites. (B) Upright view of the same patient shows multiple scattered air-fluid levels throughout the peritoneal cavity in a pattern concerning for ileus.

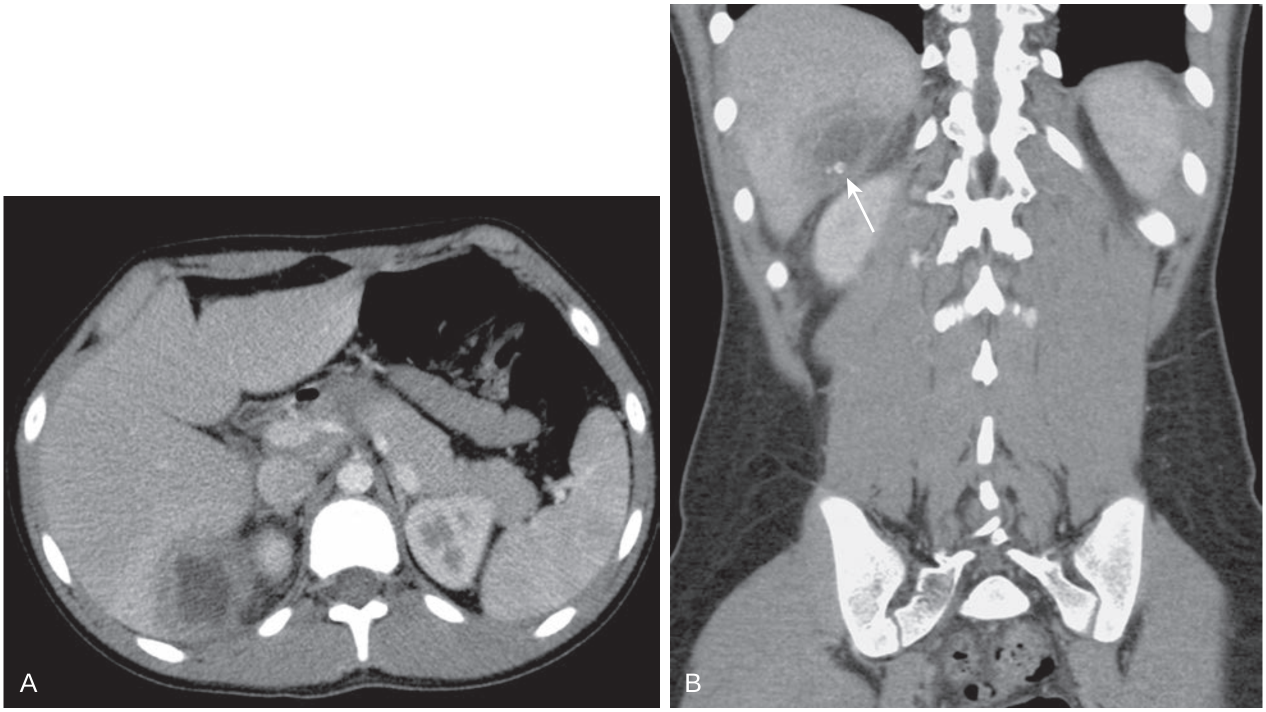

**Figure 86.18. Ruptured appendicitis with intraabdominal abscess.** (A) Axial contrast-enhanced CT image in a patient with perforated appendicitis shows an irregular, thick-walled, peripherally enhancing abscess adjacent to the right lobe of the liver. (B) Coronal reformat reveals the location of the mass in the subhepatic/parahepatic region. In addition, two hyperdense foci are seen *(arrow)* within the mass, most consistent with appendicoliths.

(MRI), abscesses in the peritoneum show similar findings as elsewhere, with high internal T2 signal and dense peripheral enhancement. Both gallium citrate- and indium-labeled white blood cells have been used as scintigraphic agents in the diagnosis of abscesses, although these are rarely used.

*Granulomatous peritonitis* is secondary to a spectrum of lesions, as previously discussed. *Peritoneal tuberculosis* has been subdivided into three overlapping subtypes—a wet type; a fibrotic type; and a dry, plastic type—with decreasing ascites and increasing soft tissue components along the spectrum.[2,28] The wet type is the most common and is characterized by ascites, which on CT is often (but not always) of high density[2,28,29] with free or localized fluid collections (Fig. 86.19). Dry plastic or fibrotic fixed patterns are characterized by a relative lack of ascites and a variable amount of peritoneal and omental nodules and masses, peritoneal adhesions, and fibrotic fixation of the small bowel and mesentery as the predominant features.[2] Omental involvement is usually seen as diffuse, infiltrating, ill-defined enhancing lesions that produce a "smudged" appearance of the omentum (see Fig. 86.19). The findings in tuberculosis are indistinguishable from those in histoplasmosis.[2] Although no single CT feature is diagnostic of peritoneal tuberculosis, additional imaging features that help in diagnosis include concomitant central, low-attenuation lymph node enlargement, miliary microabscesses in the liver or spleen, splenic or lymph node calcification, and inflammation that involves the terminal ileum and cecum.[29,30]

***Treatment.*** The treatment of peritonitis includes correction of the underlying etiology and supportive therapy. General supportive measures include vigorous intravenous rehydration, correction of electrolyte disturbances, and infection control. Early control of the infection can be achieved medically, operatively, and through image-guided percutaneous interventions.

## Abdominal Wall and Peritoneal Calcification

***Overview.*** Abdominal wall calcification is uncommon in infants and children. The etiology depends upon the location of the calcification (skin, muscles, soft tissue, or peritoneum) and on the age of the patient. Most causes of intraabdominal calcification are related to specific organs, and these are discussed in the appropriate chapters.

***Etiology.*** Fat necrosis is one of the causes of abdominal wall calcification in neonates and infants.[31] Although there are many causes of fat necrosis, the majority are associated with neonatal asphyxia, sepsis, gestational diabetes, and hypothermia.[32] Older children with hypothermia, hepatic failure, and renal failure may also experience subcutaneous fat necrosis.[31]

Abdominal wall calcification may be seen in fibrodysplasia ossificans progressiva and in myositis ossificans, but are more common in the thoracic wall. Calcifications secondary to dermatomyositis are more likely to be in the extremities than in the trunk, but calcifications can be found in the abdominal wall. Subcutaneous hemangiomas may contain phleboliths. Abdominal wall calcification in infants has also been described after subcutaneous emphysema and in prune-belly syndrome.[33]

The most common cause of peritoneal calcification in the neonate is meconium peritonitis,[34] discussed in Chapter 102. Peritoneal calcification in older children is rare. Intestinal perforation with subsequent peritonitis may cause calcification. Other causes include granulomatous peritonitis, peritoneal dialysis (Fig. 86.20), calcification along surgical scars, hyperparathyroidism, and peritoneal malignancies such as ovarian adenocarcinoma.[34]

***Clinical Presentation.*** Clinical presentation is strongly dependent on the underlying cause. Subcutaneous fat necrosis appears clinically as firm, erythematous plaques. Patients may develop hypercalcemia, particularly when involvement is extensive.[35]

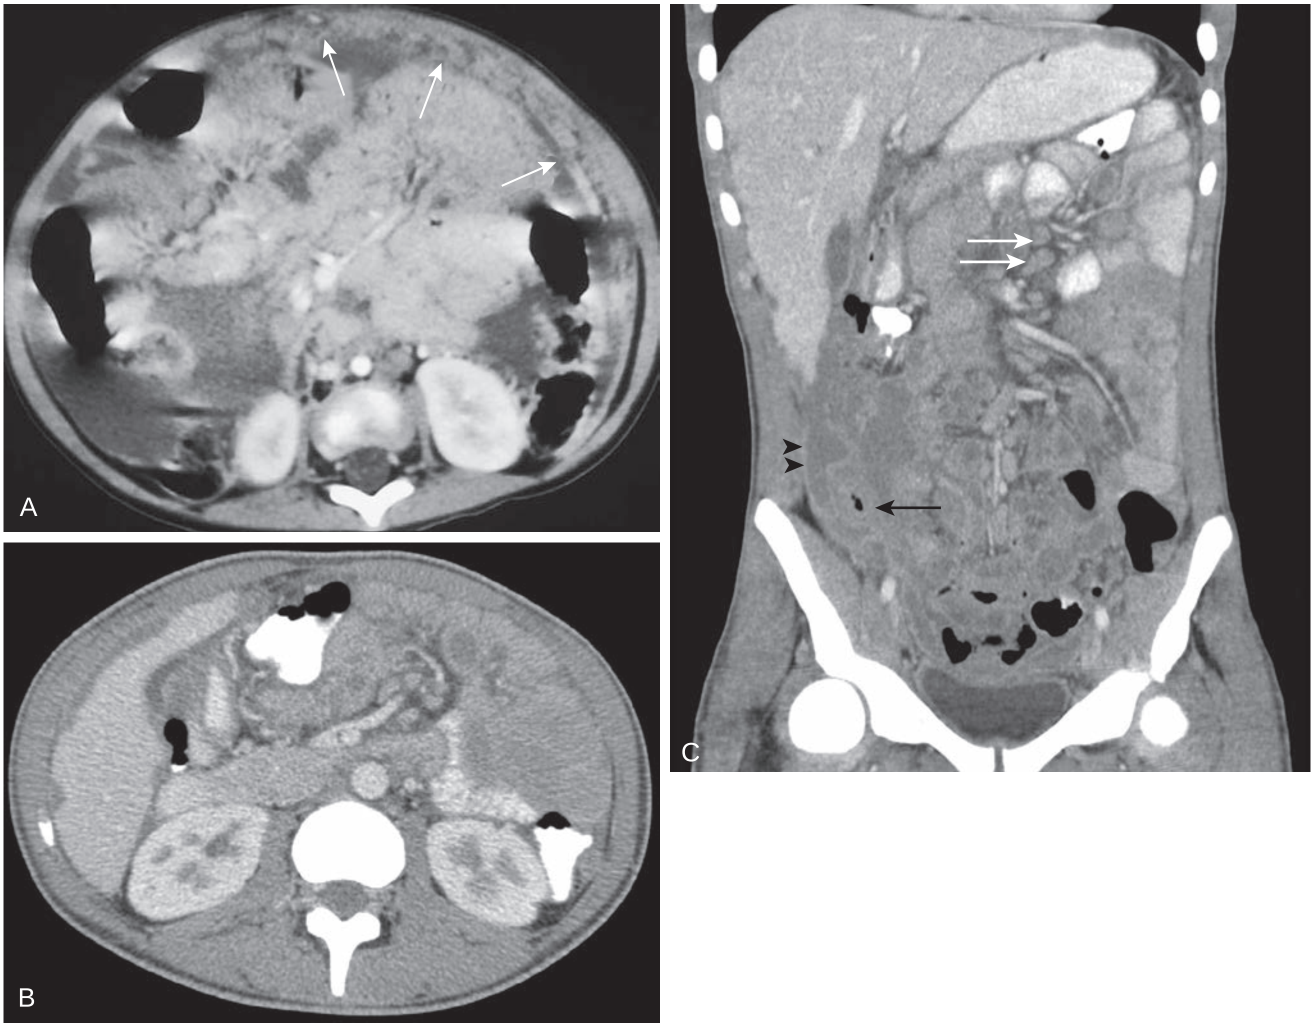

**Figure 86.19. Peritoneal tuberculosis subtypes.** (A) Contrast-enhanced CT image shows a 14-month-old girl with a large amount of ascites displacing bowel loops centrally, and studding of the peritoneal surface *(arrows)*. This is an example of wet type peritoneal tuberculosis. (B and C) Axial and coronal contrast-enhanced CT images demonstrate dry plastic or fixed fibrotic manifestation of peritoneal tuberculosis in a different patient. Note the relative lack of free fluid, with loculated fluid collections scalloping the anterior liver surface and along the right peritoneal cavity *(arrowheads)* causing adhesions of the bowel *(black arrow)*. Omental and mesenteric nodules *(white arrows)* were biopsied laparoscopically and demonstrated necrotizing caseating granulomas.

***Imaging.*** Most abdominal wall and peritoneal calcifications are detected incidentally on plain radiographs and/or CT scans obtained for other clinical indications. Shape of calcifications, location, and correlation with any predisposing condition may help identify the underlying etiology. Peritoneal calcification associated with calcified lymph nodes is significantly more likely to be associated with malignancy, whereas a sheetlike appearance of peritoneal calcification is associated more frequently with benign disease (see Fig. 86.20).[34]

## ANTERIOR ABDOMINAL WALL ABNORMALITIES

***Overview.*** Anterior abdominal wall defects encompass a variety of conditions, most commonly omphalocele and gastroschisis. *Omphalocele* refers to a midline defect larger than 4 cm that typically contains both gut and the liver and may or may not include other abdominal organs. It has a covering bilayer membrane consisting of the peritoneum as the inner layer and the amnion as the outer layer, with Wharton jelly in between (Fig. 86.21A).[36] It is differentiated from the less common *umbilical cord hernia* in that the latter is less than 4 cm, does not contain liver, has a normal abdominal wall, and has few associated anomalies. *Gastroschisis* is a defect located lateral to the umbilical cord insertion, most commonly to the right, with no covering membrane (Fig. 86.21B), and typically containing gut without abdominal organs although a gonad may occasionally protrude. Unlike all of the previously mentioned defects, an umbilical hernia is not associated with gut malrotation, is covered by skin, and usually becomes apparent several weeks after birth.[37]

### Omphalocele

***Overview.*** Omphaloceles are the second most common anterior abdominal wall defect (gastroschisis is the first), with a prevalence of approximately 1 to 5 in 10,000 live births. It is more common in boys.[36,37]

***Etiology.*** An omphalocele forms when fusion fails in the lateral folds of the body wall, the rectus muscles fail to meet in the

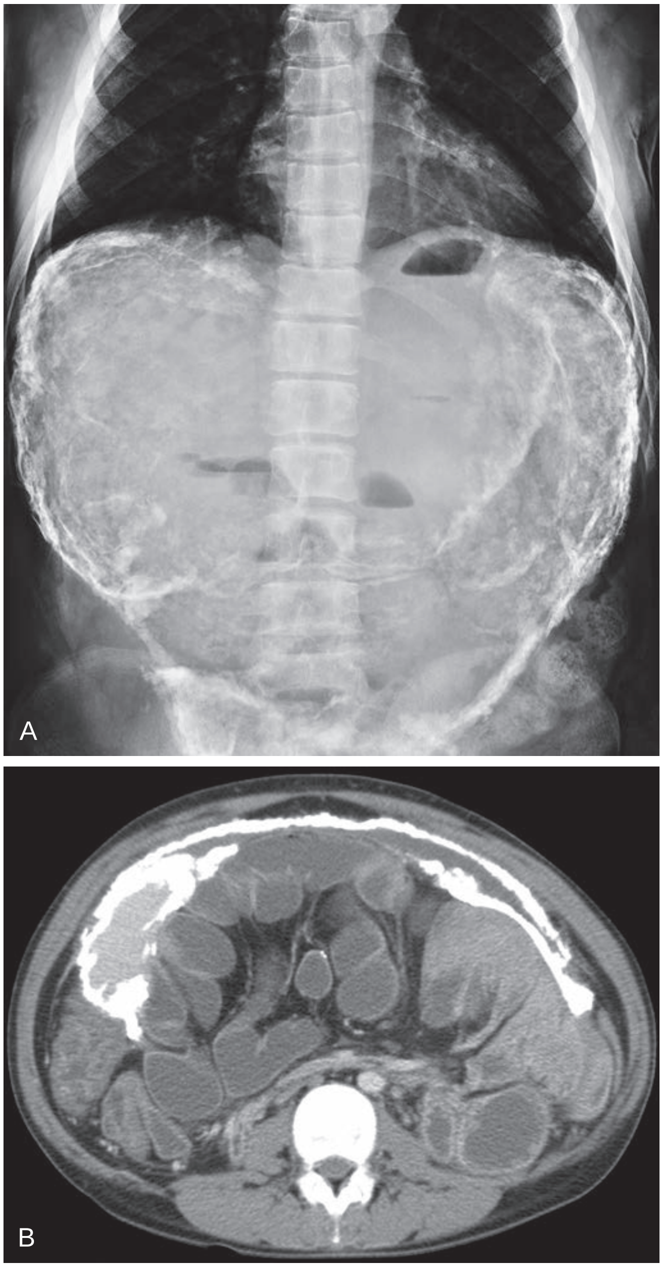

**Figure 86.20. Peritoneal calcifications from dialysis.** (A) Abdominal radiograph in a patient with a history of peritoneal dialysis shows diffuse peritoneal calcifications. Sheetlike calcifications tend to be benign. (B) Axial contrast-enhanced CT image is a patient with chronic peritoneal dialysis causing adhesions and small bowel obstruction, also known as *sclerosing peritonitis*. Notice the dilated bowel loops and the calcified, loculated effusion.

midline, and the herniated bowel fails to return into the peritoneal cavity, with the umbilical cord inserting into the covering membrane (see Figs. 86.21 and 86.22).[36,37] Involvement of the cephalic folds results in the spectrum of pentalogy of Cantrell: midline supraumbilical abdominal wall defect, defect in the diaphragmatic pericardium, deficiency of the anterior diaphragm resulting in herniation of the heart, congenital intracardiac abnormalities, and sternal clefts (e-Fig. 86.23).[36,38] Failure of caudal fold development results in cloacal exstrophy.

***Clinical Presentation.*** Associated anomalies are present in 50% to 70% of cases. Chromosomal anomalies, primarily trisomies, occur in 40% to 60%.[39] Smaller defects, absence of liver in the sac, and abnormal amounts of amniotic fluid are associated with an increased incidence of other anomalies, and 50% of these patients have congenital heart disease. Omphaloceles are also associated with Beckwith-Wiedemann syndrome and omphalocele–bladder exstrophy–imperforate anus–spinal defect complex.[39] Intrauterine growth retardation and prematurity commonly coexist.[36]

***Imaging.*** Diagnosis is usually made on antenatal US. Antenatal evaluation includes assessment of umbilical cord insertion, presence or absence of a covering membrane, contents of the omphalocele, and coexisting anomalies.[40] Multiple associated anomalies indicate a poorer prognosis, as do oligohydramnios and polyhydramnios.

***Treatment.*** Definitive treatment is surgical and may consist of primary closure or a staged procedure. If primary closure is not possible, the sac may be covered with nonadherent dressings to prevent trauma to the sac and exposure of the underlying bowel until delayed closure is possible.[36,37]

## Gastroschisis

***Overview.*** For unclear reasons, the prevalence of gastroschisis has been rising over the past three decades, particularly in infants born to young mothers,[36,37,41] with a prevalence of approximately 2 to 5 per 10,000 live births.[42] Gastroschisis is not usually associated with chromosomal abnormalities or congenital anomalies outside of the GI tract. Complex gastroschisis results when associated GI complications are present.[43]

***Etiology.*** The etiology of gastroschisis remains uncertain, but it is postulated to result from ischemia to the paraumbilical abdominal wall causing its involution. The defect occurs much more commonly on the right. This may be related to mistiming of the involution of the right omphalomesenteric artery and right umbilical vein, with herniation of the bowel through the defect.[36] A vascular genesis of the defect is supported by reported incidence of cases of maternal use of vasoactive compounds, such as cocaine and cigarettes.[44]

***Clinical Presentation.*** Infants with gastroschisis are typically born prematurely. At birth, the bowel may appear normal, but soon after, it may be covered with fibrinous exudates.[37] The maternal α-fetoprotein level is elevated because lack of a covering membrane allows the bowel loops to be exposed to the amniotic fluid. The incidence of associated anomalies is approximately 10% to 20%. Most involve the GI tract[45] and include antenatal perforation, necrosis, atresia, and volvulus.[37,46]

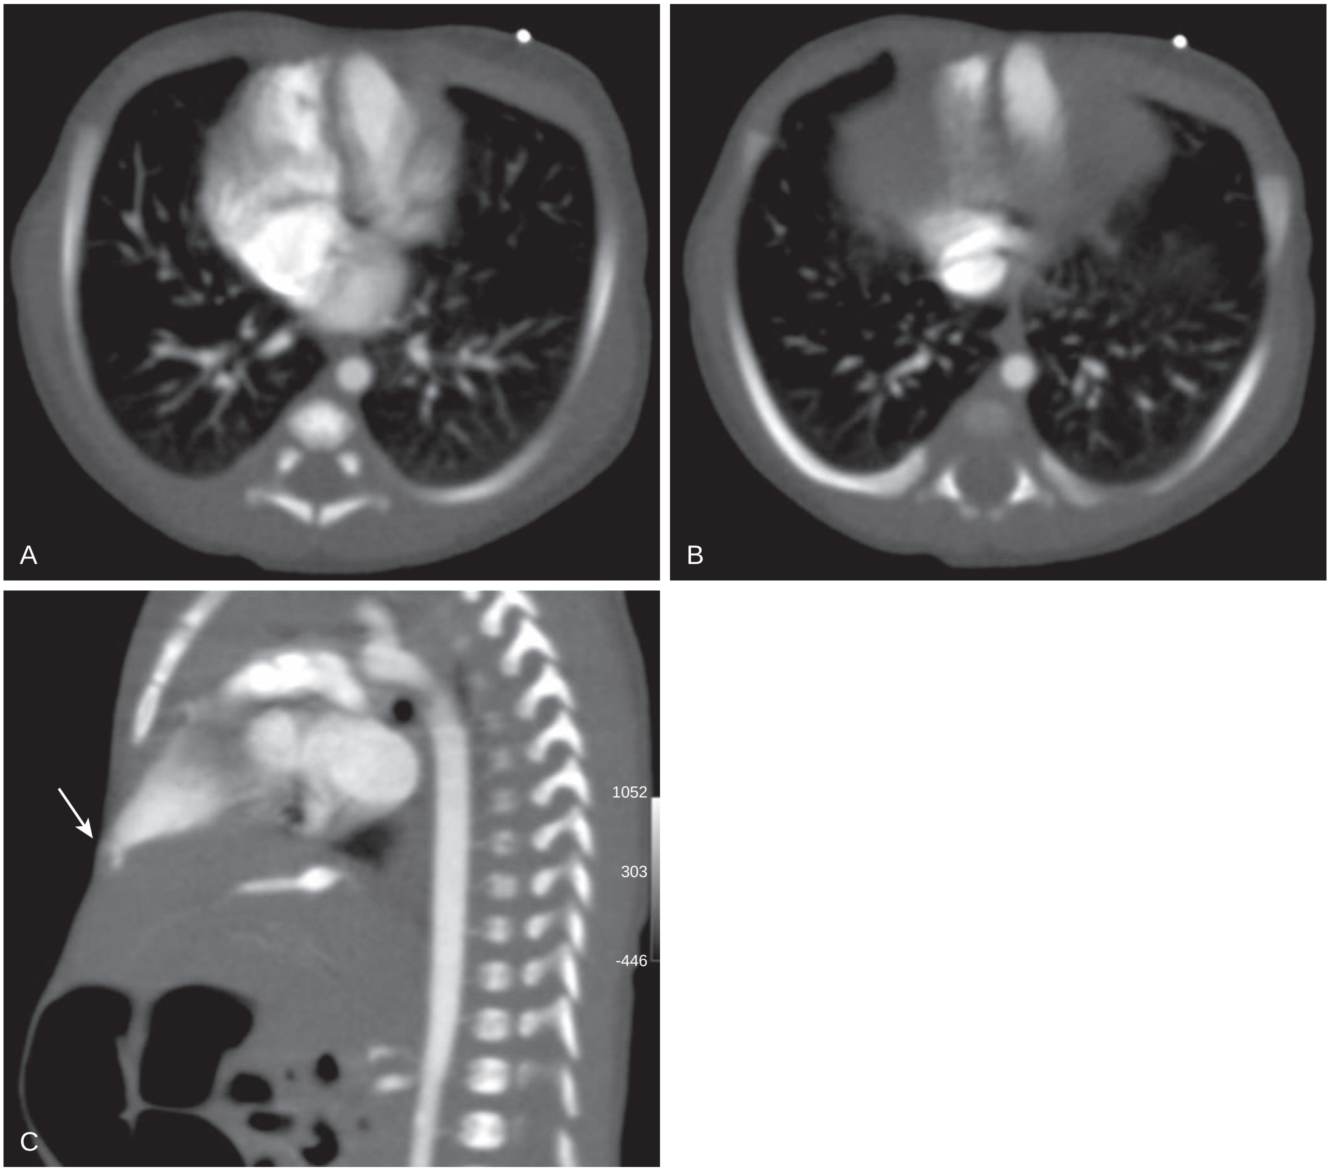
***Imaging.*** On prenatal US, gastroschisis is characterized by a normal umbilical insertion, a defect located adjacent to the umbilicus, most commonly on the right, and absence of a covering sac, which can result in an apparent lobulated contour of the herniated bowel loops (e-Fig. 86.24 and see Figs. 86.21B and 86.25). Dilatation of the bowel loops on prenatal imaging has been found to correlate with complex gastroschisis, with poorer survival and increased morbidity.

***Treatment.*** In the immediate postnatal period, close attention to heat preservation and fluid balance is important, because the large surface area of the exposed bowel leads to heat and fluid loss. Rapid coverage of the exposed bowel is a priority and may be accomplished with a silastic silo bag. The defect itself may need to be surgically enlarged if the bowel is at risk of vascular compromise.[36] Whenever possible, surgery as soon as possible after delivery is advocated.[37]

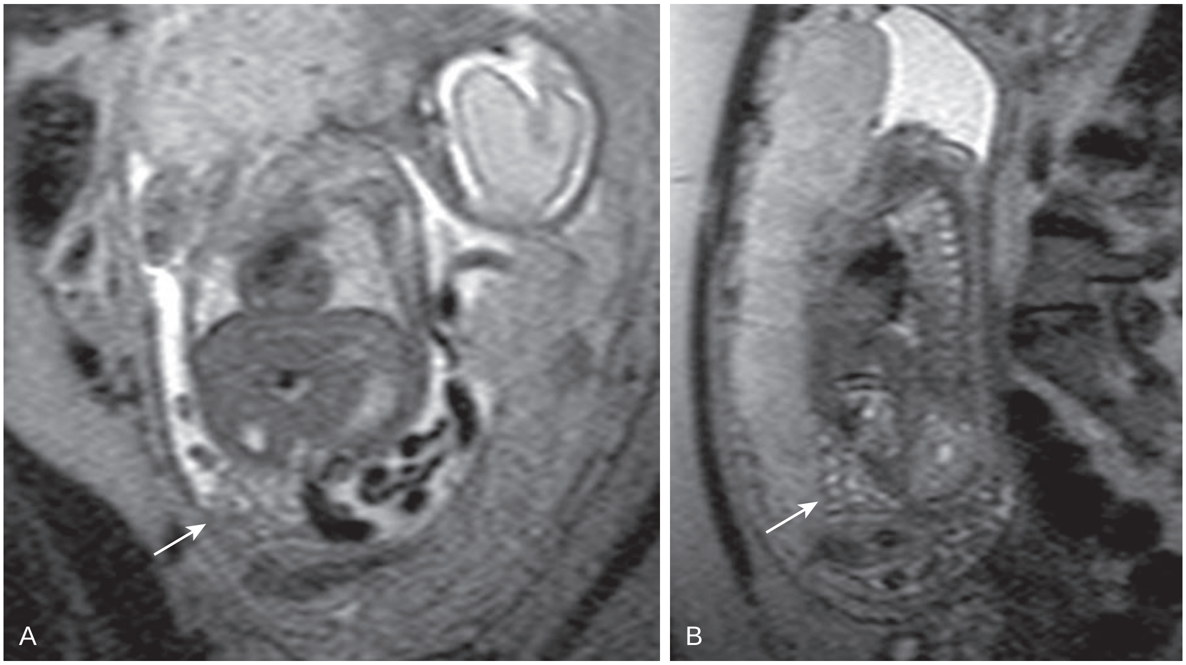
## Omphalomesenteric Duct and Urachal Remnants

### Omphalomesenteric Duct Remnant

***Overview.*** *Omphalomesenteric duct remnant* refers to a variety of conditions that range from a Meckel diverticulum to ligamentous and umbilical abnormalities (Fig. 86.26).



**e-Figure 86.23. Pentalogy of cantrell.** Neonate with an inferior sternal defect and protrusion of anterior abdominal wall with deficient epigastric abdominal wall musculature. (A and B) Axial contrast-enhanced CT images show a midline heart with a left ventricular diverticulum. (C) Sagittal reformat demonstrates the herniating left ventricular diverticulum to better advantage *(arrow)*. *(Courtesy of Marta Hernanz-Schulman, MD, Nashville, TN.)*



**e-Figure 86.24. Gastroschisis.** Coronal (A) and sagittal (B) images from a fetal MRI examination show meconium-filled bowel loops *(arrows)* freely floating in the amniotic fluid outside the abdominal cavity in a 26-week fetus with gastroschisis.

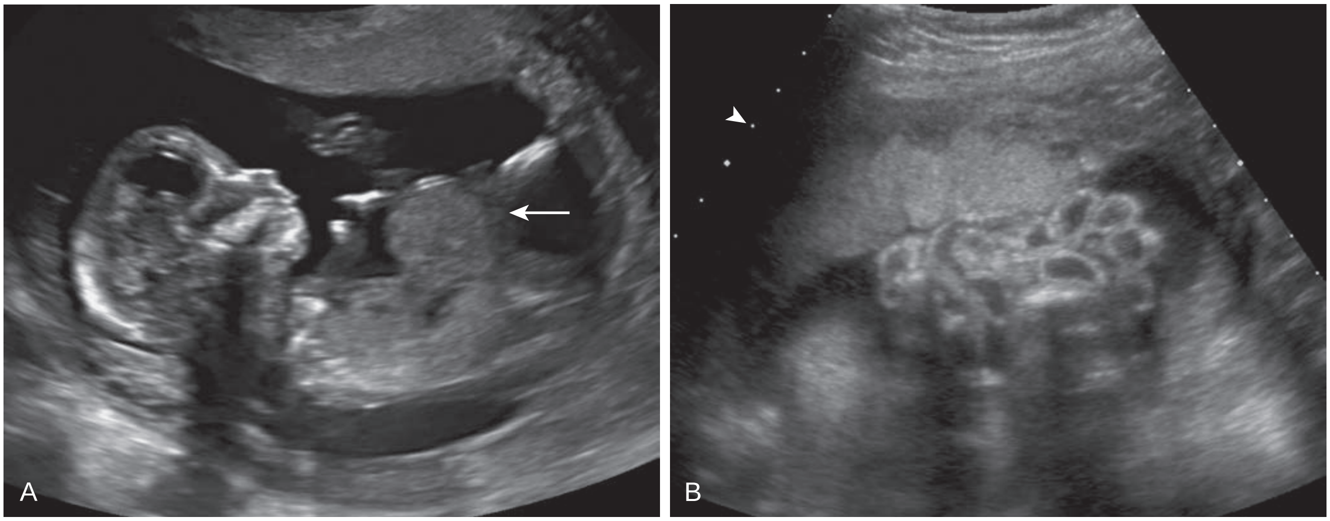


**Figure 86.21. Omphalocele versus gastroschisis.** (A) Prenatal sonogram of an omphalocele demonstrates a covered midline abdominal wall defect at the base of the umbilical cord insertion *(arrow)*. The herniated defect contains liver and bowel loops. (B) Prenatal sonogram of gastroschisis show mildly dilated bowel loops free-floating in the amniotic cavity. Besides the location adjacent to the umbilical insertion, the lobulated contour of the herniated bowel contents (versus smooth contours in omphalocele) is another clue.

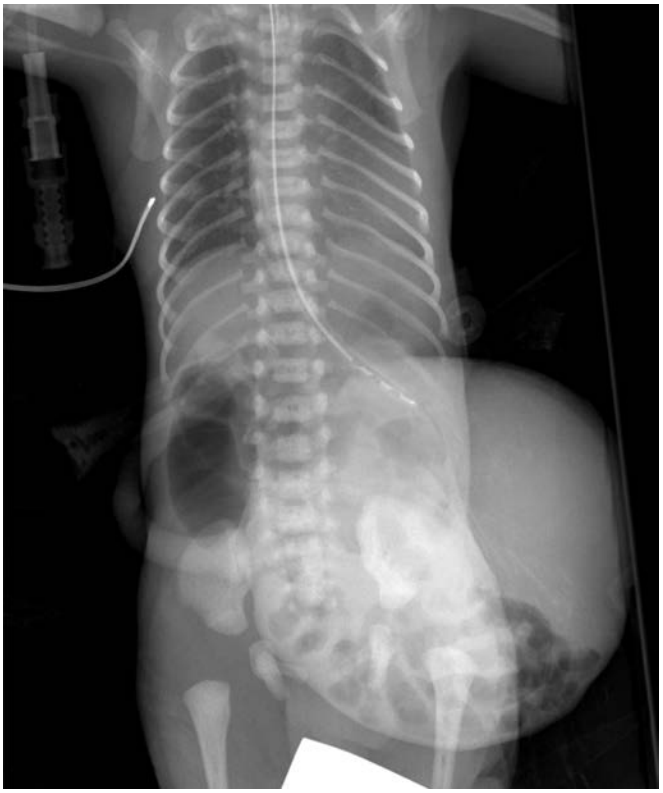

**Figure 86.22. Omphalocele.** Frontal radiograph of the chest and abdomen in a neonate shows a large anterior wall defect covered by a membrane and containing the liver, which is well visualized adjacent to air-filled and mildly distended bowel loops. The umbilical cord inserts on the omphalocele.

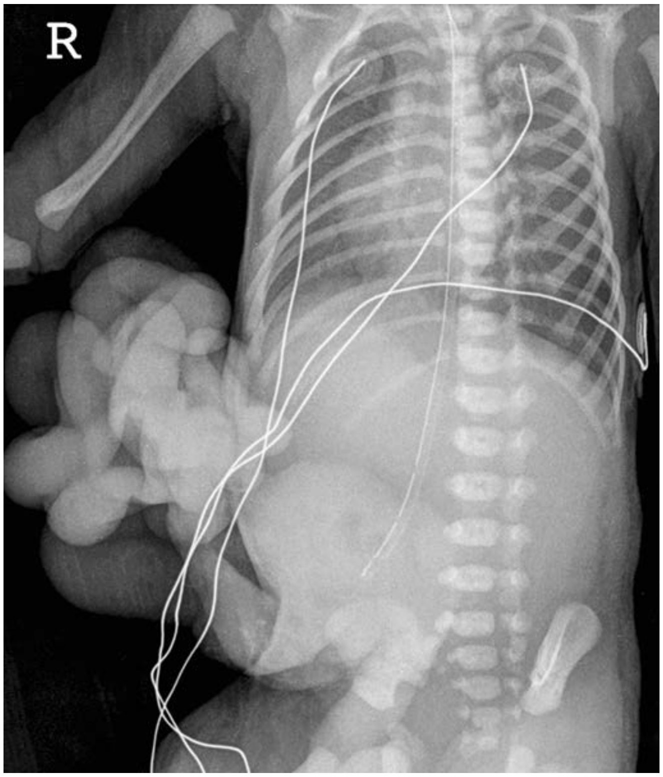

**Figure 86.25. Gastroschisis.** Frontal radiograph of the chest and abdomen of a newborn shows bowel loops outside the abdominal cavity. The bowel loops are not covered by a membrane, and the defect is to the right of the insertion of the umbilical cord into the anterior abdominal wall.

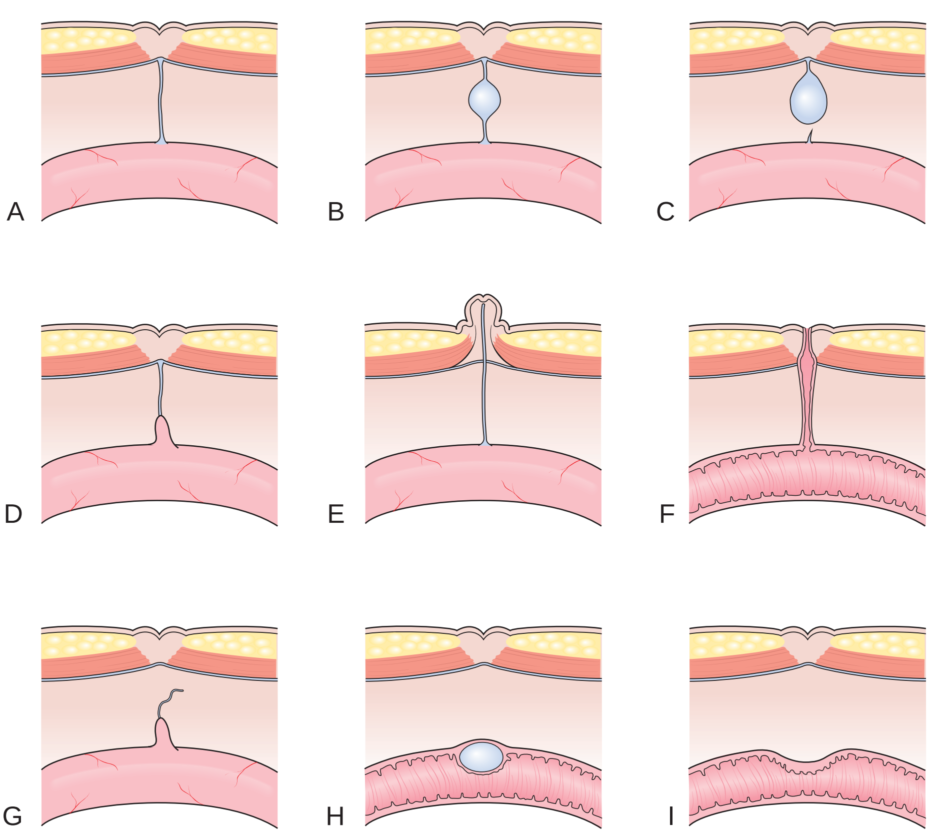

**Figure 86.26. Variants of omphalomesenteric duct remnants.** (A) Persistent cord between the ileal wall and the closed umbilicus. (B) Cyst in the same cord. (C) Cyst anchored at the umbilical end of the cord but free at the ileal end. (D) Meckel diverticulum attached to the closed umbilicus by a closed cord. (E) Everted mucocele of the umbilicus with the cord attached to the ileal wall. (F) Fecal fistula open at both the umbilical and ileal ends. (G) Meckel diverticulum open at the ileal end but blind at the umbilical end, which is unattached. (H) Intramural cystic diverticulum. (I) Local stenosis of the ileum at the site of the mouth of the omphalomesenteric duct. *(From Cullen TS.* Embryology, anatomy and diseases of the umbilicus, *Philadelphia: Saunders; 1916.)*

***Etiology.*** The *omphalomesenteric duct*, also called the *vitelline duct*, connects the primitive midgut, the future ileum, to the yolk sac remnant; normally, it obliterates during the fifth to seventh week of embryonic development. However, if this process does not proceed normally, a spectrum of abnormalities may ensue. Closure of the duct with failure of complete involution results in a ligamentous remnant. Failure of duct closure has been subdivided into three general categories.[47] In a *type 1 abnormality*, the entire duct is open. A *type 2 abnormality* refers to a duct that is open at one end but ends blindly at the other; when open at the ileal end, it represents a *Meckel diverticulum* (see Chapter 102). A *type 3 abnormality* refers to a focal patency along the duct that becomes a cyst.

***Clinical Presentation.*** Patients with a type 1 abnormality present with fecal material draining from the umbilicus. Patients in whom the duct is open only along the umbilical end are seen with discharge from the umbilicus that consists of secretions produced by the lining of the tract. A type 3 abnormality, or *vitelline duct cyst*, is often asymptomatic but may become infected, in which case it can manifest with acute symptoms. Omphalomesenteric duct remnants or attachments may also lead to mechanical bowel obstruction.

***Imaging.*** In a type 1 abnormality, contrast injected through the umbilicus passes directly into the ileum (Fig. 86.27). In a type 2 defect, contrast injection reveals a blind-ending sinus tract of varying length. Imaging over the palpable abnormality in a type 3 defect may demonstrate a simple or complex cystic mass on US or other cross-sectional imaging. These may also be discovered as incidental findings.

***Treatment.*** Management depends on the clinical presentation. Definitive treatment is surgical with resection of the omphalomesenteric duct remnant.[48]

## Urachal Remnant

***Overview.*** The urachus connects the bladder to the allantois; when normally obliterated, it becomes the median umbilical ligament. In a manner analogous to the omphalomesenteric duct, the urachus can be open throughout its course from the bladder to the skin surface at the umbilicus. Alternatively, a portion of the urachus can be open as a blind-ending sinus, from either the dome of the bladder, as a vesicourachal diverticulum, or from the umbilicus, as an umbilicourachal sinus, which is seen in approximately 15% of cases. If only the midportion remains patent, it is known as a *urachal cyst*, seen in approximately 30% of cases.[49]

***Etiology.*** Urachal remnants result from failure of obliteration of a portion of or the entire embryonic urachus.

***Clinical Presentation.*** Periumbilical discharge is the most common presenting complaint, whether due to leaking urine in a fully patent urachus or intermittent discharge from an umbilicourachal sinus.[50,51] Patients may also present with symptoms of an infected urachal remnant. Vesicourachal diverticula, although

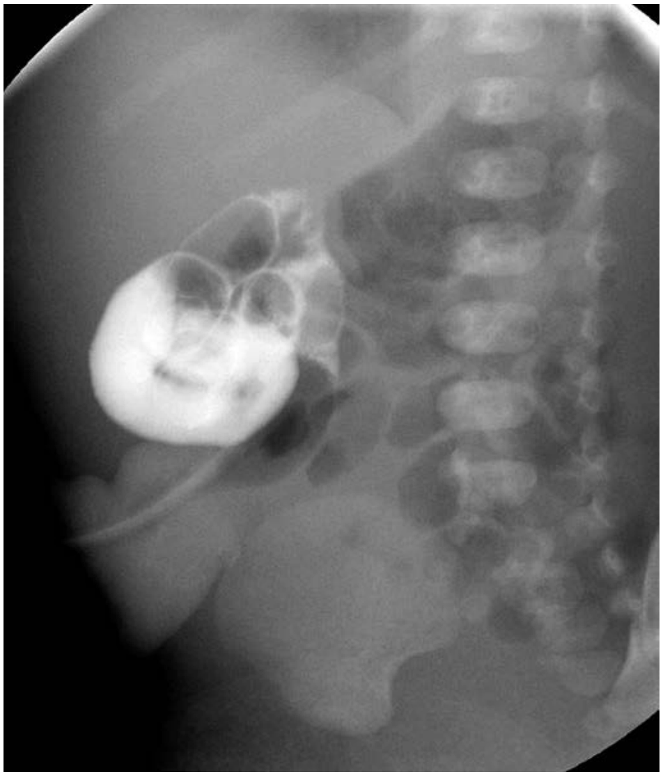

**Figure 86.27. Patent omphalomesenteric duct remnant.** Neonate with history of discharge from umbilicus and bowel loops prolapsed into umbilicus. Oblique view of the abdomen from a gastrointestinal study demonstrates contrast flowing from patent omphalomesenteric remnant into small bowel loops. *(Image courtesy of Geetika Khanna, MD, MS.)*

typically asymptomatic, may serve as a reservoir for stone formation or for development of malignancy in adulthood.[49,52] Other urologic abnormalities—such as hypospadias, posterior urethral valves, or urethral atresia—have been reported in a few cases.[49,53]

***Imaging.*** US is a good initial diagnostic test of choice, followed by CT if unsuccessful.[50,51] The patent urachus may be seen as a fluid-filled tubular structure that extends from the anterosuperior aspect of the bladder to the umbilicus (e-Fig. 86.28). The vesicourachal diverticulum appears as an extension of the anterosuperior bladder, often found in patients being imaged for prune-belly syndrome.[49] An urachal cyst is seen as a well-circumscribed cyst in the anterior abdominal wall, with mural thickening and increased enhancement if complicated by infection (Fig. 86.29).[54] Voiding cystourethrograms may also be used to demonstrate a patent connection to the umbilicus or fistulogram to demonstrate an umbilical sinus tract.

***Treatment.*** Definitive treatment is surgical, using either an open or laparoscopic technique with complete resection of the urachal remnants. If infection has supervened, this is treated before surgical resection.

## Groin and Pelvic Hernias

***Overview.*** Inguinal hernias may be direct or indirect, depending on their relationship to the inferior epigastric vessels. Direct inguinal hernias, with the hernia sac medial to the epigastric vessels, are acquired rather than congenital, and are uncommon in children. Indirect inguinal hernias, with the hernia sac lateral to the epigastric vessels, are the most common form of inferior abdominal wall herniation. The true incidence of inguinal hernias is difficult to determine, but it ranges from 0.8% to 4.4% in children and is more common in boys.[55] Premature infants are at increased risk of developing inguinal hernia, with an approximate 30% incidence.[56] Patients with bladder exstrophy, Ehlers-Danlos syndrome, or prune-belly syndrome also have an increased incidence.[55]

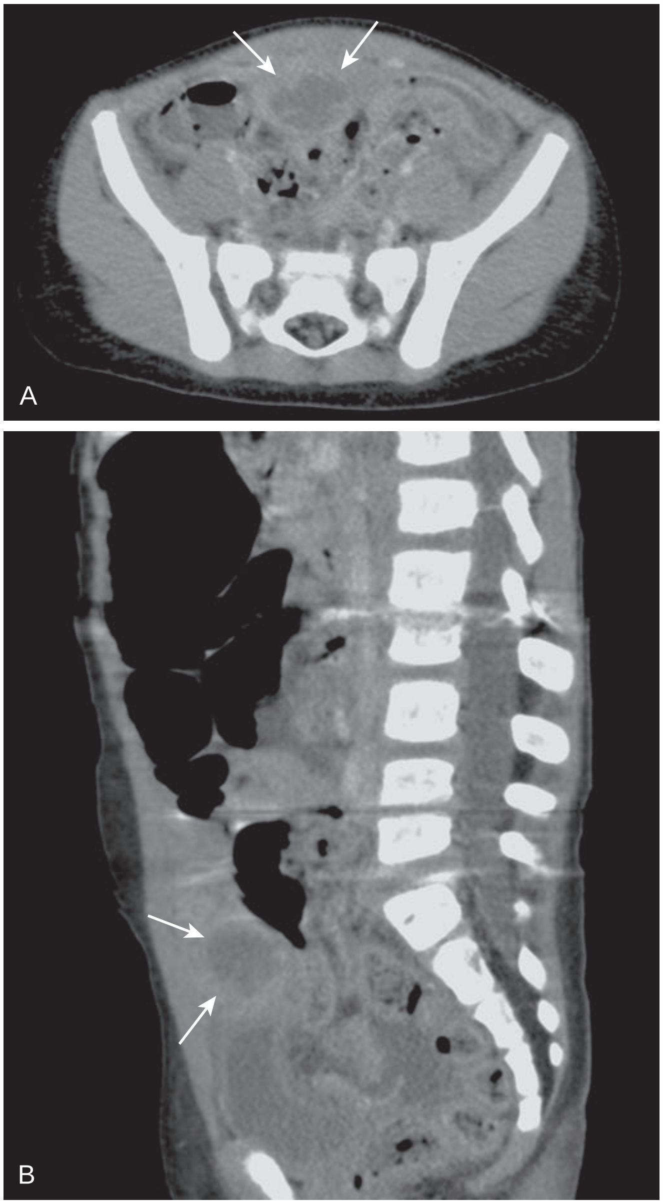

**Figure 86.29. Infected urachal cyst.** (A) Axial contrast-enhanced CT image shows a thick-walled cyst *(arrows)* with surrounding inflammation just superior to the urinary bladder. (B) Midline sagittal reformat shows its location with respect to the bladder and umbilicus to better advantage.

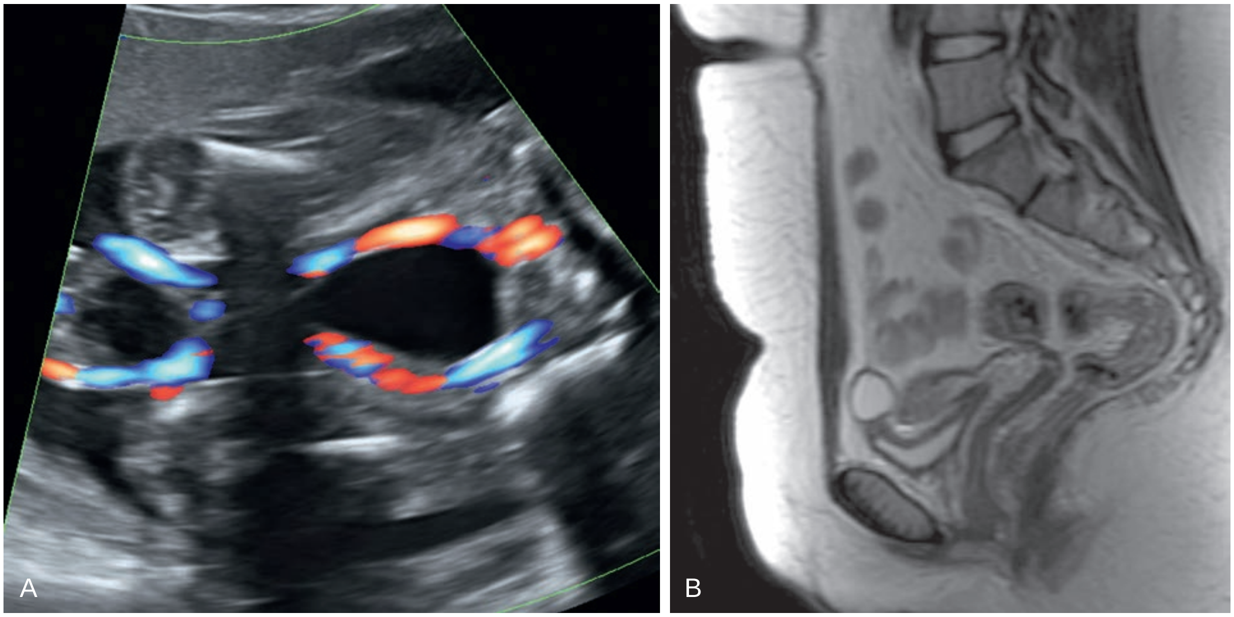
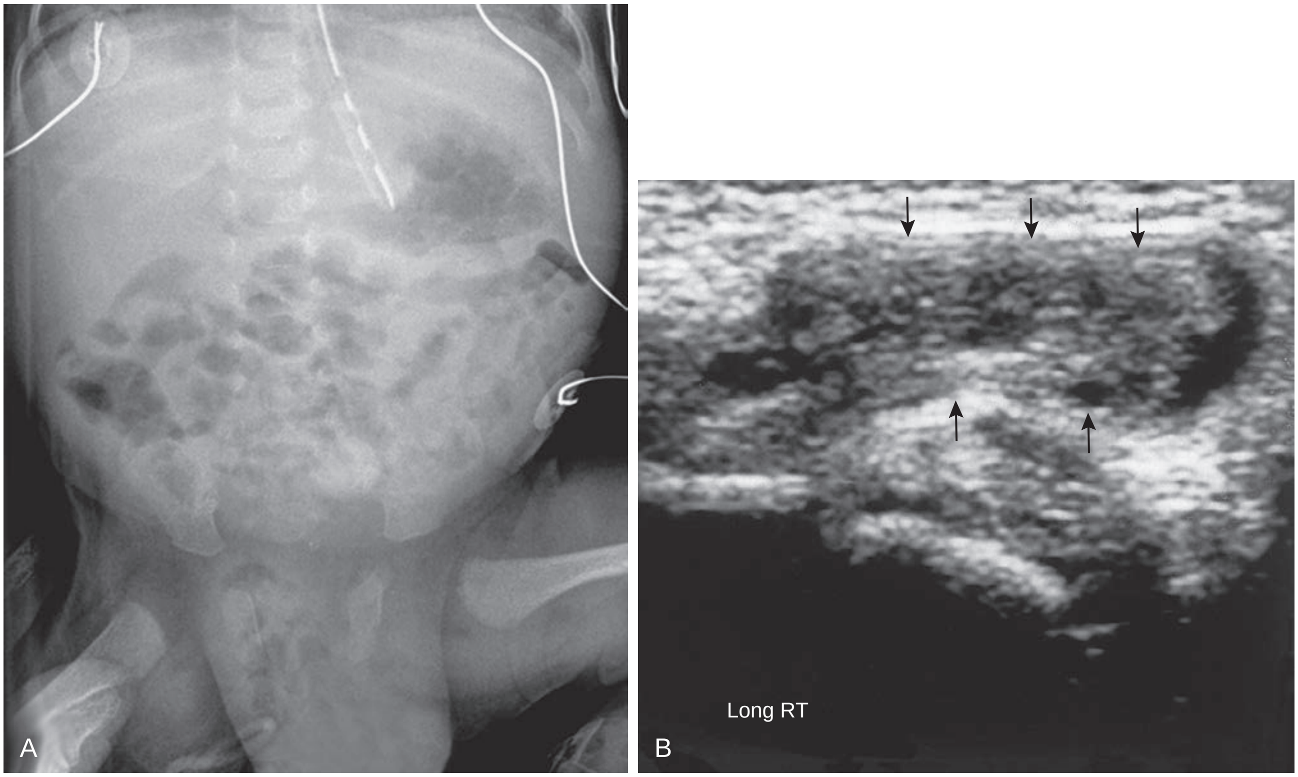
***Etiology.*** The processus vaginalis normally closes between the 36th and 40th weeks of gestation. However, if it remains open, as in indirect inguinal hernias, abdominal contents can herniate through the inguinal ring into the scrotum in boys (e-Fig. 86.30). In girls, abdominal contents or ovaries can herniate through the canal of Nuck into the labia majora (Fig. 86.31).

Although rare in children, femoral hernias, obturator hernias, sciatic hernias, and perineal hernias need to be included in the differential diagnosis of pelvic masses that extend into the buttock or perineum.

***Clinical Presentation.*** Patients usually come to medical attention with an intermittent painless bulge in the inguinal region, scrota,



**e-Figure 86.28. Urachal remnants.** (A) Fetal sonogram demonstrates a large incidental urachal remnant in a 22-week gestational age fetus. The paired umbilical arteries surround the urachal remnant as well as the bladder. (B) Incidental urachal cyst seen on a T2-weighted sagittal MR image. Note the positioning anterior and superior to the bladder in the expected location of the urachus.



**e-Figure 86.30. Inguinal hernia.** (A) Anteroposterior view of the abdomen and pelvis in a newborn boy shows an enlarged scrotum, with multiple air-filled loops of intestine within it, secondary to indirect right inguinal hernia. (B) Ultrasound in the inguinal region of an infant girl with a labial mass confirms a herniated ovary *(arrows)* in the canal of Nuck.

or labia that is noticed when the abdominal pressure rises, such as during crying, straining, or coughing.[55,56] If the bowel loop becomes entrapped or incarcerated in the hernia (e-Fig. 86.32), the patient may exhibit signs and symptoms of bowel obstruction, such as abdominal distension or vomiting. If the hernia is not reduced, the blood supply to the trapped bowel loops may be compromised, leading to bowel necrosis and perforation. Incarceration occurs most frequently in the first 6 months of life.[56]

***Imaging.*** In patients with equivocal clinical findings, US is highly accurate (95%) in demonstrating an inguinal hernia (Fig. 86.33).[57] US can identify the intestinal wall surrounding fluid-filled loops of bowel or may show bubbles of air or peristalsis. Color Doppler US can show blood flow in the wall of the herniated bowel loop. These findings help differentiate a hernia from a hydrocele.

Inguinal hernias may be seen on radiographs as an air-filled loop of bowel in the scrotum (see e-Fig. 86.30), but this is often obscured by gonadal shielding. Herniating bowel loops may be an incidental finding on small bowel series. In contrast enemas for infants with intestinal obstruction, reflux into the small intestine may show a pinched-off loop at the entrance to the inguinal canal.

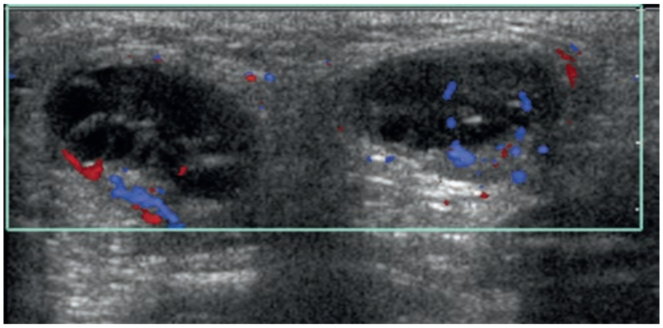


**Figure 86.31. Canal of Nuck hernia.** Transverse ultrasound image through labia majora in a newborn with bilateral palpable labial masses demonstrates ovaries herniated through the canal of Nuck into the labia.

Hernias are well seen on CT (see e-Fig. 86.32) and MRI,[58,59] though these studies are rarely indicated as first-line modalities for diagnosing hernias.

***Treatment.*** The treatment of inguinal hernia is surgery using open or laparoscopic technique.[60]

## BENIGN AND MALIGNANT NEOPLASMS

### Cystic Neoplasms

***Overview.*** Abdominal cystic lesions include lymphatic malformations, lesions related to the bowel such as duplication cysts, and those related to the urogenital system including urachal cysts. The term *mesenteric cyst* has been previously applied to cysts of variable histopathologic origin.[61,62] More recent literature classifies such "mesenteric cysts" based on their histopathologic features, such as lymphatic, mesothelial, enteric, urogenital, or dermoid cysts; mature cystic teratomas; or pseudocysts.[63,64] This section will discuss lymphatic and mesothelial cystic peritoneal lesions.

### Lymphatic Malformations

***Overview.*** *Lymphatic malformations*, formerly known as *lymphangiomas*, are the most common type of vasculolymphatic malformation to affect the peritoneal cavity and mesentery, although they are rare in this region and most commonly occur in the head and neck.[65] Lymphatic malformations have an endothelial lining with walls that contain smooth muscle and lymphatic spaces.[63,66]

***Etiology.*** Lymphatic malformations do not have a clear origin and have been variously postulated to be developmental, congenital, or neoplastic.[67–69] A prevalent hypotheses suggests that they result from the proliferation of abnormal lymphatic channels that do not communicate with the systemic lymphatics.[70]

***Clinical Presentation.*** Lymphatic malformations may be encountered as a palpable abdominal mass—which, if sufficiently large, could be mistaken for ascites—or incidentally during imaging for another reason. They may manifest with small bowel obstruction secondary to acute enlargement of the cyst or segmental volvulus

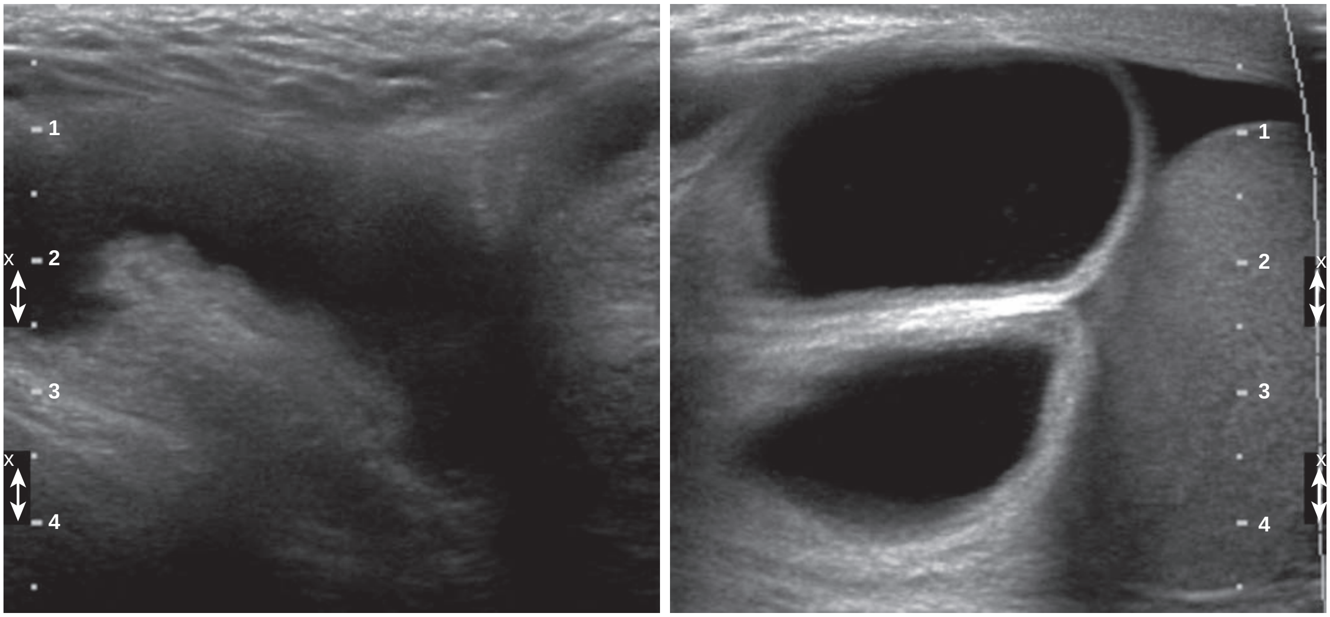

**Figure 86.33. Inguinal hernia.** Composite oblique ultrasound image along the inguinal canal from a scrotal sonogram demonstrates an inguinal hernia that contains moderately distended fluid-filled bowel loops. During real time imaging, the herniated bowel loops demonstrated peristalsis. The normal right testis is seen lower in the scrotal sac.

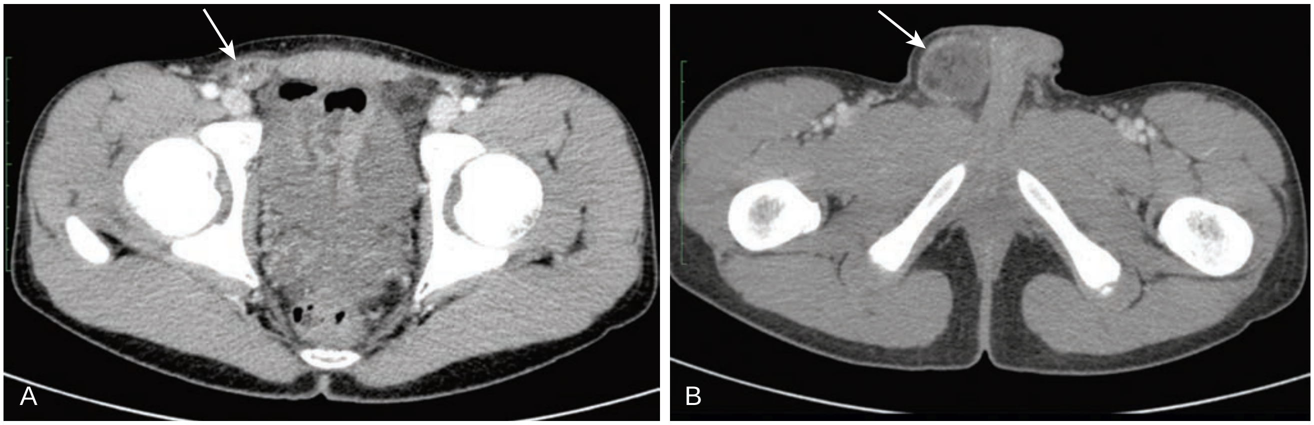

**e-Figure 86.32. Incarcerated inguinal hernia.** (A and B) Sequential axial images from a contrast-enhanced CT demonstrates an incarcerated right inguinal hernia *(arrows)* that contains omentum, with adjacent inflammatory changes *(arrows)*.

of adjacent bowel loops, with symptoms that include abdominal distension, pain, vomiting, and peritonitis or septic shock.[62,65,70,71]

***Imaging.*** On US, lymphatic malformations are typically seen as thin-walled, fluid-filled, single or multiple cysts, often with thin septations.[11] In the presence of hemorrhage or infection, internal echoes may be detected. Ascites, often chylous, can also be present.[65] Despite the internal echoes, Doppler interrogation will reveal no internal flow within the echogenic but cystic component, differentiating it from a solid mass. On real time visualization, movement of the internal echoes can be seen.

CT shows cystic or multicystic lesions with thin or imperceptible walls, and internal septations may enhance as a result of the presence of vascular structures (Fig. 86.34). The CT attenuation of the cyst contents may be lower than water because of their chylous nature.[65,67]

On MRI, lymphatic malformations typically demonstrate low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted sequences.[72] Internal hemorrhage can manifest as increased signal intensity on both T1- and T2-weighted sequences.[72] The peripheral rim and internal septations may enhance, but the majority of the lesion does not enhance and should not enhance centrally.[72] MRI may aid in distinguishing large lymphangiomatous masses that have hemorrhaged from complex intraperitoneal fluid (Fig. 86.35). Cross-sectional imaging

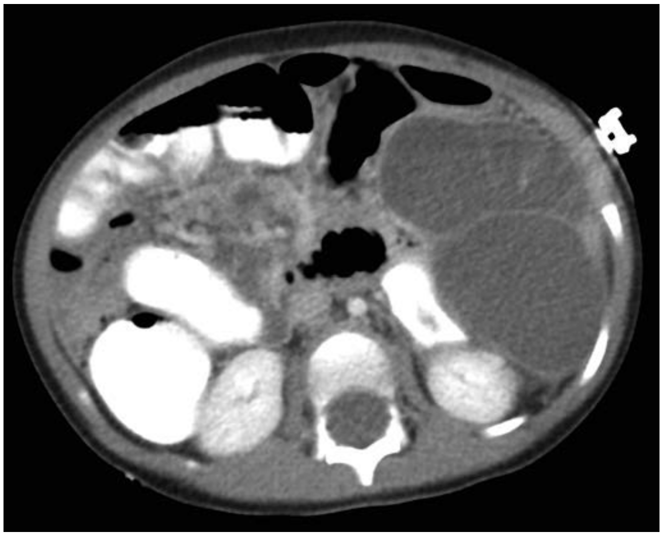

**Figure 86.34. Peritoneal lymphatic malformation.** Axial contrast-enhanced CT image demonstrates a large multiloculated lymphatic malformation in the peritoneal cavity.

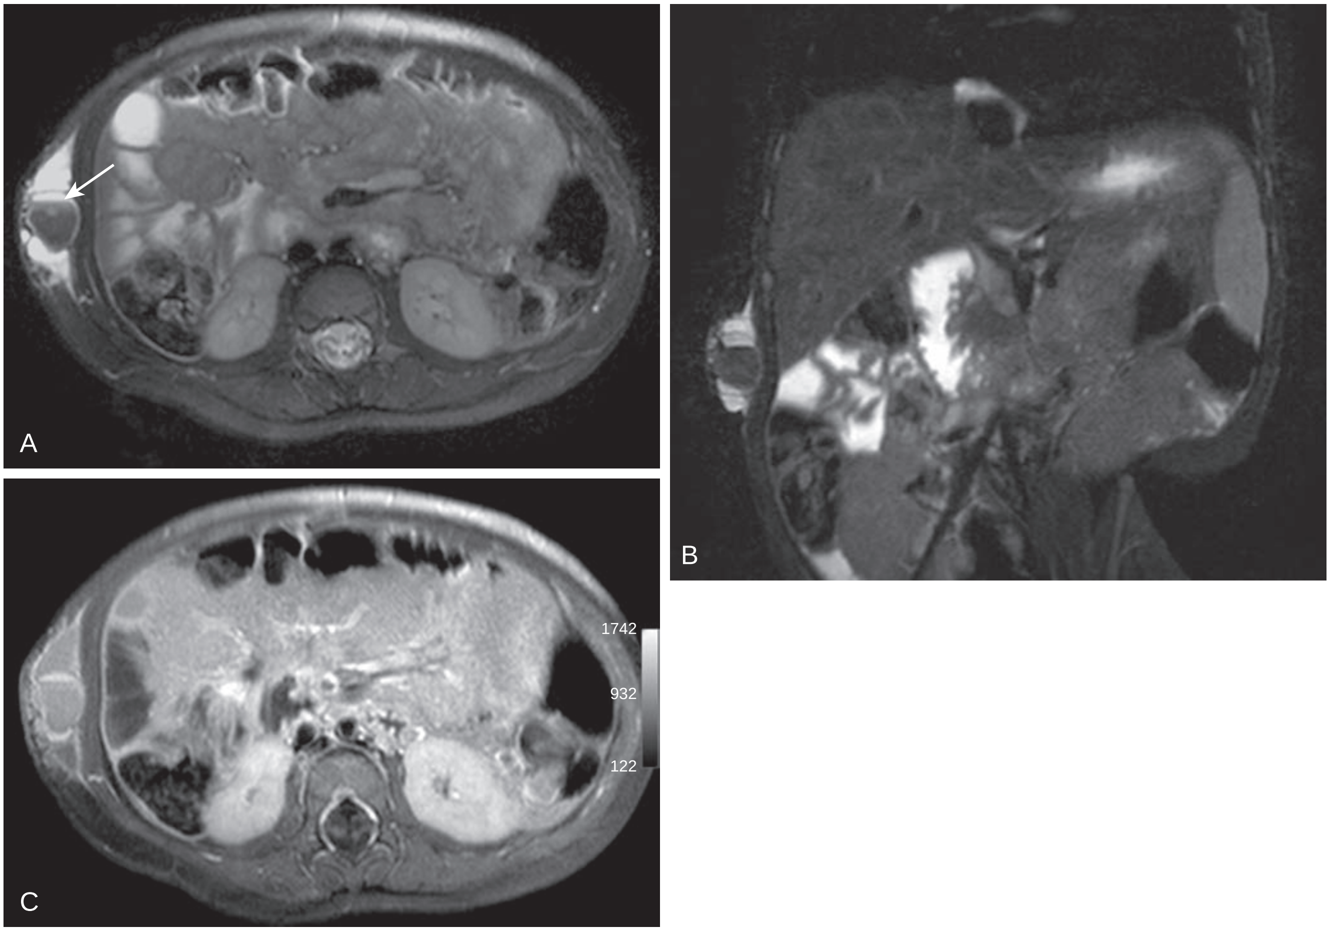

**Figure 86.35. Abdominal wall lymphatic malformation.** (A and B) Axial and coronal T2-weighted MR images with fat saturation in a 16-month-old girl with 2 weeks of localized swelling in the right flank show a multiloculated cystic lesion within the subcutaneous tissues of the abdominal wall with some mass effect upon the underlying musculature. Most of the locules are hyperintense on T2, with a large T2 hypointensity within and a fluid level *(arrow)* consistent with a hematocrit level. (C) After the administration of contrast, T1-weighted, fat-suppressed MR image shows that the septations enhance, but the internal contents do not, which is typical of a lymphatic malformation. No solid components were detected.

is useful to assess the entire extent of the lesion and to define the relationship with adjacent structures.

***Treatment.*** Lymphatic malformations may be treated with sclerotherapy or surgical resection. The decision largely depends on the location and size of the lesion. Staged sclerotherapy and/or surgical resection may be required, particularly with multicentric lesions or lesions that extend into the retroperitoneum. The prognosis is generally good, with a low recurrence rate.[70]

## Cysts of Mesothelial Origin

***Overview.*** Cysts of mesothelial origin include simple mesothelial cysts, benign cystic mesotheliomas, and malignant cystic mesothelioma. Simple cysts are unilocular and are usually 1 to 5 cm in size, whereas benign cystic mesotheliomas are large and multilocular.[63] Mesothelial cysts are lined by flat cuboidal or columnar cells without lymphatic structures; this distinguishes these lesions from lymphatic malformations.[63,66]

Benign cystic mesotheliomas are rare, most commonly arising from the peritoneal surface of the pelvis. This lesion has many alternative names that include *peritoneal inclusion cyst*, *multilocular inclusion cyst*, and *benign multicystic mesothelioma*.[1] Although most commonly found in middle-aged women, it can also occur in children.[1,73–75] Malignant degeneration to peritoneal cystic mesotheliomas has been infrequently described in adult patients.[73,76]

***Etiology.*** The cause of mesothelial cysts remains unclear, although theories postulate developmental, neoplastic, and reactive etiologies. The reactive hypothesis suggests that a stimulus produces chronic irritation that can lead to reactive and loculated proliferation of mesothelial cells, resulting in a cystic fluid collection with mesothelial lining.[72]

***Clinical Presentation.*** Similar to lymphatic malformations, mesothelial cysts can be detected as masses,[66,71] ascites,[76] or they may present with acute abdominal symptoms that can mimic appendicitis.[61,62,77]

***Imaging.*** Because differentiation from cystic lymphatic malformations is based on histologic elements, imaging findings in these lesions are very similar to those in lymphatic malformations.[73]

***Treatment.*** The goal is complete surgical resection[70] because these tumors recur in as many as 75% of cases and because malignant degeneration has been reported.[73]

## Other Benign Lesions

### Lipoblastoma

***Overview.*** Lipoblastoma is a rare, benign, mesenchymal fat-containing tumor seen almost exclusively in infants and children, with a slight male predilection. Multiple series support that 70% to 90% of these tumors occur in children under 3 years of age.[78–83] The most common sites involved are the subcutaneous and superficial soft tissue of the neck and extremities[78,80,81]; approximately 7% of lipoblastomas occur in the abdomen.[84] Lipoblastoma differs from lipoma in that it contains both mature and immature adipocytes and is almost exclusively found in young children.[85] Lipoblastoma differs from lipoblastomatosis in that it is a well-circumscribed, encapsulated lesion, whereas lipoblastomatosis is a diffuse infiltrating process.[78,84]

***Etiology.*** Lipoblastomas arise from embryonal white fat, in contradistinction to hibernomas, which arise from brown fat.[83] The etiology of the lesions is not known, but lipoblastomas demonstrate chromosomal abnormalities with deletions or abnormal sequencing. The vast majority of cases have characteristic cytogenetic abnormality containing a 8q11-13 clonal chromosomal rearrangement that affects *PLAG1*.[86–88] Distinction from liposarcoma, particularly the myxoid variety, may be difficult: histologic criteria are based on a uniform growth pattern, absence of nuclear atypia, and cytogenetics; clinical criteria include patient age, because liposarcomas in children younger than 10 years are very rare.[82,88]

***Clinical Presentation.*** Clinical manifestations depend upon mass size and location and its effect on adjacent structures. Lipoblastomas frequently manifest as rapidly growing painless masses. Abdominal lipoblastomas may result in symptoms of vomiting, anorexia, abdominal pain, and diarrhea secondary to mass effect upon adjacent structures.[84]

***Imaging.*** Imaging features of lipoblastoma reflect the underlying pathology and vary depending upon the extent of underlying myxoid stroma versus adipose tissue.[88] Abdominal radiographs may demonstrate radiolucency,[89] although US may be the initial modality to confirm the presence of a mass and to assess its characteristics and location. A lipoblastoma is seen as a homogenously hyperechoic solid lesion, but mixed echogenicity and fluid-filled spaces can be present.[88,90] On CT and MRI, lipoblastoma appears as a lobular, fat-containing, well-circumscribed mass, often with internal septations (Fig. 86.36). The amount of fat will depend on the maturity of the cells that make up the tumor, with the proportion of mature adipocytes correlating with fat attenuation and signal characteristics respectively on CT and MRI.[88] If fat is the predominant component, the lipoblastoma is usually indistinguishable from a lipoma, with the diagnosis suggested based on patient age. If myxoid stroma is the predominant component, as seen in very young children, imaging will reflect decreased fat[85] and a variable amount of contrast enhancement.[88]

Differential diagnosis includes liposarcoma, which may be difficult to distinguish based solely on imaging findings.[82,88] Benign cystic teratomas also contain fat, but these may be distinguished from lipoblastoma by calcification or ossification.[88]

***Treatment and Follow-up.*** Treatment for lipoblastoma is complete surgical resection. Lesions may locally recur in up to 9% to 25% of cases. Recurrences are more often seen with lipoblastomatosis, likely related to incomplete resection. Current management suggests that extensive surgery to achieve complete resection is not required, because the lesions have no malignant potential and spontaneous regression and maturation into lipoma may occur.[88,91,92]

### Desmoid Tumors

***Overview.*** Desmoid tumors are histologically benign but locally aggressive, nonmetastasizing tumors that belong to a group of disorders known as *fibromatoses*.[93,94] Approximately 37% to 50% of desmoids arise in the abdominal region.[95] In the abdominal wall, desmoid tumors arise from the aponeuroses of fascia and near surgical scars.[89]

These tumors can occur sporadically or in association with familial adenomatous polyposis (FAP) and Gardner syndrome, and they occur in as many as 20% of affected patients.[89,96] They can also occur in FAP patients after prophylactic colectomy and are one of the leading causes of death after colectomy in these patients.[97,98]

***Etiology.*** The etiology of desmoid tumors is unknown but is thought to be multifactorial.[95] Their development within the setting of the polyposis syndromes suggests a genetic correlation. Desmoid tumors tend to develop after trauma and often arise 6 to 30 months after colectomy in FAP patients[96] or after chemotherapy or radiation treatment.[88] There is also evidence of hormonal influence, and some tumors express estrogen receptors.[88] These lesions are more common in women, with a ratio as high as 4:1.[95]

***Clinical Presentation.*** Abdominal desmoids may be asymptomatic. However, as they enlarge, they may infiltrate adjacent structures and lead to symptoms related to compression of bowel, vascular, or other retroperitoneal structures.[95]

***Imaging.*** Desmoid tumors vary in imaging characteristics, depending upon the amounts of collagen, proliferating fibroblasts,

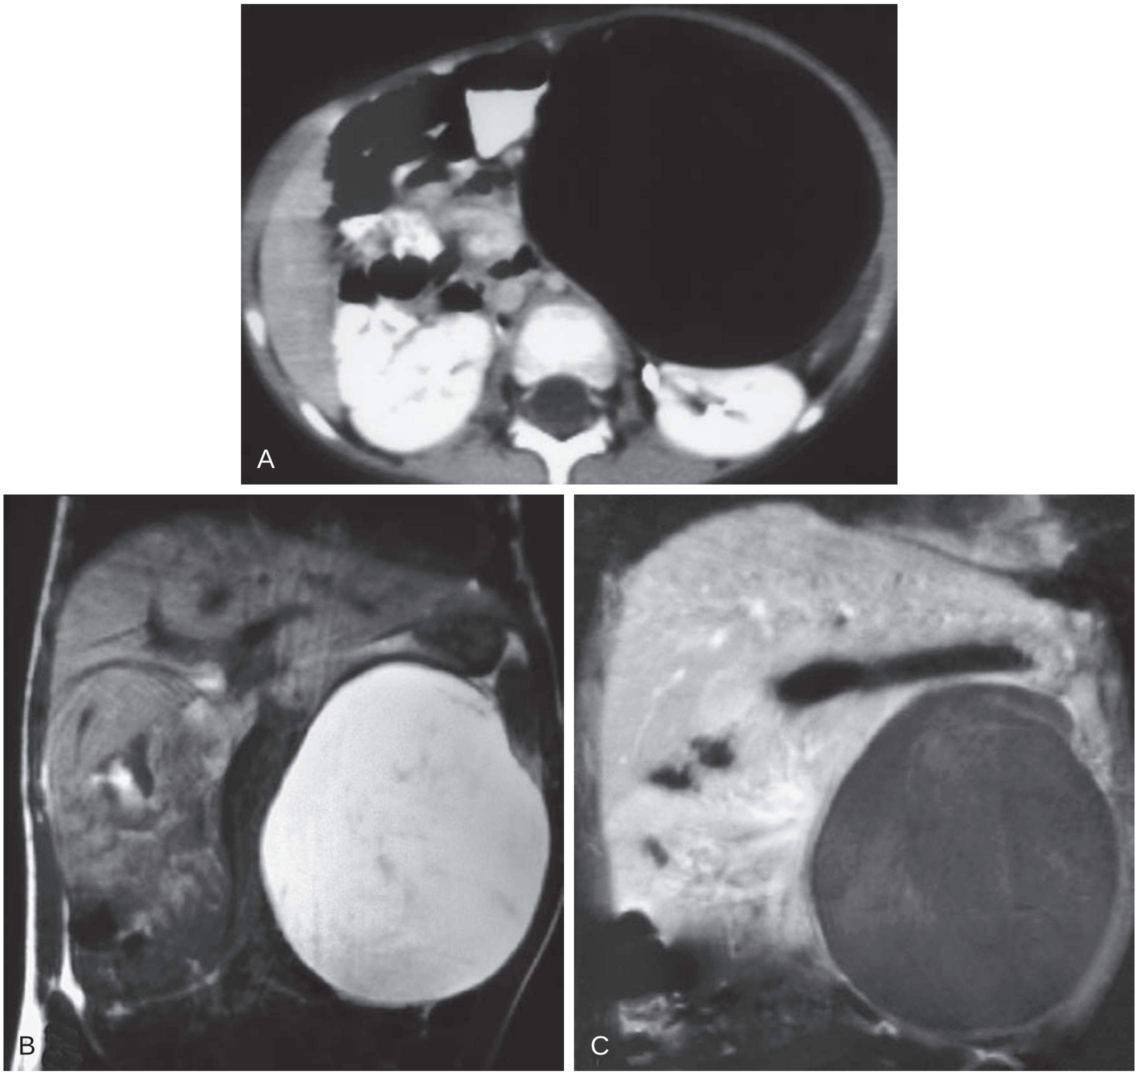

**Figure 86.36. Lipoblastoma.** Encapsulated left upper quadrant lipoblastoma attached to the pancreatic tail of a 2-year-old girl. (A) Axial contrast-enhanced CT image through the midabdomen shows a large fatty mass. Coronal MR T1-weighted sequences without (B) and with (C) fat saturation depict the fatty nature of the entire mass as well as some internal septations.

fibrosis, and vascularity. The fibrous and cellular composition of desmoid tumors varies with the stage of their evaluation.

On US, the margins may be ill-defined or irregular, and echogenicity is variable. CT density and margins likewise vary. On magnetic resonance (MR), desmoid tumors typically demonstrate decreased signal intensity on T1- and variable signal intensity on T2-weighted sequences compared with muscle. An association has been found between increased tumor cellularity, as shown on T2-weighted images, and tendency for rapid tumor growth.[89] Enhancement patterns are variable (Fig. 86.37). MRI is a useful method for staging desmoid tumors and detecting recurrence.

***Treatment.*** Surgical resection has been the mainstay of treatment; however, many abdominal desmoids are discovered when they are no longer easily resectable, particularly with sufficiently wide margins to prevent recurrence, thus risking significant morbidity and mortality.[93] The goal of resection is negative margins; positive margins or incomplete resection are treated with adjuvant radiotherapy.[77,96,99] Other systemic therapies have been tried, including steroids, antiestrogen agents, nonsteroidal antiinflammatory agents, and chemotherapeutic agents.[91,94]

## Pseudomyxoma Peritonei

***Overview.*** Pseudomyxoma peritonei occurs when the omental and peritoneal surfaces are caked with copious amounts of mucinous or gelatinous material.[2]

***Etiology.*** Pseudomyxoma peritonei arises from most commonly from rupture of an appendiceal mucinous adenoma into the peritoneal cavity. Pseudomyxoma peritonei may also originate from, or may secondarily involve, the ovary.[95] Abundant amounts of mucus, which may or may not contain epithelial cells, spreads through peritoneal pathways and accumulates in spaces such as the cul-de-sac, Morison pouch, and paracolic gutters.[2,100]

***Clinical Presentation.*** Pseudomyxoma peritonei is more common in adults and affects women more than men.[95] Patients typically present with abdominal pain and weight loss, despite increasing abdominal size.[2]

***Imaging.*** Imaging findings are generally similar to those seen in massive ascites. US reveals ascitic fluid that demonstrates nonmobile internal echoes.[2] Septations and occasionally solid-appearing masses can be seen. On CT, the mucinous material is

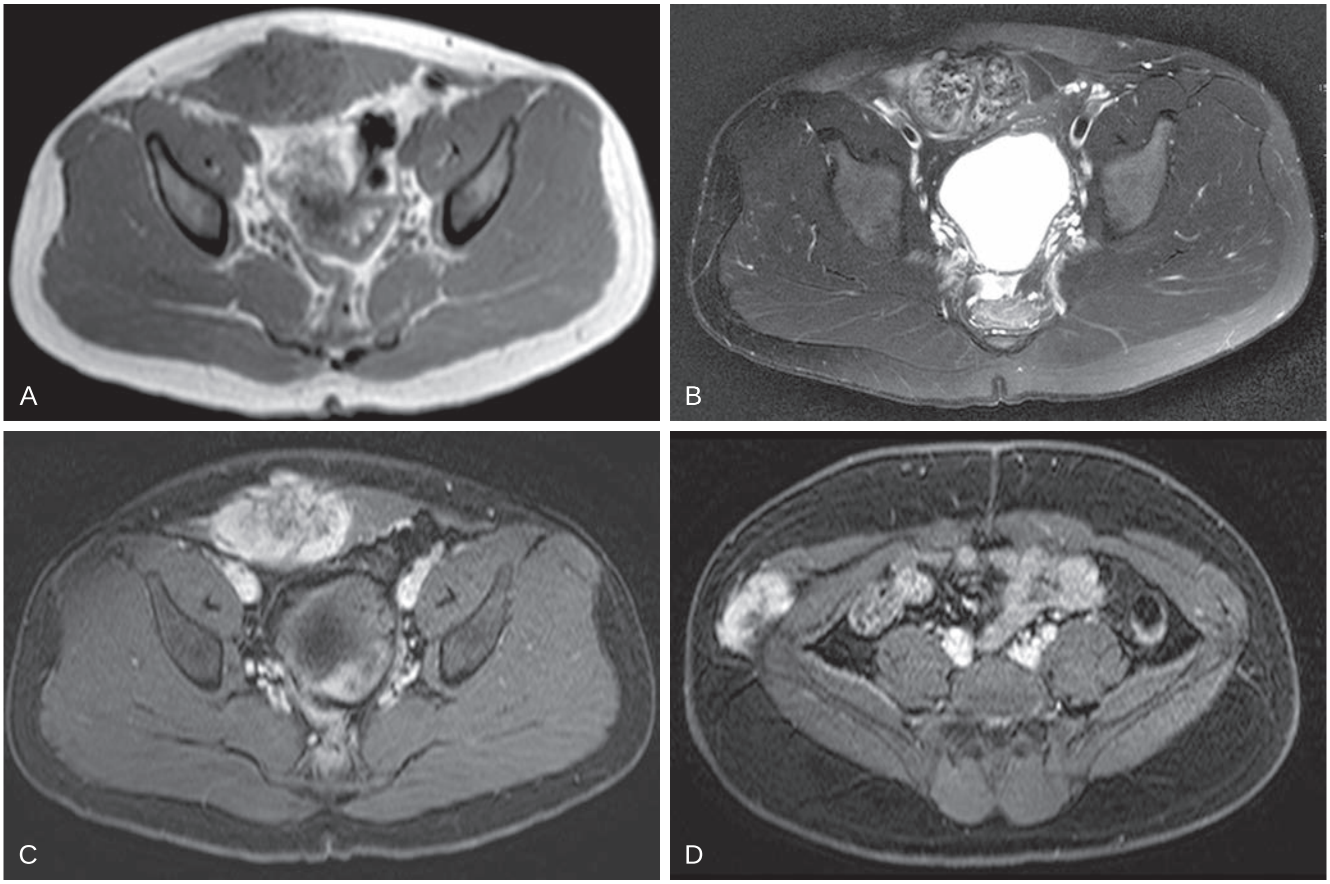

**Figure 86.37. Desmoid tumor.** (A) Axial T1-weighted MR image in a 16-year-old girl with an abdominal wall mass for 1 year shows a relatively well-defined rounded mass within the right rectus muscle. (B) Axial T2-weighted image with fat saturation shows a heterogeneous appearance to the mass. (C) T1-weighted fat saturation MR image after administration of contrast shows avid enhancement, especially when compared with adjacent muscle. (D) An additional lesion with similar imaging characteristics is also identified more laterally in the abdominal wall.

typically low density and accumulates in dependent areas as previously discussed. Scalloping of visceral surfaces, particularly the liver, is an important imaging sign to differentiate pseudomyxoma peritonei from ascites.[2] On imaging it is difficult to differentiate the benign form of pseudomyxoma peritonei from peritoneal mucinous carcinomatosis. Adenopathy, pleural involvement, enhancing masses, and invasion of visceral organs favors a malignant process.[2]

***Treatment.*** The treatment for the benign forms of pseudomyxoma peritonei consists mainly of surgical evacuation and appendectomy, with the potential need for resection of other involved structures. Malignant causes need additional treatment, such as intraperitoneal instillation of chemotherapeutic agents and radiotherapy.[101,102]

## MALIGNANT LESIONS

### Peritoneal Metastases and Carcinomatosis

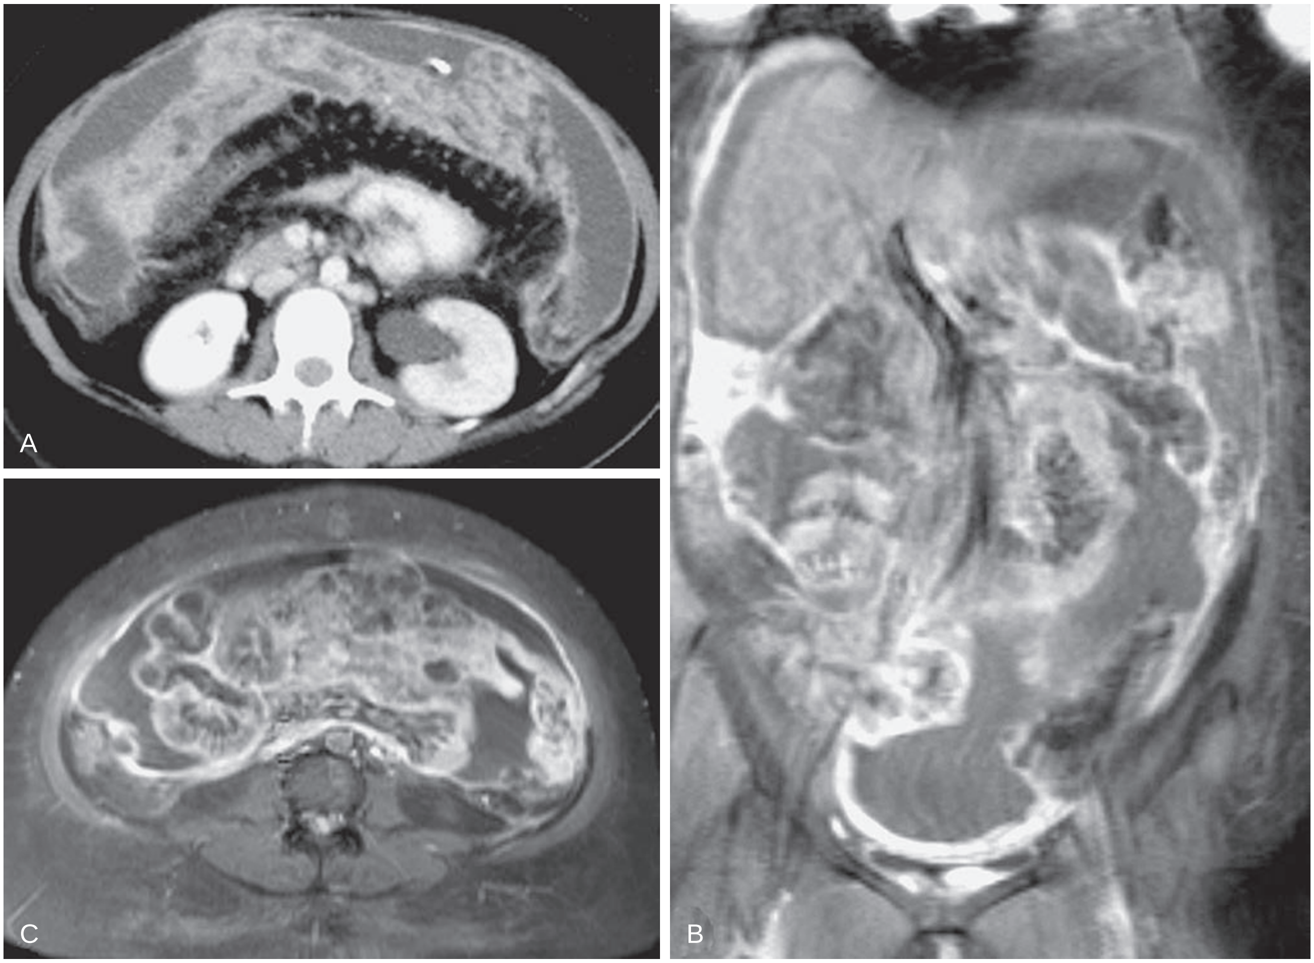
***Overview.*** Peritoneal metastatic spread is rare in pediatric patients. Germ cell tumors or carcinoma of the colon account for up to 47% of cases of peritoneal carcinomatosis in children.[103] Other tumors that can be seen with diffuse peritoneal dissemination include Wilms tumors, neuroblastoma, melanoma, teratoma, leiomyosarcoma, epithelioid carcinoma, desmoplastic small round cell tumor (DSRCT), and non-Hodgkin lymphoma.[103,104]

***Etiology.*** Malignancy disseminates throughout the peritoneum by intraperitoneal seeding, direct invasion, hematogenous spread, or lymphatic dissemination.[2] Peritoneal metastases frequently occur in the presence of other sites of metastatic disease. Seeding may occur at the time of operative intervention through tumor rupture and intraperitoneal spillage, with rare instances of intraabdominal spread of intracranial disease via ventriculoperitoneal shunt.

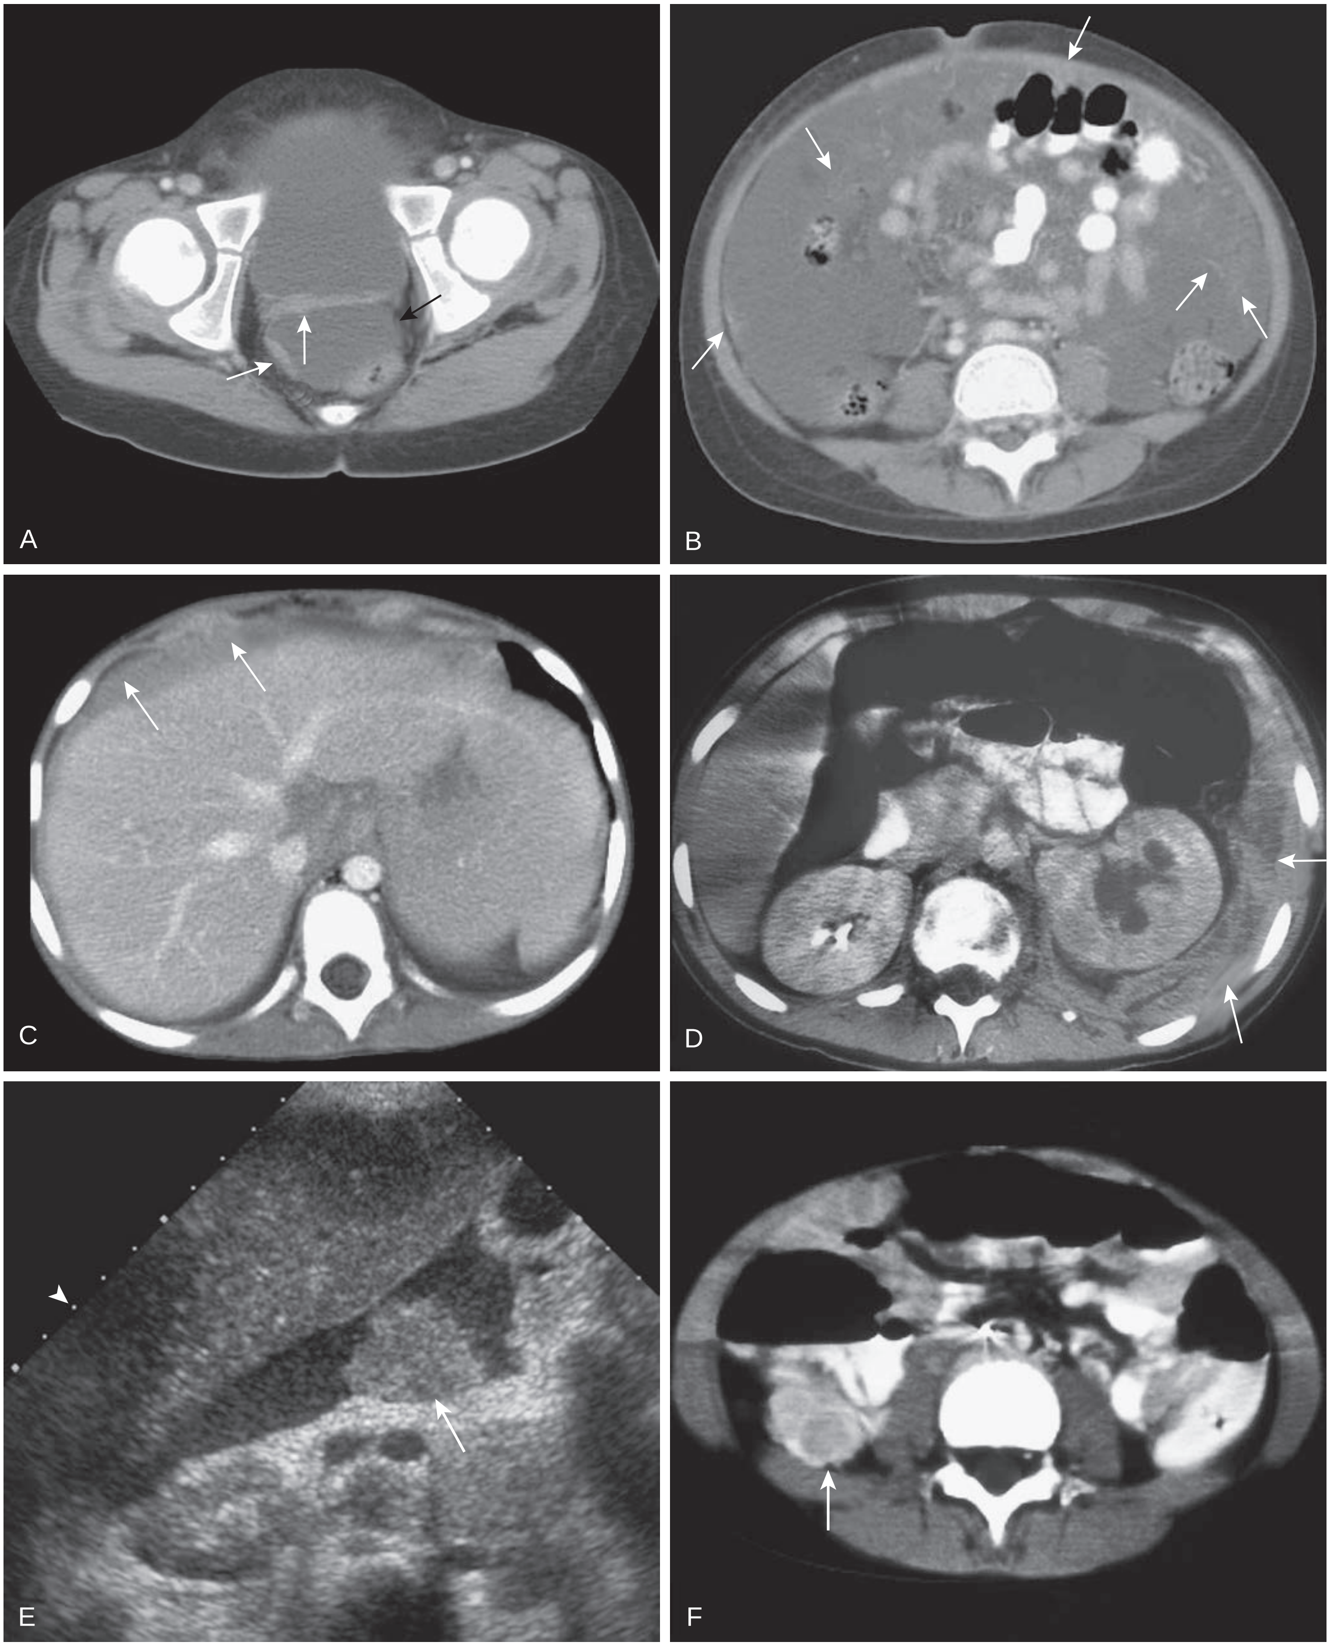
Malignant cells migrate through the normal circulation of the peritoneal fluid. The adhesion of tumor cells to mesothelial cells is believed to be mediated through the expression of intercellular adhesion molecules.[2,105] Ascites results when disseminated disease interferes with the absorptive capacity of the mesothelial lining of the peritoneum.[105]

***Clinical Presentation.*** Peritoneal metastases may initially be asymptomatic; with progression of disease, patients may present with abdominal enlargement, ascites, nausea, and abdominal pain.[103,104] Approximately 20% are seen with bowel obstruction and 50% with ascites.[105,106] CT may demonstrate solitary or multiple masses, diffuse peritoneal thickening, peritoneal enhancement, and tumor studding of the peritoneal surfaces.[98] Diffuse caking is a feature of peritoneal metastases from rhabdomyosarcoma, non-Hodgkin lymphoma, and germ cell tumors (e-Figs. 86.38 and 86.39).[98]

MRI detection of peritoneal implants may be improved over CT because of the inherent tissue contrast and multiplanar capabilities.[2] Peritoneal implants tend to be hypointense on T1- and



**e-Figure 86.38. Peritoneal mesothelioma.** An 18-year-old patient with a history of posterior fossa medulloblastoma is seen with new onset of hemorrhagic ascites. (A) Axial contrast-enhanced CT image through the midabdomen demonstrates abundant ascites and abnormal enhancement of the peritoneal surfaces. Note diffuse, enhancing omental caking. Coronal (B) and axial (C) contrast-enhanced T1-weighted magnetic resonance images of the abdomen and pelvis demonstrate the thickened, intensely enhancing peritoneal surfaces and abundant ascites.



**e-Figure 86.39. Peritoneal metastases may have a varied appearance.** (A) Axial contrast-enhanced CT image of the deep pelvis shows a moderate amount of pelvic ascites *(black arrow),* resulting from the peritoneal metastases evidenced by abnormal thickening and enhancement of the peritoneal surface *(white arrows)* in a patient with history of desmoplastic small round cell tumor (DSRCT) and recurrent ascites. (B) Contrast-enhanced CT through the midabdomen in a patient with epithelioid sarcoma shows more extensive peritoneal disease and complex ascites. Note tiny masses studding the peritoneum *(arrows)* and numerous strands of solid disease throughout the ascites *(arrows)*. Contrast-enhanced CT images in a patient with Burkitt lymphoma. (C) Patient with metastatic melanoma. (D) Diffuse thickening of the peritoneal surface (*arrows* in C and D). (E) Transverse ultrasound image shows metastatic disease manifested as a discrete mass *(arrow)* surrounded by ascitic fluid. (F) Contrast-enhanced CT image shows a cystic peritoneal metastasis *(arrow)* in a patient with neuroblastoma.

hyperintense on T2-weighted sequences, with variable enhancement.[105] Delayed images obtained 10 to 15 minutes after gadolinium administration may show lesions better, because they are slow to enhance.[2,105] However, respiratory and bowel motion may degrade identification of peritoneal and serosal lesions. Positron emission tomography (PET) or CT scan may also help to identify peritoneal carcinomatosis with greater confidence, depending on the size of the lesions.[2]

***Treatment.*** Surgical cytoreductive procedures are employed to remove gross or bulky disease, followed by hyperthermic intraperitoneal chemotherapy. However, tumor recurrence rates as high as 70% are reported.[105]

## Desmoplastic Small Round Cell Tumor

***Overview.*** DSRCT is a rare and aggressive abdominal malignancy.[106–108] Intraperitoneal involvement is most common, and less common sites include paratesticular, pleural, lung, ovary, sinus, central nervous system, kidney, and stomach.[102,109,110]

***Etiology.*** The etiology of DSRCT is unknown; it has been hypothesized that the tumor originates from the mesothelial, submesothelial, or subserosal mesenchyma.[105] Pathologically DSRCTs are part of the small round blue cell family that includes Ewing sarcoma, neuroblastoma, Wilms tumor, rhabdomyosarcoma, and primitive neuroectodermal tumors. Immunocytochemical staining is usually required to distinguish DSRCTs from other small round cell tumors.[111]

***Clinical Presentation.*** DSCRTs typically affect adolescents and young adults aged 15 to 25 years, and there is a strong male predilection with ratios that range from 3 : 1 to 9 : 1. Patients generally come to medical attention with vague abdominal pain and/or distension, and palpable abdominal masses may be present on physical examination.[106,109]

***Imaging.*** On CT imaging, DSRCT is usually seen as multiple, scattered peritoneal masses without an apparent primary parenchymal source. The masses are generally of low attenuation and have a variable degree of central necrosis or hemorrhage with mild to moderate contrast enhancement.[102,112] US and MRI findings for DSRCT are variable and nonspecific (e-Fig. 86.40). The utility of fluorodeoxyglucose PET/CT is still evolving and is currently used to evaluate metastatic progression and response to systemic therapy.[113,114]

Tumor spread by direct peritoneal seeding results in multiple omental and mesenteric masses. Liver metastases, both intrahepatic (hematogenous) and serosal (direct spread), are seen in up to 50% of patients (Fig. 86.41).[104,112] Other hematogenous metastatic lesions are less common. In addition, hydronephrosis and small bowel obstruction may result from mass effect. Multiple studies have found a correlation between retroperitoneal lymphadenopathy and ascites with a large pelvic mass (see Fig. 86.41).[1,104,115] Although imaging features are usually nonspecific, the combination of scattered small peritoneal masses, a dominant pelvic mass, retroperitoneal lymphadenopathy, and ascites is somewhat characteristic for this entity. Primary differential diagnostic considerations include

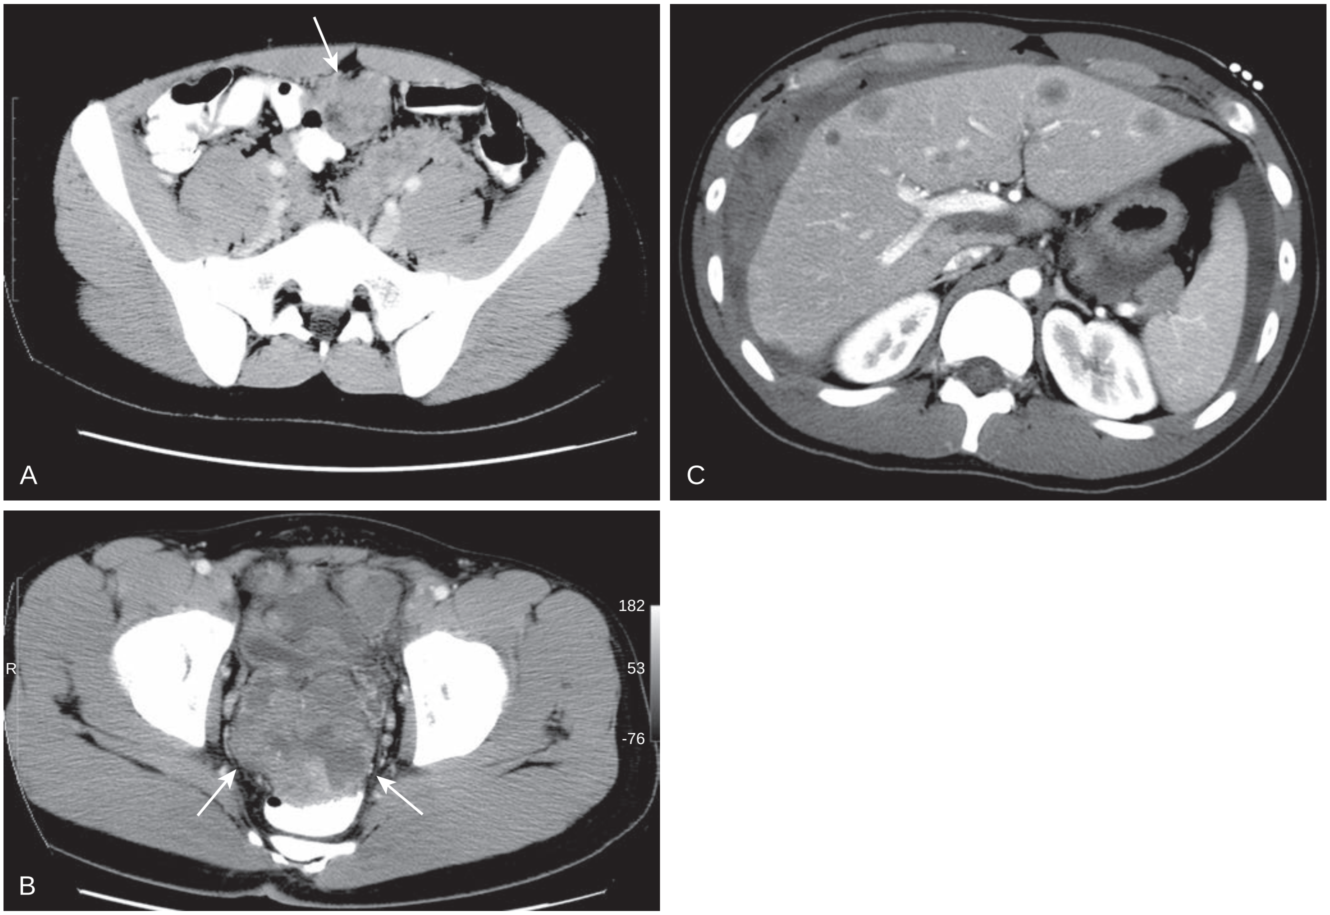


**Figure 86.41. Desmoplastic small round cell tumor.** (A and B) Axial contrast-enhanced CT images in a 17-year-old boy show multiple heterogeneously enhancing pelvic masses *(arrows)* with a dominant mass seen within the rectovesical pouch. (C) Metastatic spread and peritoneal seeding are evident as multiple enhancing nodules within the liver with a large, heterogeneous, peritoneal subcapsular mass indenting the hepatic surface.

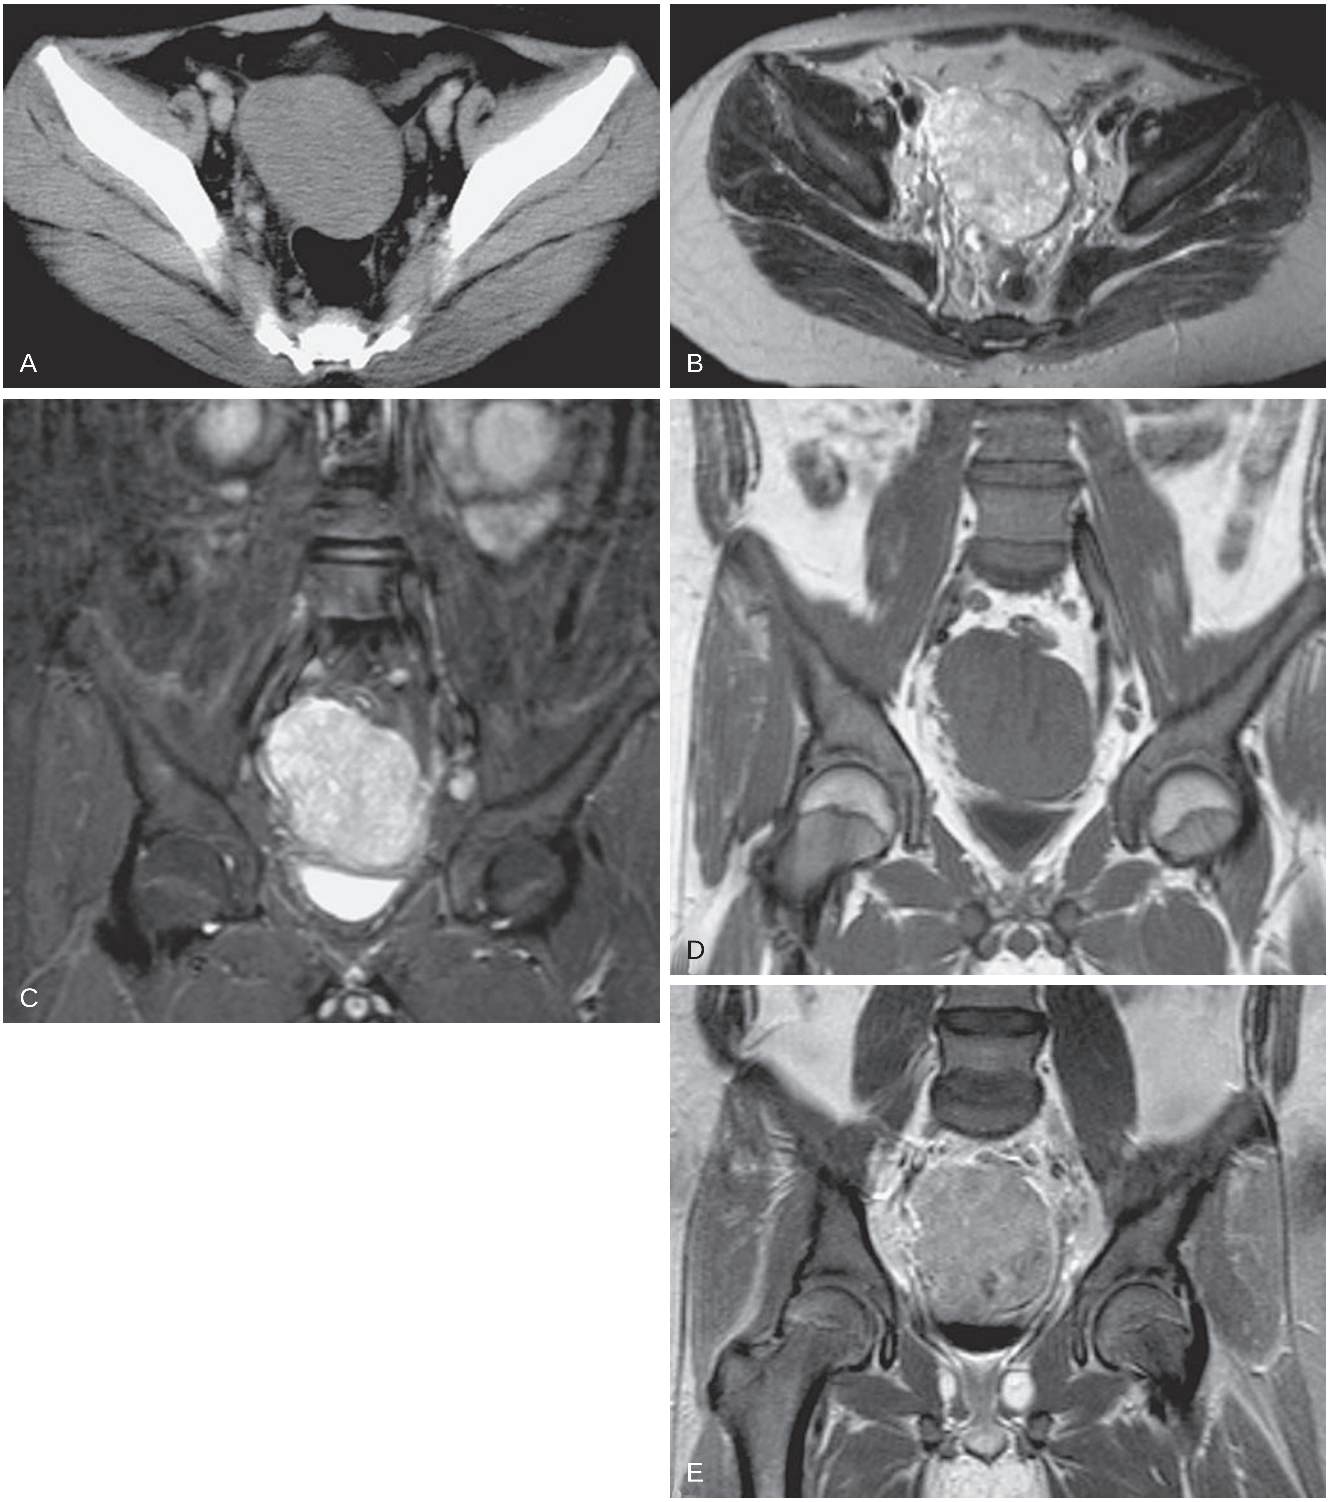

**e-Figure 86.40. Desmoplastic small round cell tumor in a 14-year-old boy with 2-month history of fatigue, poor appetite, and anemia.** (A) Axial contrast-enhanced pelvic CT image shows a well-defined midline pelvic mass that is of homogenous intermediate density. (B) Corresponding axial T2-weighted MR image shows the mass to have diffusely increased signal with mild heterogeneity. (C) The appearance in a short-tau inversion recovery sequence is similar to (B). (D) Coronal T1-weighted MR image shows the mass to be isointense with muscle. (E) Coronal T1-weighted contrast-enhanced fat-saturated MR image demonstrates mild heterogeneous enhancement of the lesion.

peritoneal carcinomatosis, rhabdomyosarcoma, neuroblastoma, lymphoma, and germ cell tumors.[104,115,116]

***Treatment.*** Treatment generally includes a combination of chemotherapy and surgical resection. Chemotherapy may be useful to reduce tumor bulk before surgery, because improved outcomes have been reported in patients with complete resection.[102,103,117] However, DSRCT is an aggressive malignancy that has poor prognosis despite treatment, with a reported 29% survival at 3 years.[117]

## Miscellaneous Tumors

*Rhabdomyosarcoma* comprises about half of pediatric soft tissue sarcomas but is less common in the trunk (Fig. 86.42).[118] Abdominal wall and other truncal rhabdomyosarcomas have a poorer prognosis when compared with other sites.[118] Truncal tumors are more likely to be of the embryonal than the alveolar type, are more likely to be greater than 5 cm at presentation, and tend to present with advanced disease. The ability to undergo gross total resection

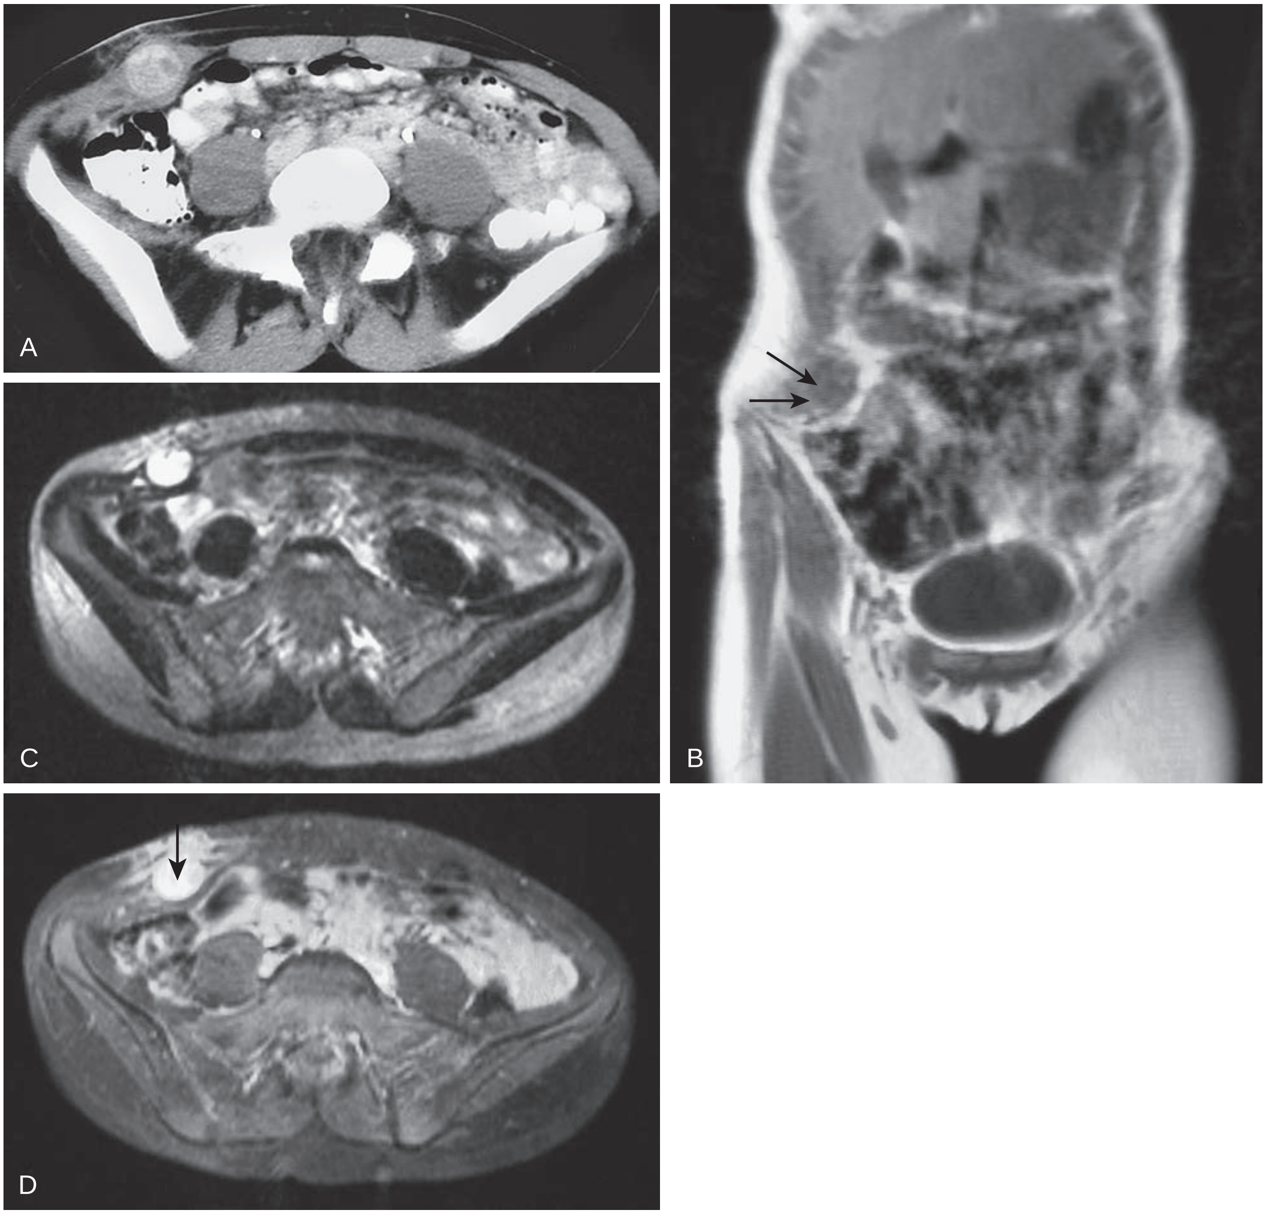

**Figure 86.42. Embryonal rhabdomyosarcoma.** (A) Axial contrast-enhanced image of the lower abdomen in a 13-year-old girl with a firm subcutaneous mass in the right lower abdominal wall shows a heterogeneously enhancing mass that causes focal enlargement of the right lateral oblique muscles. Edema is evident within the subcutaneous fat overlying the mass. Local infiltration by tumor cannot be excluded on this image. (B) Oblique, coronal, noncontrast T1-weighted MR image shows the 3-cm round tissue mass within the right lateral oblique muscles *(arrows)*. (C) On an axial T2-weighted MR image, the mass exhibits intense signal (as it did on short-tau inversion recovery sequence, *not shown*). (D) Intense enhancement is seen with intravenous contrast administration in the soft tissue mass and in the overlying subcutaneous fat *(arrow)*. This finding warrants concern about tumor infiltration.

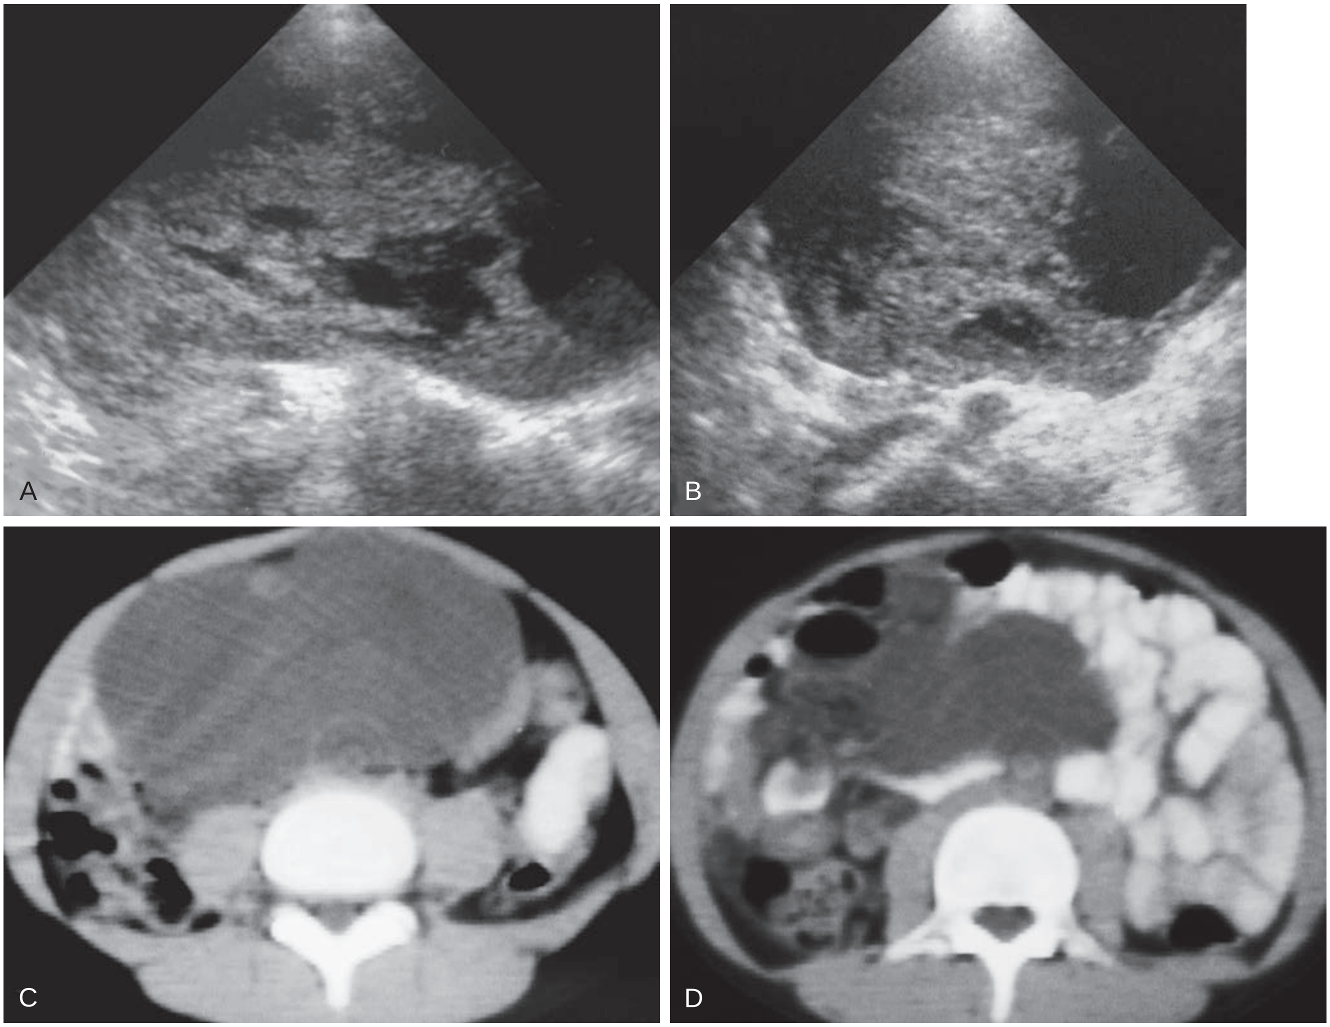

**Figure 86.43. Leiomyosarcoma.** Longitudinal (A) and transverse (B) sonograms through the midabdomen in a 10-year-old boy show a large, heterogeneous, solid and cystic mass. (C and D) CT images without intravenous contrast show a large, homogenous, low-density, midline soft tissue mass displacing bowel.

influences the prognosis, and gross total resection should be the goal of therapy.

*Synovial sarcoma* is a rare malignancy constituting 5% to 6% of pediatric soft tissue sarcomas. It most often originates in the extremities and near large joints, but it may rarely affect the anterior abdominal wall.[119]

*Leiomyosarcoma* often originates in the retroperitoneum, genitourinary or GI tract, and lower extremity.[120] Rarely, such a lesion may arise in the omentum (Fig. 86.43 and e-Fig. 86.44).

*Liposarcoma* has been briefly discussed; the presence of fat may help to distinguish this tumor from other sarcomas unless it is dedifferentiated. It is more commonly seen in the retroperitoneum. It is the least frequent soft tissue sarcoma to occur in childhood.[121]

*Fibrosarcoma* has two forms in children: the *congenital* or *infantile form* occurs in children up to 2 years of age, and the *childhood form* affects the 10- to 15-year-old age group (Fig. 86.45). The histology of the two forms is similar, but the infantile form has a distinct chromosomal translocation. Infantile fibrosarcoma has been reported to involve the trunk and retroperitoneum in children.[120,122] After complete surgical resection, prognosis is better for the infantile form than for the childhood form.[122]

*Malignant mesenchymomas* are very rare soft tissue tumors seen predominantly in adults. These tumors contain at least two distinct

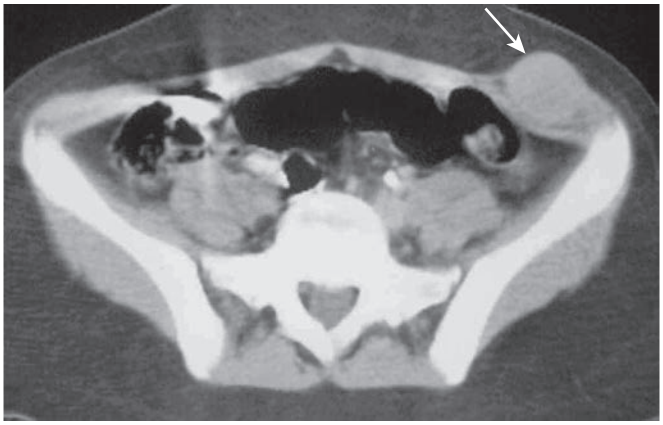

**Figure 86.45. Fibrosarcoma.** Axial contrast-enhanced CT image through the upper pelvis in a 14-year-old girl shows a well defined, round 3-cm mass in the left anterior abdominal wall. The mass expands and is isointense with the left lateral oblique muscles *(arrow).*

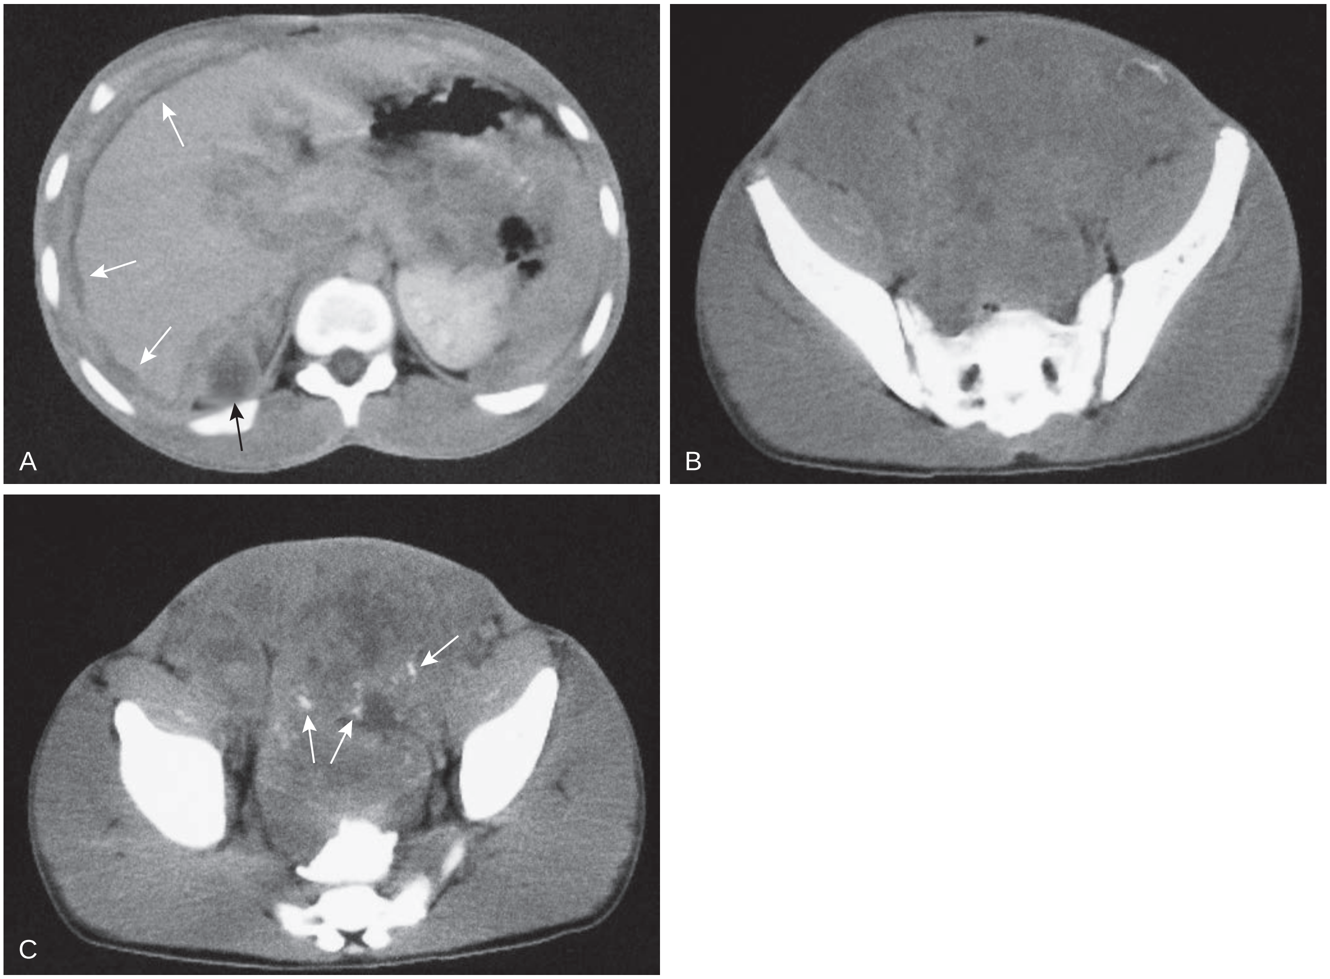

**e-Figure 86.44. Leiomyosarcoma.** (A) Contrast-enhanced CT image in a 16-year-old boy shows extensive peritoneal metastases around the liver *(white arrows)* and surrounding the pancreas in addition to a cystic peritoneal metastasis *(black arrow)*. (B) Lower image in the upper pelvis shows that the mass occupies most of the lower abdomen and pelvis. (C) Another image lower in the pelvis shows scattered calcifications *(arrows)*. Bowel contrast is present in the rectum.

histologic sarcoma subtypes and are considered to be high-grade tumors with an overall poor prognosis. The most common sites of primary malignant mesenchymoma are the retroperitoneum or the thigh, though various locations have been reported.[123] CT demonstrates a soft tissue mass with mixed attenuation often containing areas of necrosis and calcification, with heterogeneous enhancement and moderate vascularity (e-Fig. 86.46). On MR, these lesions are typically heterogeneous on T2-weighted images.[124] Treatment includes a combination of surgical incision, radiation, and chemotherapy.

*Malignant mesothelioma* of the peritoneum is rare in children and does not seem to be related to radiation or asbestos exposure.[1,125] Children with peritoneal malignant mesothelioma come to medical attention with ascites and multiple tumor nodules along the peritoneal surface (see e-Fig. 86.38).[120] Treatment with cytoreduction and hyperthermic intraperitoneal chemotherapy improves median survival to between 2.5 and 9 years.[126]

## KEY POINTS

- Upright radiographs and decubitus abdominal radiographs for detection of free air have similar sensitivity.
- Abdominal compartment syndrome is a clinical diagnosis that includes elevation of intraabdominal pressure to 20 mm Hg or greater, coupled with impaired function of at least one organ.
- Fat necrosis is one of the causes of abdominal wall calcification in neonates and infants. The majority of such calcifications are associated with neonatal asphyxia, sepsis, gestational diabetes, and hypothermia.
- Peritoneal calcification associated with calcified intraabdominal lymph nodes is more likely to be associated with a malignant process.
- Lipoblastomas can have a variable amount of macroscopic fat and may not appear completely fatty on imaging.
- MRI is preferred for detection of peritoneal implants given the inherent tissue contrast and multiplanar capabilities.
- Scalloping of visceral surfaces, particularly the liver, is one of the most important imaging signs to differentiate pseudomyxoma peritonei from ascites.
- DSRCTs usually are seen as multiple, scattered peritoneal masses without an apparent primary parenchymal source.

# Congenital Hepatobiliary Anomalies

*Govind B. Chavhan*

## INTRODUCTION

Hepatorenal fibrocystic disorders are a group of associated congenital anomalies of the liver and kidney caused by malformation of the embryonic ductal plates formed by bipotential progenitor hepatoblasts surrounding portal venous ramifications (Fig. 87.1).[1,2] They include choledochal cysts, Caroli disease, hepatic fibrosis, biliary hamartomas, and cystic liver disease. The specific type of fibrocystic disorder depends on the size of the embryonic duct with faulty development (Table 87.1) and may be associated with renal cystic disease.

## CHOLEDOCHAL CYST

***Overview.*** Choledochal cysts, which are among the most frequent of congenital hepatobiliary anomalies, are a fusiform or saccular dilation of the bile ducts. The Todani classification system is commonly used to categorize these anomalies into five general types (with several subtypes) that differ based on etiology, pathogenesis, appearance, and presentation[3] (Fig. 87.2).

The most common choledochal cyst is the Todani type I, found in 80% to 90% of cases.[4] It involves variable lengths and degrees of common bile duct dilatation and is further classified into subtypes IA, IB, and IC.[4] Todani types IA, B, and C describe cystic dilation of the entire extrahepatic bile duct, segmental dilation below the cystic duct, and fusiform/cylindrical dilation of entire extrahepatic bile duct, respectively. Type I choledochal cysts are more common in girls than boys in Western countries, but the sex ratio is equal in Asia.[4,5] About 65% of all reported cases are from Japan.[4] Todani type II choledochal cysts are rare, found in only 2% of cases, and consist of one or more diverticula of the common bile duct.[5] Todani type III occurs in 1.5% to 5% of cases and involves dilation of the intraduodenal portion of the duct forming a cystlike mass termed a *choledochocele* with both the common bile and pancreatic ducts emptying into it. Todani type IVA consists of multiple intrahepatic and extrahepatic biliary dilatations and occurs in 10% of patients with choledochal cysts.[3,5] Type IVB involves multiple extrahepatic biliary cysts, without intrahepatic involvement, and it is extremely rare. Todani type V is synonymous with Caroli disease.[3] It may be difficult to differentiate between a type I cyst with intrahepatic dilatation from stagnation and the true type IV A cyst. This differentiation, however, is not necessary for treatment.[6] Intrahepatic dilation will improve postoperatively in type I cysts.

***Etiology.*** Several theories for the pathogenesis of type I choledochal cysts exist. In addition to the ductal plate malformation described previously, other theories suggest cyst formation due to obstruction of the distal biliary duct and/or reflux of pancreatic enzymes into the biliary tree, due to anomalous pancreaticobiliary junction (PBJ).[7,8]

When the junction of a common bile duct and pancreatic duct form a common channel outside the sphincter of Oddi, it is considered anomalous.[9] The anomalous junction outside the sphincter mechanism is thought to allow reflux of pancreatic secretions into the biliary tree and vice versa, and likely plays a role in pathogenesis of choledochal cysts and predisposes to pancreatitis[10] as well as the formation of stones, polyps, and cancer.[11]

Type II choledochal cysts, have been theorized to result from prenatal rupture of the common bile duct with subsequent healing.[5] Type III choledochal cysts may be the sequelae of ampullary obstruction or congenital duplication of the duodenum at the ampulla. The intrahepatic cysts seen in types IV and V are thought to be due to primary ductal ectasia resulting from ductal plate malformation.

***Clinical Presentation.*** Choledochal cysts may present in infancy with cholestatic jaundice, clinically inseparable from neonatal hepatitis or biliary atresia.[4] In older children and young adults, the clinical presentation is variable. The characteristic triad of abdominal pain, obstructive jaundice, and fever is seen in a minority of patients present. Abdominal pain is the most characteristic presentation, followed by obstructive jaundice, fever, pale stools, splenomegaly, hepatomegaly, and a palpable mass.[12] Pancreatitis can be a presentation in older children, particularly in type IV A.[13] The most common complication of a choledochal cyst is ascending cholangitis.[14] Long-term complications, such as hepatic cirrhosis with subsequent portal hypertension, can occur.[12] Carcinoma of the biliary tree has a 20-fold increased incidence in patients with choledochal cysts. This risk is low in the first decade but increases with advancing age.[15,16] Spontaneous cyst rupture has also been reported.[12]

***Imaging.*** Sonography is usually the initial imaging study. The markedly dilated common bile duct in types I and IV choledochal cyst is readily discernible. The gallbladder can usually be identified adjacent to the dilated common duct (Fig. 87.3). Sludge or stones may be identified within the dilated ducts. Type III cysts may cause mass effect at the Ampulla of Vater (e-Fig. 87.4).

Abdominal magnetic resonance imaging (MRI) with cholangiopancreatography (MRCP) is the modality of choice to delineate the type of cyst, the length of the involved duct, the presence and location of protein plugs or calculi, the PBJ, and the length of the common channel[9,17,18] (Figs. 87.5 and 87.6). A common pancreaticobiliary channel of more than 15 mm in length is considered abnormal in adults.[10] However, there is limited data on normal length of common channel in children, with one recent study using 5 mm as a cut-off value[19] while another found an average length of 9.25 mm.[9]

MRI is also useful for evaluation of any associated abnormalities such as masses, portal hypertension, and renal abnormalities. Contrast-enhanced MRCP with hepatocyte specific contrast media such as gadobenate and gadoxetate can be used to demonstrate communication between choledochal cyst and the biliary tree and to evaluate postoperative bile leak,[20] as can hepatobiliary scintigraphy. Computed tomography (CT) may have a limited role in evaluation of choledochal cyst when MRCP is not available.

With improved diagnostic imaging, the role of percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP) is usually reserved for therapeutic intervention.

***Treatment.*** Due to the potential long-term sequelae, surgical excision and hepatojejunostomy are performed as definitive treatments. Patients with intrahepatic cysts are closely monitored for cholangitis, cholestasis, and stone formation. Antibiotics are administered in the setting of acute cholangitis. Medical therapy

## Abstract:

Congenital biliary hepatobiliary anomalies include hepatorenal fibrocystic disorders, biliary atresia and Alagille syndrome. Hepatorenal fibrocystic disorders are a group of associated congenital anomalies of the liver and kidney caused by malformation of the embryonic ductal plates that form intrahepatic bile ducts. These disorders include choledochal cysts, Caroli disease, hepatic fibrosis, biliary hamartomas and cystic liver disease. The anomalous pancreatobiliary junction outside the sphincter mechanism is thought to allow reflux of pancreatic secretions into biliary tree and vice versa and likely plays a role in pathogenesis of choledochal cysts and one of the predispositions for pancreatitis. Imaging plays important role in the assessment of fibrocystic disorders. In utero biliary inflammation is thought to be the cause of biliary atresia for which ultrasound is 98% accurate when a combination of the triangular cord sign and gallbladder size <15mm is used. Alagille syndrome is a multisystem disorder including cholestasis from bile duct paucity and multiorgan vasculopathy.

## Keywords:

hepatorenal fibrocystic disorders
choledochal cyst
caroli disease
congenital hepatic fibrosis
biliary hamartoma
biliary atresia
Alagille syndrome

*ADPKD,* Autosomal dominant polycystic kidney disease; *ARPKD,* autosomal recessive polycystic kidney disease.

can be instituted to reduce the risk of cholestasis and promote bile flow.

## CAROLI DISEASE

***Overview.*** Caroli disease, also classified as Todani type V choledochal cyst, is a segmental nonobstructive dilation of the intrahepatic bile ducts. It is characterized by multifocal saccular dilation of intrahepatic ducts.[14] It can be associated with stone formation, cholangitis, hepatic abscesses, and cholangiocarcinoma later in life.[16]

***Etiology.*** Leading theories on the etiology of Caroli disease include maldevelopment of the large intrahepatic ductal plates. Other postulated mechanisms include: occlusion of the hepatic artery in the neonatal period with associated ischemia of the bile ducts versus abnormal growth rate of the biliary epithelium and supporting connective tissues with lack of the normal involution of ductal plates. This process leads to ectatic biliary ducts surrounding the portal triads. In *Caroli syndrome*, which involves large and small ductal plate abnormalities, there is associated hepatic fibrosis. Caroli hepatic ductal ectasia may also be associated with extrahepatic ductal plate abnormalities and choledochal cysts (Todani IVA choledochal cyst) as discussed previously. An association also exists with renal disorders including autosomal recessive polycystic kidney disease (ARPKD), medullary sponge kidney, and nephronopthisis.[14] Although typically a diffuse process, monolobar Caroli disease has been reported, with 88% involving the left lobe.[21]

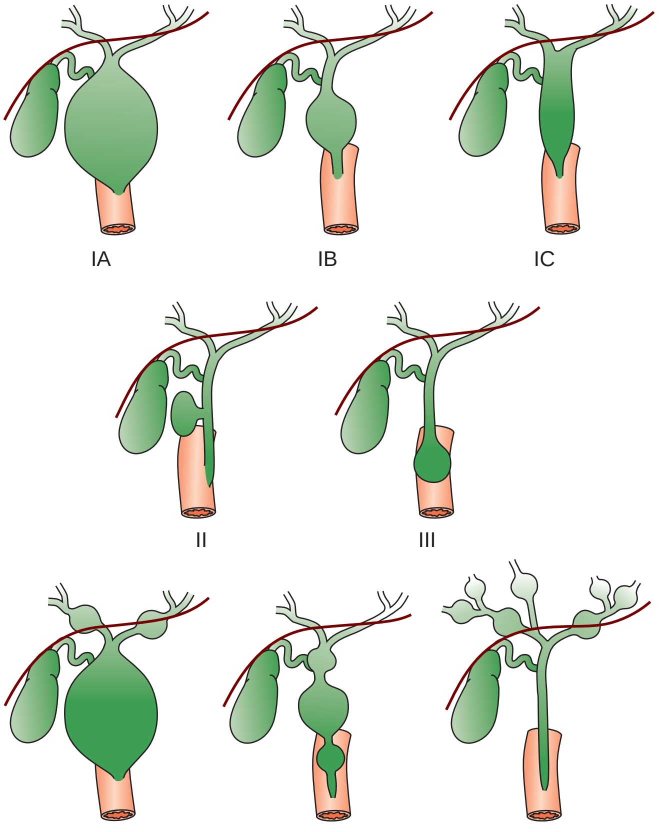

**Figure 87.2. Todani classification of choledochal cysts based on cholangiographic morphology.** Type *IA* and *IB* involve cystic dilatation of the common duct, with *IB* limited to the area below the insertion of the cystic duct; *IC* is cylindrical dilatation of the duct. Type *II* is a saccular diverticulum from the common bile duct. Type *III* is a choledochocele at the ampulla of Vater. Types *IVA* and *IVB* are multiple cystic dilatations of the both intra- and extrahepatic ducts and extrahepatic biliary tree only, respectively. Type *V* is equivalent to Caroli disease with numerous intrahepatic cystic dilatations throughout the biliary tree and liver. *(From Kim OH, Chung HJ, Choi BG. Imaging of the choledochal cyst.* Radiographics. *1995;15:69–88.)*

***Clinical Presentation.*** Although the disease is present from birth, most patients do not present until later in life when abdominal pain secondary to cholangitis and cholestasis leads them to seek medical attention. The abdominal pain may also be related to hepatic abscesses (secondary to cholangitis) or to biliary stones (secondary to cholestasis). Patients with associated hepatic fibrosis may present with symptoms and signs of portal hypertension.[22]

***Imaging.*** In most patients, sonography reveals large and irregular ectatic ducts.[14,23] Recognition that the ectatic ducts connect with one another and with the ductal system is important to distinguish Caroli disease from hepatic cysts (Fig. 87.7). The ectatic ducts surround portal vein radicles and hepatic arterial branches producing the "central dot" sign, which has been considered pathognomonic for Caroli disease.[24] Biliary sludge and calculi are common findings within the dilated bile ducts.[14] If an abscess develops, one or more cysts will show mixed echogenicity.

MRI and CT show the extent of disease well. An enhancing central dot may be seen that corresponds to the portal vein radicles seen sonographically.[25] If an abscess is present, the affected cyst may show higher attenuation or peripheral enhancement compared with adjacent uninfected cysts.[14] Contrast-enhanced MRCP can be used to demonstrate connection to the biliary tree.

In all patients with Caroli disease, the kidneys should be examined. Kidneys may appear normal, polycystic, or have increased medullary echogenicity with loss of corticomedullary differentiation (Fig. 87.8).

***Treatment.*** Ursodeoxycholic acid can decrease cholelithiasis and its complications. Broad-spectrum antibiotic coverage can be used to prevent and treat cholangitis. Supplementation of fat-soluble vitamins may help alleviate symptoms of cholestasis. In addition, serologic screening for carbohydrate antigen (CA) 19-9 and carcinoembryonic antigen (CEA) are helpful. PTC may be used for abscess drainage or to alleviate obstructed biliary ducts. Surgical resection has been used successfully in patients with monolobar disease. For patients with diffuse involvement and progression beyond medical management, orthotopic liver transplant is the definitive treatment.[26]

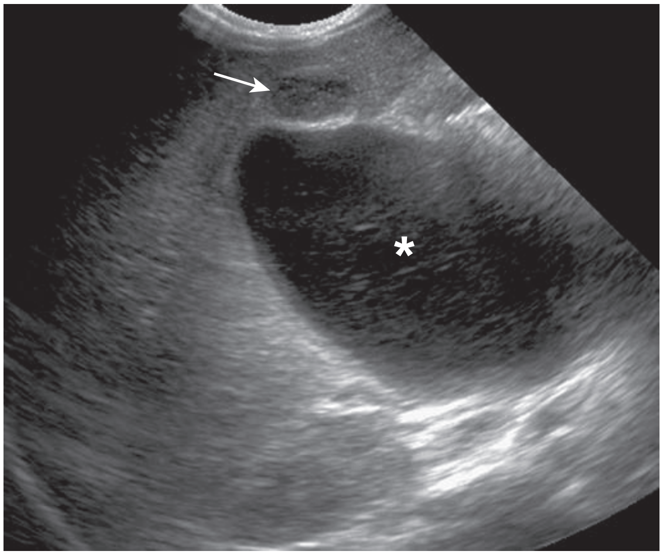

**Figure 87.3. Choledochal cyst (Todani type I) in an 8-day-old girl with jaundice.** Transverse sonogram shows a large fusiform cyst at the porta hepatis *(asterisk)* just beneath a small, contracted sludge-filled gallbladder *(arrow)*.

## CONGENITAL HEPATIC FIBROSIS

***Overview.*** Congenital hepatic fibrosis is a ductal plate malformation involving the small interlobular ducts.[27] Periportal fibrosis occurs from scarring between adjacent biliary tracts and ductal plate remnants. It is a progressive condition that leads to portal hypertension. ARPKD and congenital hepatic fibrosis are part of a fibrocystic disease mainly caused by mutation of the *PKHD1* gene, which encodes firbocystin/polycystin.[28] Hepatic fibrosis can be associated with Caroli disease, which is a large ductal plate anomaly; this association is known as Caroli syndrome.[29]

***Clinical Presentation.*** The onset of congenital hepatic fibrosis is variable with less severe disease presenting later in childhood or in adulthood, frequently with splenomegaly and portal hypertension.[14,27,30] Major complications include ascending cholangitis, hepatic failure, and an increased risk of cholangiocarcinoma[28] and hepatocellular carcinoma.[14,31]

***Imaging.*** Ultrasound (US) is the initial imaging modality. Increased hepatic echogenicity and poorly defined portal vessels are seen, with increased echogenicity of the portal triads (e-Fig. 87.9A). If associated with Caroli syndrome, large ectatic biliary cysts are seen encircling irregular portal vein radicals. When portal hypertension supervenes splenomegaly, multiple collaterals bypassing the hepatic sinusoids can be seen with US but are more easily and completely revealed with contrast-enhanced CT or MRI. CT and MRI reveal areas of hepatic parenchymal heterogeneity with variable CT attenuation (e-Fig. 87.9B) and T1 and T2 MRI parenchymal signal.[14] MR angiography can demonstrate the vascular sequelae of portal hypertension, and MRCP is useful to ascertain the anatomy of the biliary tree.[27,30] MR elastography can be used to detect the presence of fibrosis and quantify it.[32]

***Treatment.*** Medical management of hepatic fibrosis and portal hypertension consists of diuretics as first-line pharmacotherapy used to reduce ascites and increase glomerular filtration. When hepatic cirrhosis and portal hypertension become severe, hepatic transplantation may be required.

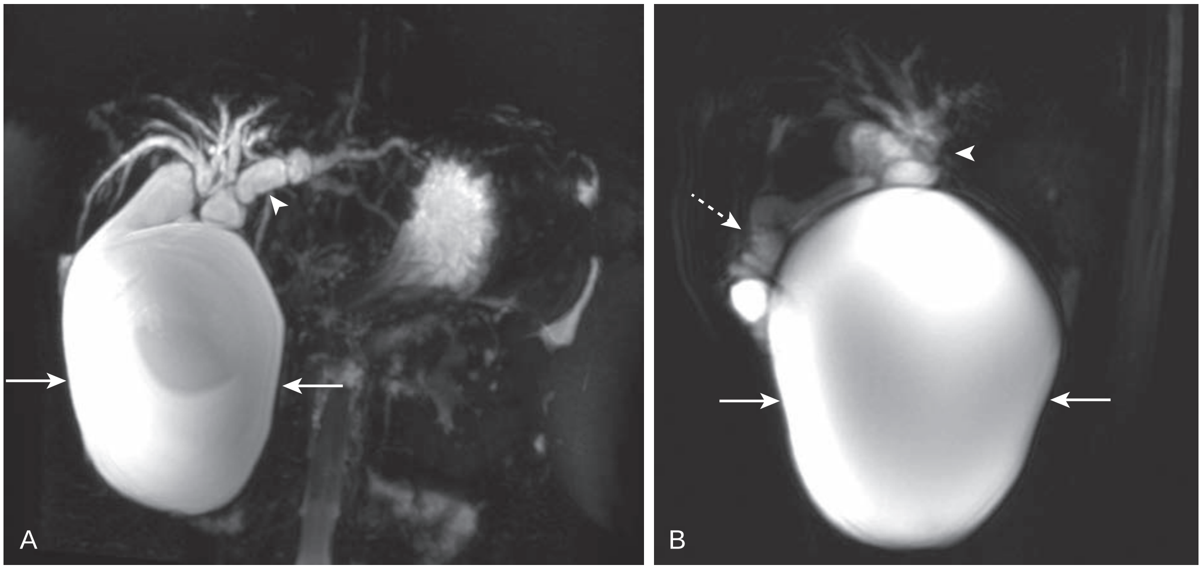

**Figure 87.5. Choledochal cyst type I in a 13-year-old girl with abdominal pain.** Frontal (A) and lateral (B) maximum intensity projection (MIP) images from 3D MRCP demonstrate a large choledochal cyst involving almost entire extrahepatic bile duct *(arrows)*. There is mild dilatation of central intra-hepatic ducts *(arrowhead)* from stasis related to the cyst. *Dashed arrow* on (B) = gallbladder.

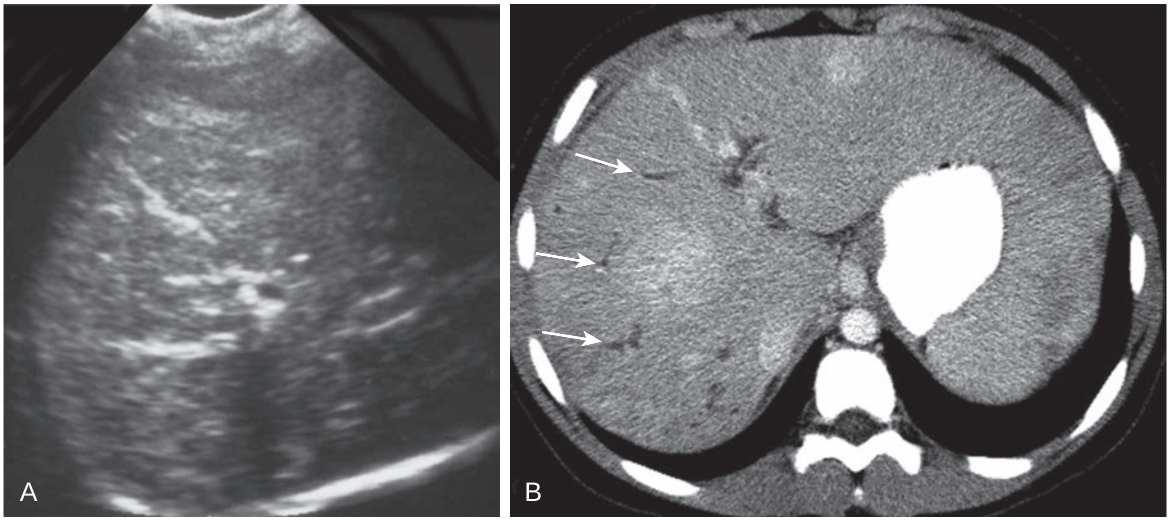

**e-Figure 87.9. Congenital hepatic fibrosis complicated by portal hypertension in a 12-year-old girl.** (A) Transverse sonogram shows heterogeneous increased periportal echogenicity of the liver due to advanced fibrosis. (B) Axial contrast enhanced CT images show heterogeneous hepatic enhancement and linear branching hypoattenuating tubular structures indicating ductal dilatation *(arrows)*. Extensive collateral vessels caused by portal hypertension were also present *(not shown)*.

## BILIARY HAMARTOMAS

***Overview.*** Biliary hamartomas, also known as microhamartomas and Von Meyenburg complex,[33] are rare and result from ductal plate malformations of the small bile ducts. They are usually multiple and typically without associated abnormalities, although they can at times coexist with simple hepatic cysts, Caroli disease, or polycystic kidney and congenital hepatic fibrosis.[31,34] Patients usually have many well-defined, similar-sized lesions measuring less than 15 mm; their uniform size helps distinguish these lesions from metastatic disease, although biopsy is required in some cases.[14,35] Because microhamartomas are small in size, they are usually asymptomatic. There is a small increased risk of hepatobiliary carcinomas.[14]

***Imaging.*** Biliary hamartomas are seen sonographically as multiple tiny hypo- or hyperechoic foci with some showing comet tail artifact scattered throughout the liver.[36,37] There is often increased heterogeneity of the hepatic architecture.[35] On CT, the lesions are of low attenuation, and of decreased signal on T1- and increased signal on T2-weighting on MRI[14] (e-Fig. 87.10).

***Treatment.*** The majority of biliary hamartomas are asymptomatic, so no treatment is required. However, monitoring with periodic imaging may be useful due to the rare possibility of malignancy.

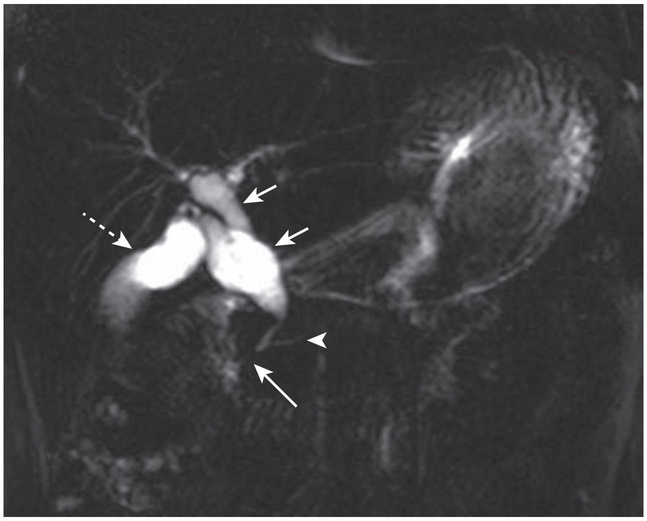

**Figure 87.6. Choledochal cyst with common channel in a 7-year-old girl.** Frontal projection of radial slab MRCP image demonstrates dilatation of extrahepatic bile ducts involving common hepatic, common bile duct, and cystic duct *(short thick arrows)*. The pancreaticobiliary junction is anomalous and away from the duodenal wall with a long common channel *(long thin arrow)*. *Arrowhead* = pancreatic duct; *dashed arrow* = gallbladder.

## BILIARY ATRESIA

***Overview.*** Biliary atresia is the most common cause of neonatal cholestasis and the most common indication for pediatric liver transplantation. Biliary atresia is more common in Asian populations, in particular Chinese and Japanese infants.[38] Biliary atresia is characterized by obliteration or discontinuity of the extrahepatic ducts. The obliteration can involve a segment or entire common bile duct only, but more commonly it also involves right and left hepatic ducts apart from extrahepatic biliary tree. A rare variant of biliary atresia with cyst formation at porta is termed cystic biliary atresia.[39] Biliary atresia can be isolated (neonatal form) accounting for 65% to 90% of cases or associated with congenital anomalies such as situs inversus or polysplenia (fetal/embryonic form) accounting for 10% to 35% cases.

***Etiology.*** The etiology of biliary atresia remains unknown with viral, genetic, toxic, and autoimmune origins suggested as possibilities. Recent theories suggest that biliary atresia and hepatitis are inflammatory cholangiopathies on two ends of a spectrum.[4] With severe inflammation, bile ducts are obliterated and the patient develops biliary atresia. Less severe inflammatory cholangiopathy does not cause duct obliteration, thus hepatitis ensues. Distinguishing between biliary atresia and hepatitis is important to determine therapy.[40]

***Clinical Presentation.*** Biliary atresia usually presents in the first month of life with jaundice, light colored stools, and direct hyperbilirubinemia.[4] Untreated, it progresses to end-stage liver disease and death within the first 3 years of life.[38] The majority

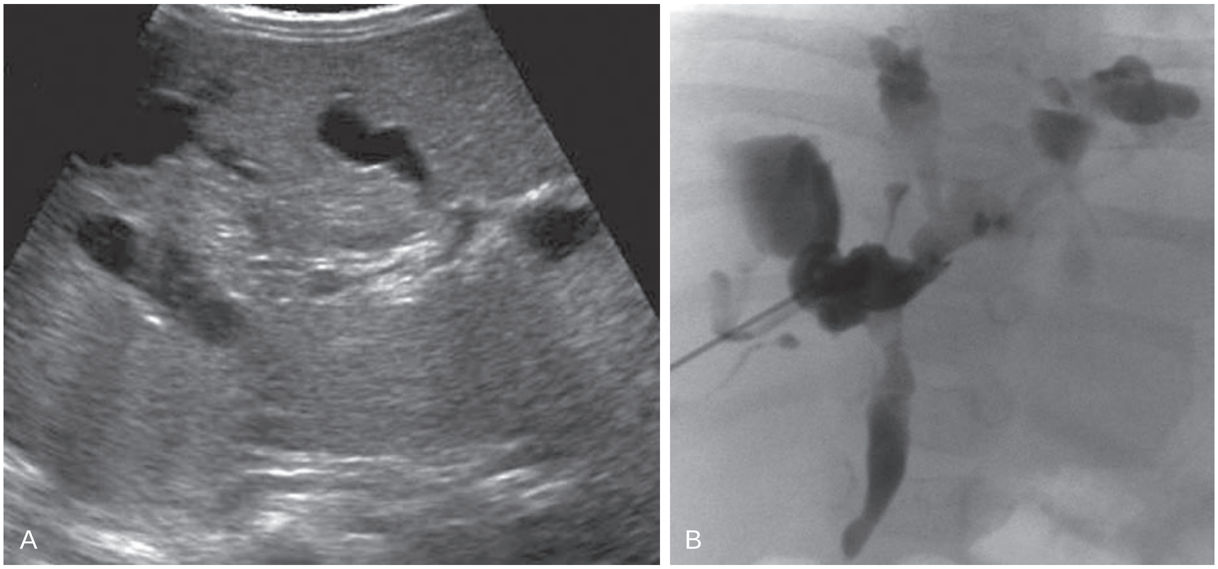

**Figure 87.7. Caroli disease (type V choledochal cyst) in a 6-month-old girl with failure to thrive.** (A) Transverse hepatic sonogram shows multiple large hypoechoic well-defined variably shaped dilatations scattered throughout the liver. (B) Percutaneous transhepatic cholangiogram confirms variable shaped patulous bile lakes connected to the biliary tree.

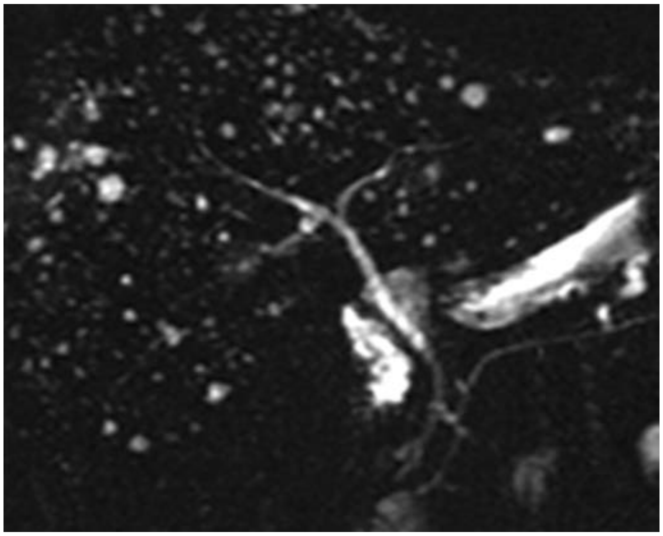

**e-Figure 87.10. Biliary hamartomas.** MRCP demonstrates innumerable small, well-defined hyperintense foci throughout the liver. Note the normal-sized ductal system. *(Image reproduced with permission from Brancatelli G, et al. Fibropolycystic liver disease: CT and MR imaging findings.* Radiographics*. 2005;25(3):659–670.)*

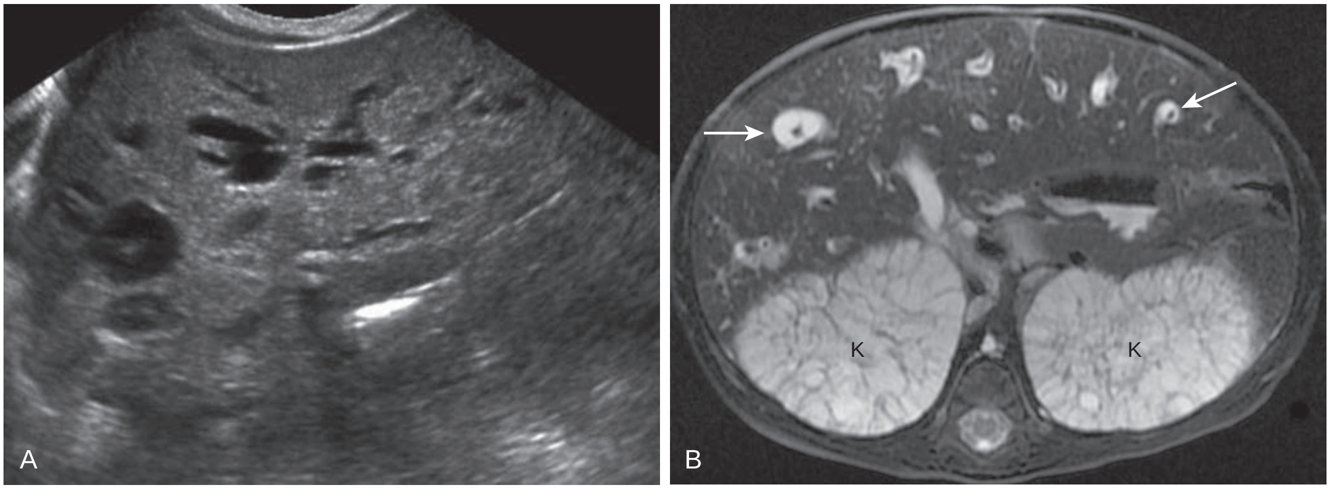

**Figure 87.8. Caroli disease (type V choledochal cyst) in a 3-day-old girl with organomegaly and associated autosomal recessive polycystic kidney disease.** (A) Longitudinal sonogram through the liver shows focal dilatation of the biliary ducts throughout the liver. (B) Axial T2-weighted MR image shows the central dot sign, seen as numerous T2 bright distended bile ducts each surrounding a portal vessel *(arrows)*. Associated enlarged polycystic kidneys *(K)* are also seen.

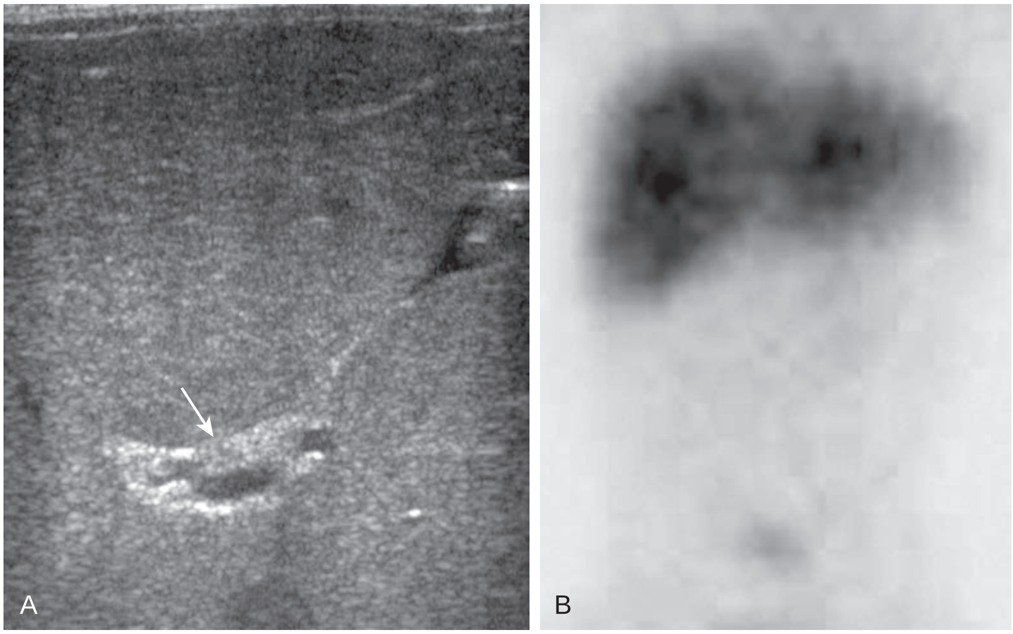

**Figure 87.11. Biliary atresia in a 2-month-old boy with persistent jaundice.** (A) Transverse image at the porta hepatis shows increased echogenicity along the expected course of the common bile duct and common hepatic ducts indicating the "triangular cord sign" *(arrow)*. Small (9 mm) gallbladder was present *(not shown)*. (B) Delayed image from a technetium-99m–labeled hepatoiminodiacetic acid shows normal radiotracer uptake in the liver, but lack of excretion into the biliary tree. This finding persisted on all images.

of patients develop portal hypertension. Benign and malignant liver tumors can develop in about 8% of children.[41]

***Imaging.*** US is the initial study for neonatal jaundice. Key findings include absent or abnormal morphology of the gallbladder including a small gallbladder (length <15 mm) and presence of a triangular cord sign (>4 mm echogenic tissue anterior to the right portal vein) (Fig. 87.11A).[42] Identification of a triangular cord sign has been cited as 96% accurate for a diagnosis of biliary atresia. Similarly, a small or absent gallbladder has been cited as 73% accurate compared with neonatal hepatitis, where 90% of infants will have a normal gallbladder.[43] Enlargement of the hepatic artery (>1.5 mm in diameter at the porta)[44] and presence of hepatic subcapsular flow[45] have been described as important findings to differentiate biliary atresia from neonatal hepatitis. Accuracy can be improved to 98% when US findings are combined, and most infants with biliary atresia could be identified using US.[46–48] Shear wave elastography has also been shown to have the potential for differentiating biliary atresia from neonatal hepatitis, as neonates with biliary atresia have higher shear wave velocity.[49]

Biliary scintigraphy using $^{99m}$Tc iminodiacetic acid with phenobarbital pretreatment has been used to distinguish biliary atresia and neonatal hepatitis (Fig. 87.11B), although this examination is not necessary in all patients.[50,51] A study without excretion is difficult to interpret, but if there is excretion of radiopharmaceutical into

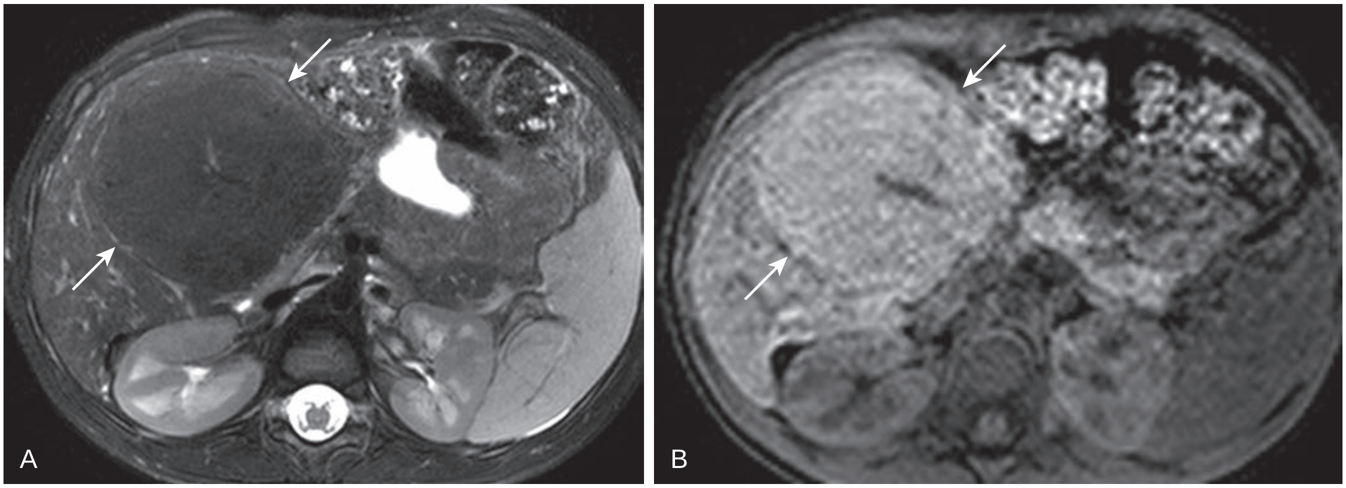

**Figure 87.12. A large regenerative nodule in a 4-year-old child with Alagille syndrome.** (A) Axial T2-weighted and (B) T1-weighted MR images demonstrate a large nodular mass *(arrows)* with vessels running through it. The nodule is hypointense on T2-weighted and hyperintense on T1-weighted images in keeping with regenerative nodule. This nodule is near right portal vein, typical for Alagille syndrome.

the bowel, biliary atresia is excluded. Diagnostic sensitivity and specificity of scintigraphy is reported to be 98.7% and 70%, respectively.[52] Currently, MRCP is limited in evaluation of biliary atresia because of poor visualization of the biliary tree in infants less than 3 months of age[53] and the need for anesthesia. Despite all of the aforementioned imaging techniques, making a definitive diagnosis of biliary atresia can be challenging. In some cases, even biopsy is nondiagnostic and diagnosis is confirmed via intraoperative cholangiogram.[54,55] US-guided percutaneous cholecystocholangiography has been used for the exclusion of biliary atresia and for determining its type.[56] Liver biopsy can be performed under the same anesthesia.

***Treatment.*** Biliary atresia is managed surgically with the Kasai procedure (hepatic portoenterostomy)[57] and neonatal hepatitis is managed medically. It is important to diagnose biliary atresia early because infants less than 2 months of age treated with the Kasai procedure tend to have a good long-term prognosis compared with infants over 2 months of age who often require future liver transplantation.[47]

## ALAGILLE SYNDROME

***Overview.*** Alagille syndrome (arteriohepatic dysplasia) is a multisystem autosomal dominant condition that produces cholestasis from bile duct paucity.[58] It is defined by pathologically proven paucity of intrahepatic biliary ducts, cardiac disease, and involvement of the face, skeleton (usually butterfly vertebrae), and eyes with variable expression of these features.[59,60] Some form of renal anomaly is seen in almost 40% of children with Alagille syndrome.[61]

***Etiology.*** Alagille syndrome is an autosomal dominant genetic disorder primarily caused by *JAGGED 1* gene mutation at the short arm of chromosome 20.[62] In some cases, it is caused by *NOTCH 2* mutation.[62]

***Clinical Presentation.*** Most children with Alagille syndrome present in early infancy with jaundice or cardiac murmur.

***Imaging.*** Imaging plays an important role in excluding structural abnormalities of hepatobiliary system causing cholestasis, showing butterfly vertebrae, and assessing the cardiac anomalies including pulmonary artery stenosis. Spine radiographs and US of the abdomen are the initial imaging methods. The common bile duct and gallbladder are normal in the majority of cases. US may show heterogeneity and coarsening of parenchyma suggesting fibrosis/cirrhosis with or without signs of portal hypertension.[63] Focal hepatic lesions can be seen in older children, with the most common being large regenerative nodules adjacent to right portal vein[63,64] (Fig. 87.12). These patients are predisposed to multisystemic vascular anomalies including aortic coarctation, renal artery stenosis, aneurysms, and moyamoya disease; vascular disease can account for up to 34% of mortality in these patients.

***Treatment.*** Medications such as ursodiol can be used to promote bile flow. Bile duct paucity and hepatic fibrosis increase with age in Alagille syndrome, and approximately 21% cases ultimately require liver transplantation.[60]

### KEY POINTS

- Fibropolycystic liver diseases are caused by mutation of the *PKHD1* gene and are associated with faulty development of the embryonic ductal plates and renal disorders including ARPKD.
- Anomalous union of the pancreatic and biliary ducts results in a common channel. Reflux of pancreatic enzymes into the biliary system and bile into the pancreatic duct through this common channel predisposes to formation of choledochal cysts and pancreatitis.
- In utero biliary ductal inflammation causes a spectrum of cholangiopathic injury ranging from mild, self-limited hepatitis up to complete ductal obliteration and biliary atresia.
- US diagnosis of biliary atresia is 98% accurate when using a combination of the triangular cord sign and gallbladder size of less than 15 mm, which individually are 96% and 73% accurate, respectively.
- Alagille syndrome is a multisystem condition that includes cholestasis from bile duct paucity and has an association of multiorgan vasculopathy.

# Acquired Biliary Tract Disease

Govind B. Chavhan

## CHOLELITHIASIS AND CHOLEDOCHOLITHIASIS

***Overview.*** Cholelithiasis, previously thought rare in children without hemolytic anemia, is diagnosed with increasing frequency since the increased ultrasound use. Gallstones have been reported in the fetus, although most resolve spontaneously.[1]

Development of gallstones in infants may be related to immature physiologic regulation of bile salt secretion. Chronic cholestasis likely plays a role in the pathophysiology of cholelithiasis. Although infantile gallstones are often discovered incidentally, many predisposing conditions have been described (Box 88.1). Infantile gallstones resolve spontaneously less often than in the fetus and are rarely complicated by biliary tract perforation and peritonitis.[2]

Although most gallstones seen in older children are idiopathic, a number of underlying states are associated (Box 88.2). Prominent among these are sickle cell disease and intestinal problems that interfere with normal enterohepatic circulation.[3] Patients with sickle cell disease have an increased incidence of gallstones with advancing age. Gallstones have also been reported after surgery and antibiotic therapy.[4]

***Clinical Presentation.*** Cholelithiasis is usually asymptomatic in most infants and young children with an increased incidence of symptoms in older children. When symptoms occur in older children and adolescents, they are similar to those seen in adults and include bloating, nausea, vomiting, and postprandial right upper quadrant colicky pain radiating to the shoulder. Younger children may present with nonspecific symptoms such as irritability and may be unable to verbalize or relate their discomfort to the right upper quadrant or to a recent meal.[5]

Choledocholithiasis results from migration of stones from the gallbladder into the common duct. Stones are more likely to be symptomatic when they pass into the cystic duct or the common bile duct. The most common complication of gallstones in children is pancreatitis,[5] although the most common cause of pancreatitis is idiopathic or posttraumatic.[6]

***Imaging.*** While radiolucent cholesterol stones are the most common type overall, they are rare in children and many pediatric gallstones are visible radiographically. Even so, sonography remains the primary imaging modality for the evaluation of cholelithiasis. Gallstones are seen as echogenic focus with posterior acoustic shadowing (Fig. 88.1), and most demonstrate twinkling artifact on color Doppler images.[7] Most stones move with change in patient position, which should be a routine maneuver during hepatobiliary sonography (Fig. 88.2). Four general sonographic patterns of cholelithiasis are described here.

The first is the simple echogenic, shadowing, mobile stone, which may be single or multiple. The second describes collections of very tiny, sandlike stones, termed *milk of calcium*, which may mimic gallbladder sludge. Acoustic shadowing may be seen only in the aggregate (see Fig. 88.2).[8] Third, if bile within the gallbladder is of high density, stones may seem to float on the surface, giving an apparent fluid-fluid level. The fourth pattern of cholelithiasis relates to stones within a contracted gallbladder when the stones produce an echogenic double arc known as the wall echo shadow (WES) complex. This pattern may also be seen in patients who have not fasted sufficiently (Fig. 88.3). Careful scrutiny must be employed so as not to confuse the WES complex with emphysematous cholecystitis, which is far more common in adults than in children.[9]

Sonography is less successful detecting choledocholithiasis than cholelithiasis due to interference from adjacent bowel gas. Dilated bile ducts (Fig. 88.4) may be the only sonographic sign of a more distal obstructing stone. If no stone is seen on sonography, yet there is evidence of biliary ductal dilation, magnetic resonance cholangiopancreatography (MRCP) is the next modality of choice. With MRCP, most stones are seen as hypointense filling defects within the gallbladder and the biliary tree[10] (Fig. 88.5). Some stones, such as pigment stones, are hyperintense on T1-weighted 3D gradient echo sequences.[11,12]

***Treatment and Follow-up.*** Treatment of infantile gallstones is generally conservative and includes addressing the underlying cause of disease. Surgery, particularly laparoscopic surgery, is the usual treatment of choice for symptomatic patients and patients with choledocholithiasis.[13] Obstructive stones in the distal common bile duct (CBD) may be treated via endoscopic retrograde cholangiopancreatography (ERCP).

## BILIARY SLUDGE

***Overview.*** Biliary sludge, particulate matter within the bile produced by cholestasis, is of debated clinical significance. Although the majority of biliary sludge is a transient finding, particularly if associated with a transient predisposing condition, it may evolve into gallstones.[14] Occasionally, the sludge itself may cause obstructive jaundice, which is termed as inspissated bile syndrome.

Sludge is formed predominantly of calcium bilirubinate particles and, depending on the underlying process, cholesterol crystals. Predisposing conditions that share the common pathway of biliary stasis include biliary outflow obstruction, intravenous hyperalimentation, hemolysis, treatment with ceftriaxone, and prolonged fasting.[15,16]

***Clinical Presentation.*** Biliary sludge is usually asymptomatic; however, it may cause symptoms if associated with microlithiasis or if "bile balls" course into the biliary ducts. When this happens, symptoms are similar to those produced by cholelithiasis.[14]

***Imaging.*** On sonography, sludge is echogenic without acoustic shadowing; it typically layers in the dependent portion of the gallbladder or other part of the biliary tree, such as a choledochal cyst, and demonstrates a fluid-sludge level (e-Fig. 88.6). Inspissated bile may be slightly more echogenic than regular sludge, but it does not cause any posterior acoustic shadowing.[2] Occasionally, sludge coalesces within the gallbladder lumen, forming a tumefactive "sludge ball" that, when fixed, may mimic a polyp or mass.[9] Differential considerations include uncommon conditions such as hemobilia, biliary mucus, and parasitic infection.

***Treatment and Follow-up.*** Because biliary sludge is generally asymptomatic and resolves spontaneously with resolution of the underlying condition, it does not require separate treatment. However, follow-up in patients in whom the underlying condition does not remit is important, particularly if the patient becomes symptomatic.[14] Inspissated bile syndrome may resolve with removal of predisposing factors but has also been treated with mucolytic agents and laparoscopic surgery.[16,17]

## ACUTE CHOLECYSTITIS

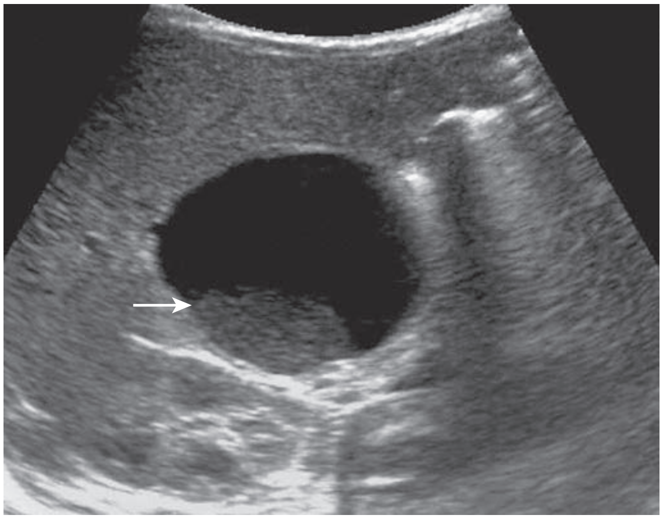
***Overview.*** Acute cholecystitis is uncommon in infants and children compared with adults. However, it has a mortality rate

## Abstract:

In this chapter, some acquired biliary tract diseases affecting children are discussed. These include cholelithiasis and choledocholithiasis, biliary sludge, acute cholecystitis, acute cholangitis, primary sclerosing cholangitis and gallbladder hydrops.

## Keywords:

cholelithiasis
choledocholithiasis
biliary sludge
acute cholecystitis
acute cholangitis
primary sclerosing cholangitis
gallbladder hydrops



**e-Figure 88.6. Biliary sludge in a 1-year-old boy with a choledochal cyst.** Transverse sonogram shows layering echogenic material within the cyst *(arrow)*; its echogenicity, which is less than that of a stone, and lack of shadowing, distinguish it from a calculus.

### BOX 88.1 Conditions Associated With Development of Gallstones in Infants

- Obstructive congenital biliary tree anomalies
- Total parenteral nutrition
- Diuretics (furosemide)
- Gastrointestinal dysfunction (short-gut syndrome or terminal ileal disease)
- Prolonged fasting
- Phototherapy
- Dehydration
- Infection
- Hemolytic anemia
- Umbilical venous catheterization
- Antibiotics

### BOX 88.2 Conditions Associated With Development of Gallstones in Children

- Sickle cell disease
- Cystic fibrosis or other pancreatic disease
- Malabsorption
- Total parenteral nutrition
- Inflammatory bowel disease (Crohn disease)
- Short-gut syndrome (intestinal resection)
- Hemolytic anemia
- Choledochal cyst
- Antibiotics

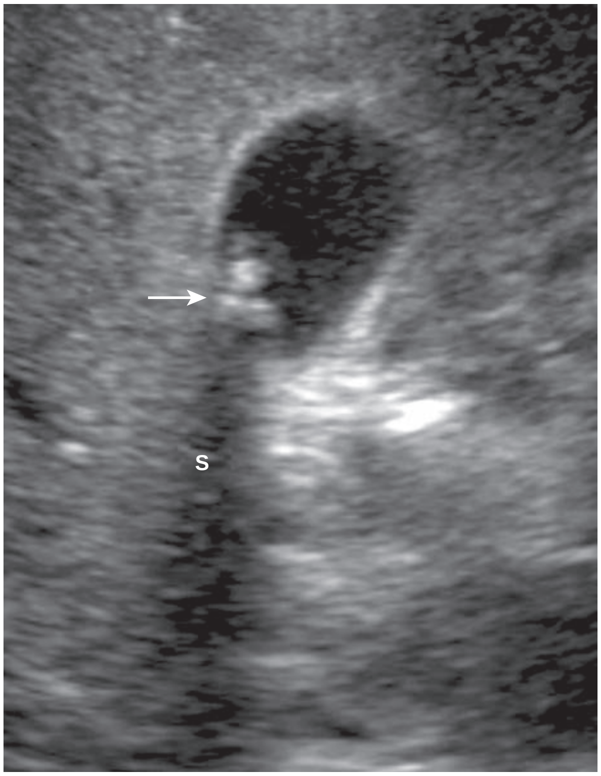


**Figure 88.1. Cholelithiasis in a 17-year-old girl with abdominal pain.** Transverse sonogram of the gallbladder shows cholelithiasis *(arrow)* with associated posterior acoustic shadowing *(S)*.

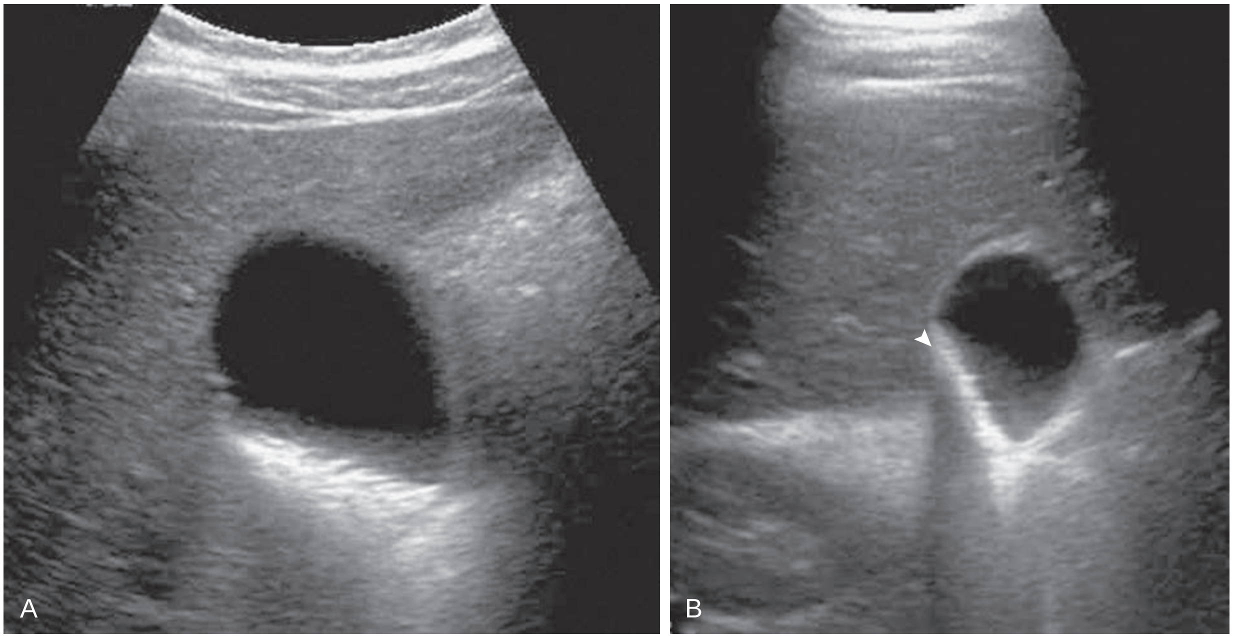

**Figure 88.2. Cholelithiasis in a 16-year-old girl with right upper quadrant pain.** Transverse sonograms in the supine (A) and decubitus (B) positions reveal echogenic layering of tiny stones. Note the change in stones with change in patient position, as well as diffuse shadowing of the stone aggregate (*arrowhead* in B).

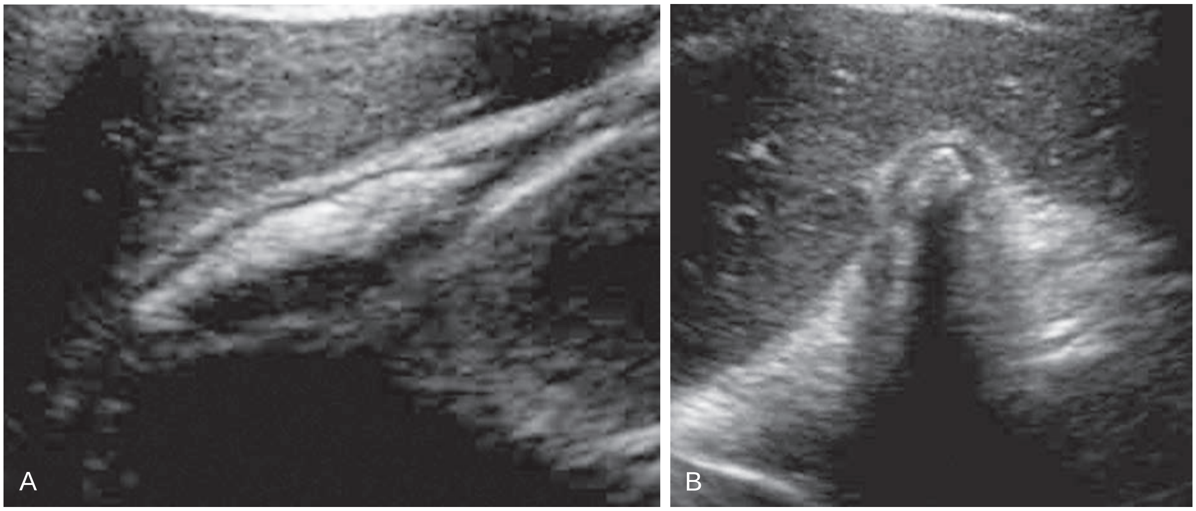

**Figure 88.3. Cholelithiasis in a 16-year-old girl with abdominal pain.** Longitudinal (A) and transverse (B) sonograms performed without fasting show the anterior gallbladder wall and multiple echogenic stones with posterior acoustic shadowing (wall-echo-shadow [WES] triad).

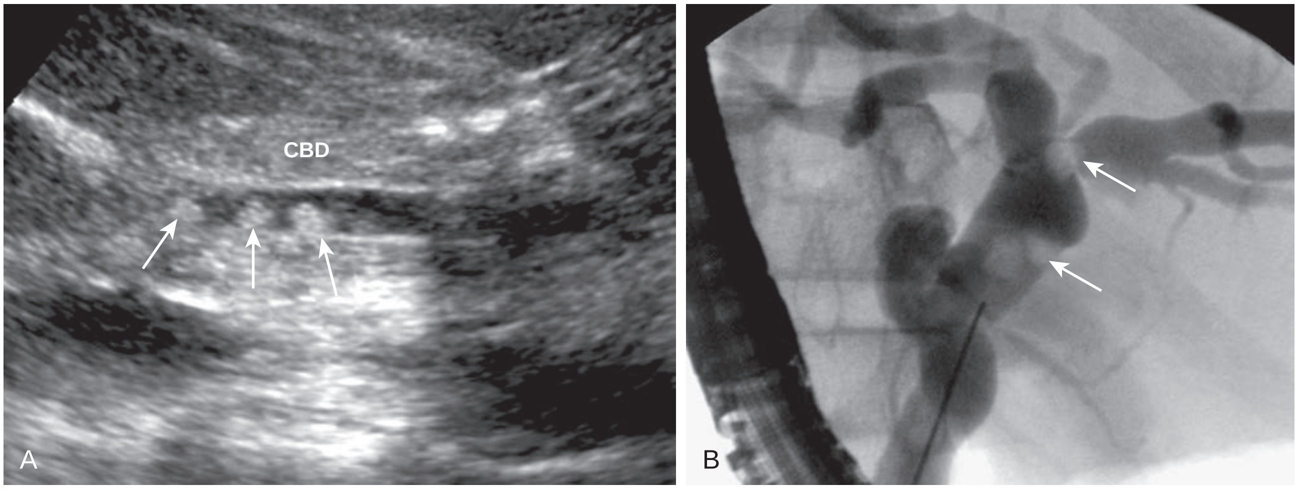

**Figure 88.4. Choledocholithiasis in a 15-year-old girl with sickle cell disease and abdominal pain.** (A) A sonogram of the common bile duct *(CBD)* reveals three stones *(arrows)*. (B) Subsequent ERCP shows dilated bile ducts and intraluminal filling defects *(arrows)*.

of at least 30% due to the potential for rapid progression with gangrene occurring in greater than 50% and perforation in greater than 10% of cases.[18]

***Etiology.*** A small percentage of children with cholelithiasis develop cholecystitis, and acute acalculous cholecystitis represents 50% to 70% of all cases of cholecystitis in children.[19] In most cases, the pathophysiology of acute cholecystitis involves obstruction of the cystic duct, which leads to gallbladder distension, followed successively by edema, ischemia, mural necrosis, and, in severe cases, perforation. The pathophysiology of acalculous cholecystitis is thought to involve biliary stasis, dehydration, gallbladder ischemia, and elevated ampullary pressures as contributing factors.[18] In neonates with acute cholecystitis, the diagnosis may not be suspected, leading to a high mortality rate. Acute acalculous cholecystitis in children can be caused by systemic infectious diseases and a variety of noninfectious systemic diseases including Kawasaki disease.[20] The majority of infectious causes are viral and include hepatitis A and Epstein–Barr.[21,22]

***Clinical Presentation.*** Diagnosing acalculous cholecystitis can be difficult. The condition is most dangerous when it occurs during a serious illness, as the underlying illness may mask clinical symptoms and laboratory abnormalities. Patients who may develop acalculous cholecystitis include patients with septicemia, postoperative patients, and patients who have sustained severe trauma or burns. Systemic infection may be more common in pediatric patients. Symptoms include jaundice, nausea, vomiting, and tenderness to palpation, and there may be fever and leukocytosis.[14,18,19,23]

***Imaging.*** The sonographic findings of calculous and acalculous cholecystitis are identical except for the lack of gallstones in the latter condition. Sonographic findings of cholecystitis when viewed individually are nonspecific, but when combined, they may indicate a specific diagnosis.[24] Ultrasound, in general, has low sensitivity and positive predictive value for the diagnosis of cholecystitis, which, according to some authors, is related to a higher prevalence of chronic cholecystitis.[25] The best indicators of acute cholecystitis include cholelithiasis, a sonographic Murphy sign (tenderness when the gallbladder is compressed with the ultrasound probe), and gallbladder wall edema with wall thickening >3.5 mm[18,26] (Fig. 88.7). Intramural edema related to acute cholecystitis is usually striated, with multiple interrupted bands of hypoechogenicity. This

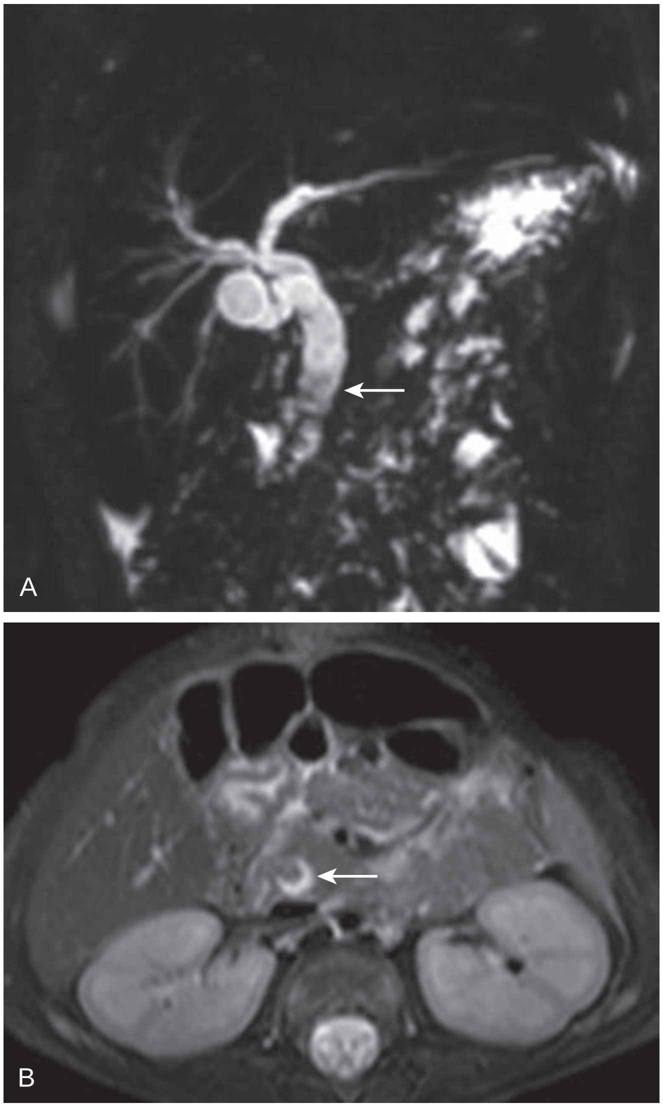

**Figure 88.5. Choledocholithiasis in a 3-month-old baby with prior history of congenital diaphragmatic hernia.** 3D reformatted T2-weighted sequence from an MRCP (A) shows subtle filling defect consistent with a stone *(arrow)* in the distal common bile duct. Axial T2-weighted thin section (B) confirms a hypointense filling defect in the distal CBD *(arrow)*.

appearance has also been associated with gangrenous cholecystitis. This should not be confused with homogeneous gallbladder wall thickening, a common nonspecific finding seen in a variety of disorders such as ascites, hypoalbuminemia, congestive heart failure, hepatitis, portal hypertension, and gallbladder wall varices. Other sonographic findings of acute cholecystitis include gallbladder distension, pericholecystic fluid (especially with perforation), adjacent rim of hypoechogenicity or hypervascularity in the liver, biliary sludge, and rarely dirty shadowing due to air-producing infection (found most often in adults with diabetes). Computed tomography (CT) is not the modality of choice in most pediatric patients with cholecystitis, but if performed for other reasons, it shows similar findings (e-Fig. 88.8).

Hepatobiliary scintigraphy with technetium-99m–labeled iminodiacetic acid derivatives is highly sensitive for the diagnosis of acute cholecystitis. Normally, radiopharmaceutical appears in the gallbladder in the first 30 minutes of the study or in the first hour with slow injection of intravenous (IV) morphine. In acute cholecystitis, gallbladder filling does not occur in the first 30 minutes or within 1 hour after IV morphine. Occasionally, a rim of increased activity is seen in the liver surrounding the gallbladder (the rim sign), and peritoneal activity may be seen with perforation[27] (Fig. 88.9).

***Treatment and Follow-up.*** Treatment for acute acalculous cholecystitis may differ depending on patient's clinical status and underlying conditions. Children may be treated medically and observed before surgery.[23,28] Percutaneous cholecystostomy is increasingly a lifesaving, minimally invasive alternative. Gallbladder perforation is a surgical emergency that occurs in 3% to 15% of patients with acute cholecystitis.[29]

## CHOLANGITIS

***Overview and Etiology.*** Cholangitis refers to acute or chronic inflammation of bile ducts. Acute cholangitis is a potentially life-threatening infection of the biliary tract associated with some form of biliary obstruction and presents with fever, chills, right upper quadrant pain, and jaundice.[30] Causes of obstruction include gallstones, benign and malignant strictures, structural abnormalities of the biliary tree, and iatrogenic causes such as sphincterotomy and choledochoenterostomy.[31] Cholangitis can be seen in endemic areas from parasitic infestations such as ascariasis,[32] liver fluke (fasciola),[33] clonorchiasis,[34] and schistosomiasis.[35] Acute bacterial cholangitis is rare in children.

***Imaging.*** Imaging demonstrates biliary dilatation and may demonstrate the cause of obstruction and complications such as cholangitic abscesses. A syndrome of recurrent bacterial cholangitis (Oriental cholangitis) is typically seen in Asia and is characterized by biliary dilatation, strictures, and intraductal stone formation.[36]

***Treatment.*** Appropriate therapy is directed toward relief of the underlying cause of obstruction, whether congenital or acquired, and any associated infection.

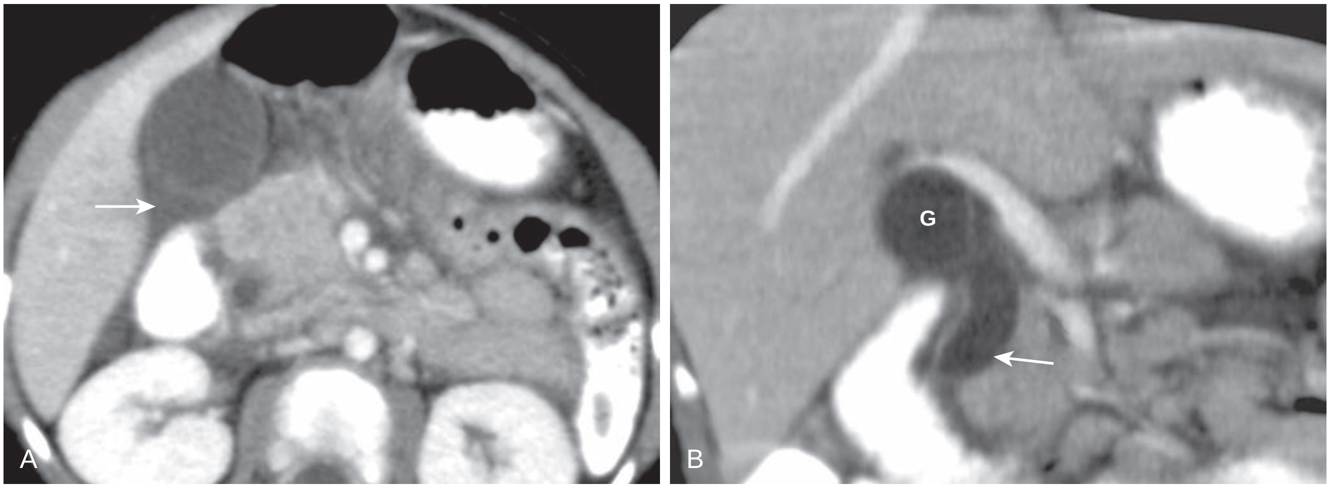
## PRIMARY SCLEROSING CHOLANGITIS

***Overview.*** Primary sclerosing cholangitis (PSC) is a chronic fibrosing inflammation of the bile ducts leading to obliteration of the bile duct lumen and cholestasis.[37,38] It involves both intra- and extrahepatic ducts that can show multifocal strictures. Even though uncommon in children as compared with adults, PSC is one of the common indications for pediatric liver transplantation.[37] It is a progressive disorder that eventually leads to cirrhosis, portal hypertension, and hepatic decompensation in most patients. Development of cholangiocarcinoma in long-standing cases of PSC is rare in children as compared with adults but can be occasionally seen.[39]

***Etiology.*** PSC is likely an immune-mediated disorder.[37] It may overlap with other autoimmune conditions such as autoimmune hepatitis in 35% to 58% of cases.[40,41] It is associated with inflammatory bowel disease (IBD) in 60% to 80% of children,[37,40,41] mainly those with ulcerative colitis. Approximately 10% of children with ulcerative colitis develop PSC.[39] Sclerosing cholangitis associated with immune deficiency states, Cryptosporidium infection, Langerhans cell histiocytosis, sickle cell anemia, Hodgkin disease, and cystic fibrosis is generally regarded as being "secondary sclerosing cholangitis."[42]

***Clinical Presentation.*** Boys are affected more often than girls and typically present in the second decade of life. Presentation is with jaundice, abdominal pain, and hepatomegaly. Alkaline phosphatase levels may be normal or elevated. Gamma glutamyltranspeptidase (GGT), alanine aminotransferase (ALT), and aspartate aminotransferase (AST) enzyme levels are elevated. In many instances, elevation of liver function tests in asymptomatic children with IBD leads to the diagnosis of PSC.

***Imaging.*** Sonography is usually the initial imaging method in evaluation of suspected PSC. It excludes other obstructive causes such as stones and choledochal cyst. It may show mild dilatation



**e-Figure 88.8. Cholecystitis and ascending cholangitis in a 25-month-old boy with subsequent confirmed passage of a gallstone.** (A) Axial contrast-enhanced CT image demonstrates pericholecystic edema *(arrow)* on the axial image. (B) Coronal reformatted image demonstrates a distended gallbladder *(G)* and dilation of the common bile duct *(arrow)*.

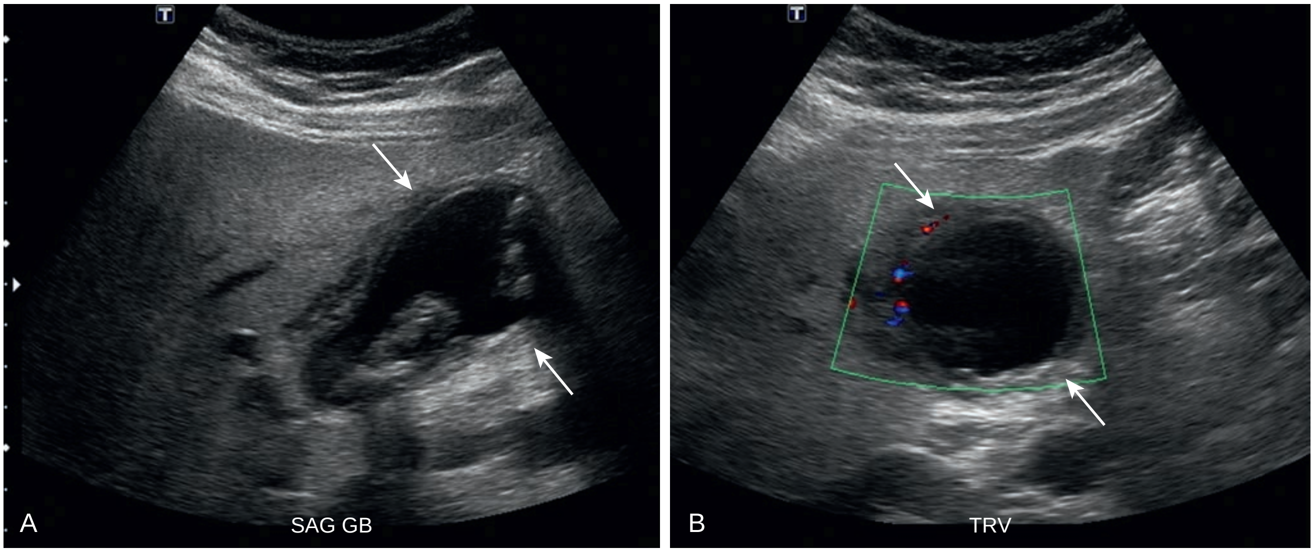


**Figure 88.7. Acute cholecystitis in a 17-year-old girl with a history of cholelithiasis.** Longitudinal (A) and transverse (B) sonogram through the gallbladder reveals a thickened, edematous gallbladder wall with multiple stones in the lumen *(arrows)*. Color Doppler image (B) demonstrates hyperemia of the thickened gallbladder wall.

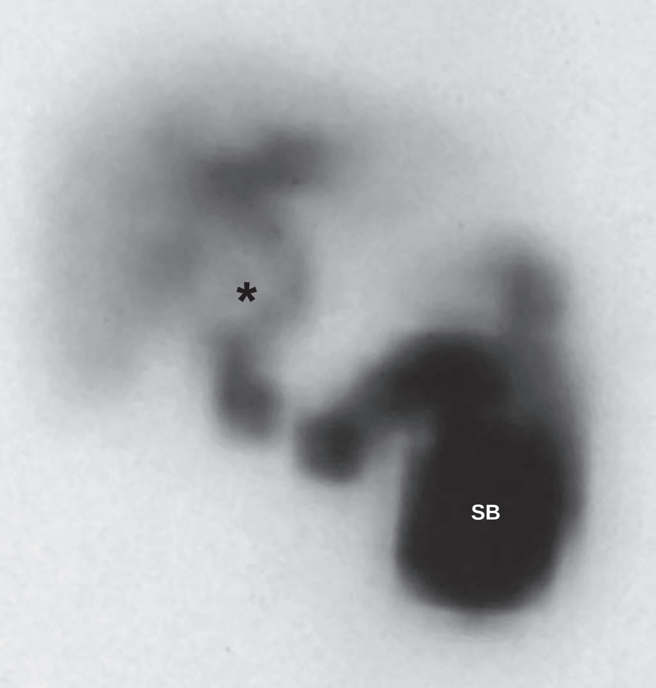

**Figure 88.9. Acute cholecystitis in a 15-year-old girl with a history of cholelithiasis.** Four-hour image from a biliary patency scan shows hepatic uptake and excretion of technetium-99m–labeled iminodiacetic acid into the biliary tree and small bowel *(SB)* without gallbladder *(asterisk)* opacification. A halo of increased activity surrounds the gallbladder fossa known as the rim sign is suggestive of hyperemia.

of ducts. Thickening of wall of the CBD is a very specific finding for PSC but may have limited sensitivity. MRCP is the modality of choice for the diagnosis of PSC in children and has replaced ERCP.[38] MRCP has been found to be 84% sensitive and accurate in the diagnosis of PSC.[38] Findings in early stages include mild diffuse dilation of the entire biliary tree with subtle irregularity of the duct outline, portal lymphadenopathy, and increased periportal signal abnormality on T2-weighted images (Fig. 88.10). As the disease progresses, irregularity of the duct wall increases with intermittent ductal dilation and narrowing. In advanced stage, there is severe structuring of the ducts with a “beaded appearance” (Fig. 88.11). Sacculations and pseudodiverticula formation is usually not seen in children. It is important to identify any dominant stricture on MRCP that can be treated. Liver parenchymal changes also progress from nonspecific increased periportal signal abnormality and heterogeneity of the parenchyma to frank imaging features of fibrosis/cirrhosis of the liver with portal hypertension. Although cholangitis is occasionally segmental, the entire biliary tract is usually involved. The intrahepatic ducts are involved in 100% of cases while the extrahepatic ducts are involved in 60%.[43] The gallbladder is rarely involved.

A variant of PSC with typical cholestatic and histologic features of PSC but without any cholangiographic abnormalities is called “small duct PSC.”[37] It accounts for about 6% to 10% of cases in children.[44]

***Treatment and Follow-up.*** PSC is a progressive disease ultimately resulting in cirrhosis and portal hypertension and may be complicated by superimposed infective cholangitis and cholangiocarcinoma. Treatment includes medical therapy (ursodeoxycholic acid), interventional dilation of dominant strictures, and drainage of infected obstructed ducts. Most patients eventually require liver transplantation. The median reported time until liver transplantation is approximately 12.7 years.[40,45] Recurrence of PSC can be seen in 10% of liver grafts.[46]

## HYDROPS OF THE GALLBLADDER

***Overview.*** Gallbladder hydrops refers to marked dilatation of gallbladder from accumulation of the sterile nonpigmented mucin. It is a rare cause of right upper quadrant mass in children.

***Etiology.*** Thought to be related to transient cholestasis and obstruction of the biliary tree, gallbladder hydrops is associated with preceding infectious disorders elsewhere in the body (Box 88.3), most notably mucocutaneous lymph node syndrome (Kawasaki disease) and parenteral hyperalimentation. It can also result from chronic obstruction of cystic duct.

***Clinical Presentation.*** Hydrops of the gallbladder is more frequent in boys and most commonly presents from ages 17 months

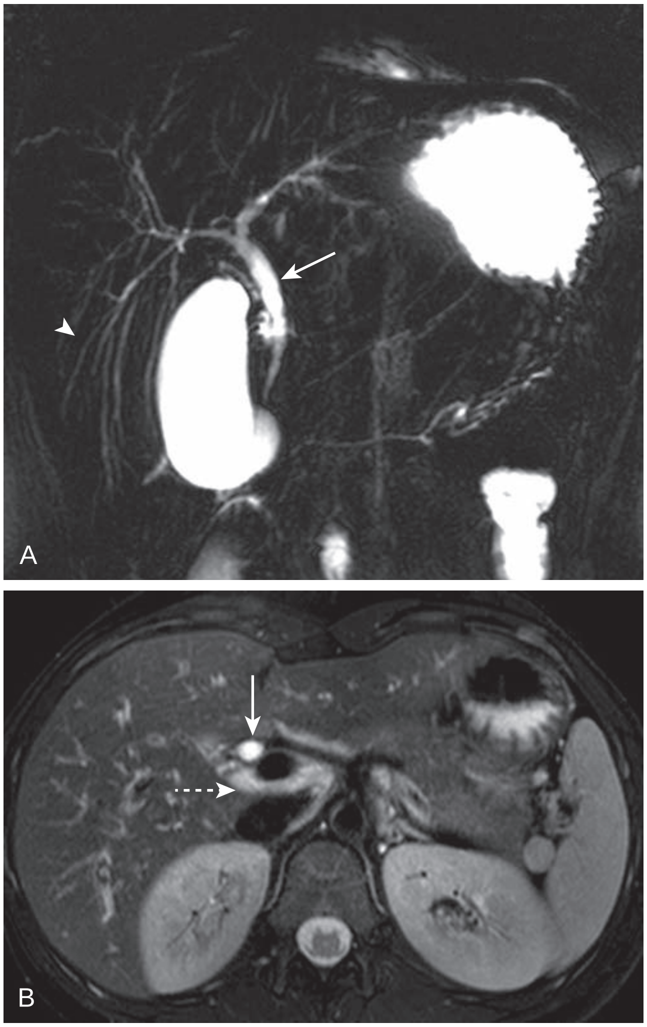

**Figure 88.10. Early primary sclerosing cholangitis (PSC) in an adolescent boy with ulcerative colitis.** Radial slab MRCP (A) demonstrates diffuse mild dilatation of intrahepatic (*arrowhead*) as well as extrahepatic bile ducts (*arrow*) with subtle irregularity of the outline. T2-weighted axial MR image (B) demonstrates a dilated CBD (*arrow*) and enlarged portal lymph nodes (*dashed arrow*).

**BOX 88.3** Causes of Gallbladder Hydrops

Mucocutaneous lymph node syndrome (Kawasaki disease)
Obstruction
Familial Mediterranean fever
Scarlet fever
Leptospirosis
Ascariasis
Typhoid fever
Sepsis
Total parenteral nutrition

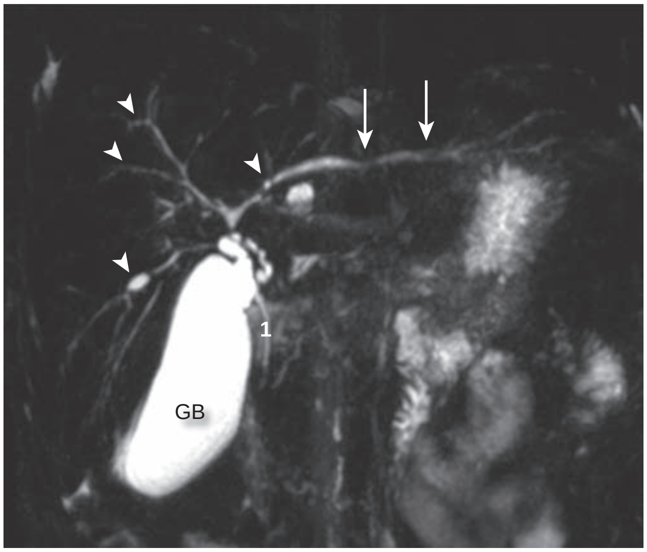

**Figure 88.11. Primary sclerosing cholangitis in a 13-year-old boy with Crohn disease.** A 5-mm-thick maximum intensity projection (MIP) image from 3D MRCP shows multiple areas of beading in the intrahepatic ducts *(arrowheads)*. Areas of low grade narrowing are seen in the left duct *(arrows)*. *1* = common bile duct; *GB* = gallbladder.

to 7 years. Presentation may include jaundice, abdominal pain, right upper quadrant tenderness, vomiting, or a palpable mass.[47]

***Imaging.*** Sonography shows gallbladder dilation without gallbladder wall thickening. The gallbladder may resemble a balloon in which normal contours are lost (e-Fig. 88.12). A normal gallbladder length is 1.5 to 3 cm in infants (<1 year old) and 3 to 7 cm in older children.[48] Maximum gallbladder transverse dimension of greater than 4 cm in adults is diagnostic of hydrops, but there is no data on this in children. Sludge is seen in some cases, and the biliary tree is otherwise normal. Serial sonographic studies may demonstrate resolution of gallbladder hydrops.[49]

***Treatment and Follow-up.*** Hydrops generally responds to conservative therapy, although gallbladder perforation has been reported in Kawasaki disease.[50]

## KEY POINTS

- Cholelithiasis and choledocholithiasis is a significant disease seen with increasing frequency in infants and children with several predisposing causes.
- Acute acalculous cholecystitis is more common in children as compared with calculous cholecystitis. There is a higher mortality in children than adults due to frequent and rapid progression to gangrene and perforation.
- Primary sclerosing cholangitis is a chronic fibrosing inflammation of the bile ducts leading to cholestasis and eventually liver failure.
- MRCP is the current modality of choice for the diagnosis of PSC with an accuracy of 84%, demonstrating mild dilatation of the biliary tree, irregularity of outline in early stage, and severe structuring with beaded appearance in advanced stages.

# Parenchymal Liver Disease

Mougnyan Cox, Monica Epelman, and Daniel J. Podberesky

## INTRODUCTION

Imaging plays a central role in the initial assessment and serial monitoring of chronic pediatric liver disease. While liver biopsy remains the accepted gold standard test for diffuse parenchymal liver disease, a single biopsy specimen only samples 1/50,000 or 0.002% of the liver,[1] and heterogeneity in severity and distribution of disease can result in sampling errors.[2] Liver biopsy is invasive even when done percutaneously, and up to 3% of patients require hospitalization after the procedure.[1] There is also significant variability in interpretation of liver biopsy specimens by pathologists with discordance in up to 33% of cases.[3] For these reasons, noninvasive methods, mainly ultrasound (e-Fig. 89.1) and magnetic resonance imaging (MRI), of assessing response to therapy and disease progression have come to play a prominent role in the management of chronic pediatric liver disease.

## HEPATIC STEATOSIS

***Overview.*** Nonalcoholic fatty liver disease (NAFLD) is the most common cause of chronic pediatric liver disease, with some series listing a prevalence of approximately 10%.[4] NAFLD is defined as the presence of microvesicular/macrovesicular fat in more than 5% of the hepatocytes after the exclusion of significant alcohol consumption, drug use, or other recognizable secondary causes that may result in fatty liver.[5] The prevalence of pediatric fatty liver increases with age and is seen in up to 17% of adolescents.[4] NAFLD is usually diagnosed between 10 and 13 years of age. The majority of patients with NAFLD also have insulin resistance or obesity.[6] NAFLD can range in severity from simple steatosis and nonalchoholic steatohepatitis (NASH), through fibrosis and cirrhosis,[7] but it also may be associated with a number of metabolic processes and toxins (Box 89.1). In addition to fat deposition, NASH patients show hepatic cell injury and inflammation. NASH significantly increases the risks of cirrhosis, hepatic failure, and hepatocellular carcinoma (HCC). At the time of diagnosis, 25% to 50% of children will have NASH, while 10% to 25% will have advanced fibrosis.[8]

***Clinical Presentation.*** Many pediatric patients with NAFLD are either asymptomatic or present with vague clinical complaints (abdominal pain, fatigue). On physical exam, hepatomegaly and acanthosis nigricans are seen in up to 40% of patients.[9] Elevation of liver enzymes is common in NAFLD patients, particularly alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Some NAFLD patients also come to clinical attention after incidental detection of a fatty liver on abdominal ultrasounds performed for other reasons.

***Imaging Findings.*** Diagnostic confidence for fatty liver on ultrasound improves with increasing severity of fatty infiltration, with a sensitivity and specificity of over 90% for moderate steatosis.[10] Deposition of fat in hepatocytes causes increased echogenicity of the liver, manifested as difficulty visualizing the portal triads (Fig. 89.2). There is increased attenuation of the sound beam as it propagates through the liver, causing loss of signal in the posterior portions of the liver and inability to visualize the hemidiaphragm. The liver may be substantially more echogenic than the adjacent right kidney (see Fig. 89.2). Areas of focal fatty sparing manifest as hypoechoic foci within the fatty liver, without mass effect, which could potentially be misdiagnosed as a mass. Ultrasound elastography is a noninvasive method of assessing liver stiffness, which is a correlate for fibrosis.[11] This method has shown promise for severe fibrosis and advanced cirrhosis but is limited in whole liver assessment due to the small acoustic window used for scanning.[12]

Computed tomography (CT) is not routinely used for the primary diagnosis of fatty liver, but this finding may be seen incidentally. Normally, the liver attenuation is at least the same as the spleen. This relationship is reversed in hepatic steatosis, and the liver is of lower attenuation than the spleen on noncontrast CT (e-Fig. 89.3).

Fat deposition in hepatocytes can readily be detected on conventional MR, with a high degree of sensitivity and specificity.[13] More specifically, the amount of fat in the liver can also be quantified using either MR spectroscopy or chemical shift imaging. MR spectroscopy is the most accurate method of hepatic fat quantification and is very sensitive to small changes in hepatic fat concentration.[14] However, the complexity of analysis and lack of reproducibility are barriers to its widespread clinical adoption.

Chemical shift imaging is the mainstay of hepatic fat quantification on MR because it is quick and easy to perform. Chemical shift imaging takes advantage of the different precession frequencies of hydrogen protons in fat and water.[14] When fat and water are present within the same voxel, there is signal loss on the opposed-phase images. Comparing the signal intensity on the opposed-phase image (short TE image) with the in-phase image (long TE image) allows for calculation of the hepatic fat fraction[15] (Fig. 89.4). Hepatic iron deposition may limit evaluation for steatosis on opposed-phase images, as signal loss also occurs from iron-related susceptibility effects. Chemical shift imaging can help resolve confusing patterns of focal fat deposition or fatty sparing in the liver when present in atypical locations. Focal fat deposition commonly occurs in specific locations, usually around the gallbladder, adjacent to the falciform ligament, and in subcapsular regions. Unlike a mass, vessels course through regions of fatty deposition unperturbed.

MR elastography (MRE) measures hepatic parenchymal stiffness using special hardware that generates shear waves and measures their propagation through the liver.[16] The hardware used in pediatric MRE is the same type used in adults, except the driver is set to lower power/amplitude settings.[17] An active driver outside the scanner transmits vibrations at 60 Hz to a passive driver on the patient's right upper quadrant.[13] Four magnitude and four phase images are obtained at four different levels in the liver, and these images are then used to generate qualitative and quantitative stiffness maps using specific postprocessing software.[13] For MRE, liver stiffness values greater than 2.74 kiloPascal (kPa) are suggestive of steatohepatitis and greater than 2.93 kPa is diagnostic for liver fibrosis.[18] Compared with ultrasound elastography, MRE has been shown to be more accurate, samples a larger portion of the liver, has greater reliability, and is less limited by ascites or obesity.[19–21]

***Treatment.*** Lifestyle modification aimed at weight loss is the first-line therapy for NAFLD, and even mild reduction in weight can improve histologic findings of steatosis and steatohepatitis.[22,23] Drugs being investigated include antioxidants such as vitamin E, metformin, and thiazolidinediones.[5] The need for accurate and reliable noninvasive monitoring of NAFLD is imperative given the recent discovery that fibrosis and early cirrhosis may be reversible in some patients.[24–26]

## Abstract:

There are myriad causes of pediatric parenchymal liver disease, of which hepatic steatosis is the most common. The major concern with diffuse parenchymal liver disease is progression to end-stage fibrosis and cirrhosis. As such, early detection and treatment of pediatric liver disease can improve patient outcomes and prolong survival. Liver biopsy remains the gold standard for diagnosis of parenchymal liver disease, but it is not without several shortcomings (sampling error and invasiveness being most prominent). Various imaging modalities can provide important information on the extent of liver involvement and development of complications without the invasiveness of a liver biopsy. Of these noninvasive modalities, MRI provides the most comprehensive evaluation of liver parenchyma. Liver MRI, including advanced MR modalities like spectroscopy and elastography, can provide noninvasive monitoring of disease distribution within the liver, as well as disease progression and response to therapy. In end-stage liver disease, MRI can also monitor for the development of hepatocellular carcinoma, and can help determine eligibility for transplantation when indicated. In this review, we summarize the more common pediatric parenchymal liver diseases encountered at any busy children's hospital, with an emphasis on the imaging appearance of the various diseases. A summary of MR applications in diffuse parenchymal liver disease is also provided.

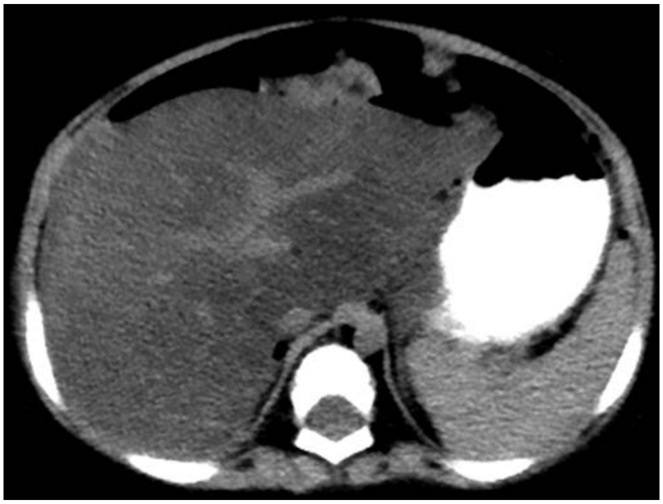
**e-Figure 89.1. Normal liver ultrasound in an 11-year-old girl.** Transverse ultrasound image of the liver shows the normal sonographic appearance of the hepatic parenchyma with visualization of the normal echogenic portal triads. The liver is homogeneous in echotexture with good sound transmission, and the posterior portions of the liver as well as the posterior right hemidiaphragm are well seen.



**e-Figure 89.3. Fatty liver.** This image shows the CT appearance of a fatty liver, with the liver being substantially less dense than the spleen due to the presence of fat in hepatocytes. Note that the liver parenchyma is even less dense than the intrahepatic blood vessels, consistent with severe fatty deposition.

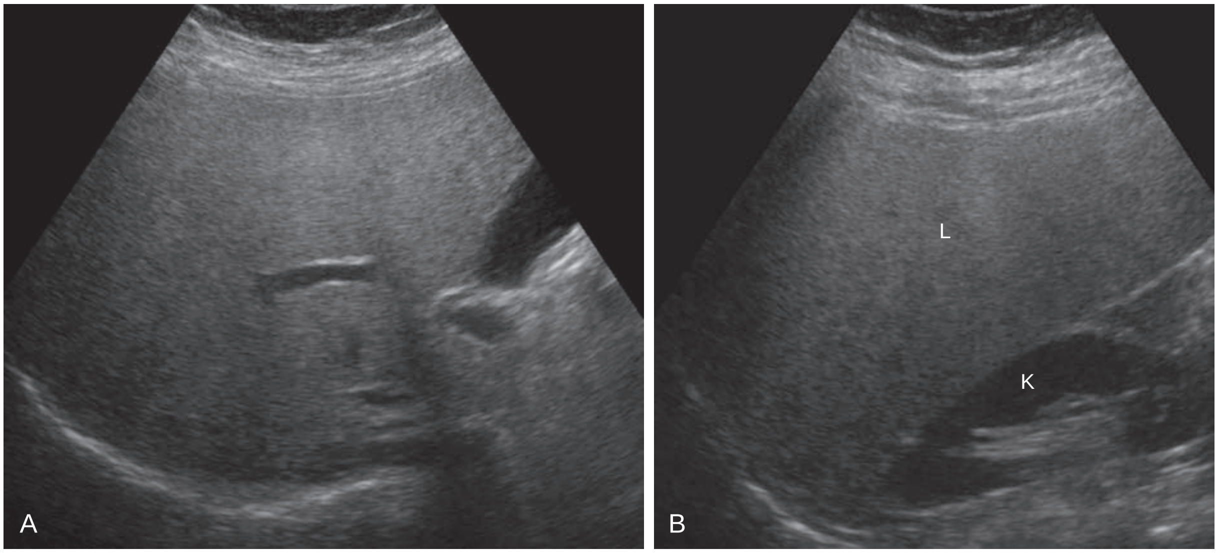


**Figure 89.2. Fatty liver in an 11-year-old girl with NAFLD.** (A) Transverse and (B) longitudinal ultrasound images show diffuse increased echogenicity of the liver *(L)* compared with the kidney *(K)* parenchyma. There is poor visualization of the portal triads. The posterior portions of the liver are less well seen when compared with e-Fig. 89.1, due to decreased sound transmission.

**BOX 89.1** Causes of Hepatic Steatosis

**METABOLIC AND GENETIC DISORDERS**

- Obesity
- Extreme malnutrition
- Total parenteral nutrition
- Cystic fibrosis

**STEROIDS (EXOGENOUS AND ENDOGENOUS; E.G., CUSHING SYNDROME)**

- Familial hyperlipoproteinemia
- Glycogen storage disease
- Wilson disease
- Galactosemia
- Reye syndrome
- Severe hepatitis
- Poorly controlled diabetes mellitus
- Chronic tuberculosis
- Chronic congestive heart failure

**HEPATOTOXINS (MOSTLY ADULTS)**

- Alcohol
- Chemotherapy
- Carbon toxins
- Phosphorus
- Amiodarone

## IRON DEPOSITION IN THE LIVER

***Overview.*** Hepatic iron overload is the result of abnormal intracellular accumulation of iron within the hepatocytes. Normally, excess iron is stored bound to intracellular ferritin. In cases of increased and sustained iron overload, the capacity of ferritin to collect and store iron is surpassed, resulting in deposition of unbound iron primarily in the liver, pancreas, spleen, and bone marrow. Unbound iron may result in cellular injury by reacting with hydrogen and lipids to produce free radicals. In the liver, this can lead to fibrosis and cirrhosis.[13]

There are two main patterns of iron deposition: parenchymal and reticuloendothelial.[27] Parenchymal iron deposition occurs in hereditary hemochromatosis (HH), an autosomal recessive disorder with a gene locus *(HFE)* on the short arm of chromosome 6. There is increased gastrointestinal absorption of iron with eventual pathologic deposition in the liver, pancreas, heart, pituitary, synovium, and other parenchymal organs. Abnormal parenchymal iron deposition results in oxidative injury and organ dysfunction over time, with patients developing liver fibrosis/cirrhosis, cardiomyopathy, and endocrinopathies including diabetes mellitus. Iron deposition in the pancreas is specific for HH, whereas splenic and bone marrow involvement is usually seen with transfusional/reticuloendothelial iron deposition. A neonatal form of primary hemochromatosis exists in which newborns present with fulminant hepatic failure, along with pancreatic and cardiac involvement.

Reticuloendothelial iron deposition occurs mainly after multiple blood transfusions. This form of iron deposition is also referred to as secondary hemochromatosis, and it is more common than the hereditary form. Iron in transfused red blood cells is taken up by reticuloendothelial cells in the liver, spleen, and bone marrow after phagocytosis. Unlike HH, organs other than the liver, spleen, and bone marrow are affected relatively late in the disease. The pancreas is usually spared in patients with reticuloendothelial iron deposition.

***Clinical Presentation.*** Men with HH become symptomatic at least a decade earlier than women (as a result of the protective effect of menstruation) after total body accumulation of approximately 20 g of iron. The most common presenting symptoms are weakness, lethargy, and elevated liver function tests, occurring in 75% of patients.[28] Patients with transfusional iron overload become symptomatic much earlier than in HH because each blood transfusion provides approximately 200 mg of iron, and there is no mechanism for iron excretion in the body other than through sweat, shedding of skin cells, and menstruation (an iron loss rate of approximately 1 mg per day for men and 2 mg per day for premenopausal women).[29] Elevated serum ferritin levels are seen in patients with iron overload, but this finding may also be seen with any inflammatory process, as ferritin is an acute phase reactant. Transferrin saturation levels can also be performed, and levels greater than 60% are over 90% accurate for identifying HH.[30,31] These tests are less helpful for transfusional iron overload. Iron overload occurs in virtually all patients requiring life-long blood transfusions, necessitating careful monitoring and

**Figure 89.4. Fatty liver in an 18-year-old boy with elevated BMI and abnormal liver function tests.** (A) Out-of-phase and (B) in-phase MR images of a fatty liver show extensive fatty infiltration evidenced by loss of signal on the opposed phase image compared with the in-phase image. Notice a large wedge-shaped region of focal fatty sparing involving segments 5 and 8 within the right hepatic lobe. (C) Liver fat fraction was estimated at 17.9% (normal is <5%). (D) MR elastography in this patient shows a mean shear stiffness value of 2.02 kPa (range 1.94–2.15 kPa), which is within normal limits.

treatment of parenchymal iron deposition to limit toxicity and avoid complications.

***Imaging Findings.*** Ultrasound is not helpful for the detection of iron deposition but may show findings of cirrhosis, portal venous hypertension, or HCC late in the disease. Noncontrast CT may show increased attenuation of the liver (>72 HU), but this is a late finding with a sensitivity of approximately 60% and may be seen with other conditions such as amiodarone therapy or glycogen storage disease (GSD).[32]

MR is the imaging modality of choice for confirming the diagnosis, determining severity, and monitoring therapy in persons with hemochromatosis. Excess iron deposition causes a proportional decrease in signal intensity on T1- and T2-weighted sequences and is most pronounced on gradient echo sequences. Skeletal muscle is relatively unaffected by iron deposition and serves as a good internal reference to compare the signal intensity of affected abdominal organs and bone marrow, which will be hypointense to skeletal muscle. On in-phase and out-of-phase imaging, decreased signal intensity is seen in the affected organs on the in-phase sequence (an opposite finding from steatosis). The key findings in HH are low signal intensity within the liver and pancreas on T2-weighted images (Fig. 89.5). Patients with reticuloendothelial iron deposition demonstrate low signal in the liver, spleen, and bone marrow (Fig. 89.6) with sparing of the pancreas.[27]

There are two main methods of MRI liver iron quantification: signal intensity ratio and relaxometry.[33] Signal intensity ratio is widely used because it is accurate and easy to perform. This method takes advantage of the effect of iron on adjacent proton spins; iron causes rapid dephasing of spins/loss of coherence with resultant loss of signal on long TE images (T2- or T2*-weighted). This effect is more pronounced on gradient echo images due to the lack of a 180-degree refocusing pulse. Signal intensity ratio is obtained by comparing the signal intensity of the liver with skeletal muscle on gradient echo imaging at varying TE and flip angles, and the values obtained are used to quantify iron deposition.[34] An online calculator is available.[35] The main limitation of this technique is that high levels of iron cannot be measured and are reported as greater than 350 umol/g.[35]

Relaxometry estimates iron content by measuring the loss of transverse magnetization caused by iron susceptibility over increasing values of TE.[36] Signal loss occurs in the liver with increasing TE values, and the rate of signal decay is measured as a constant

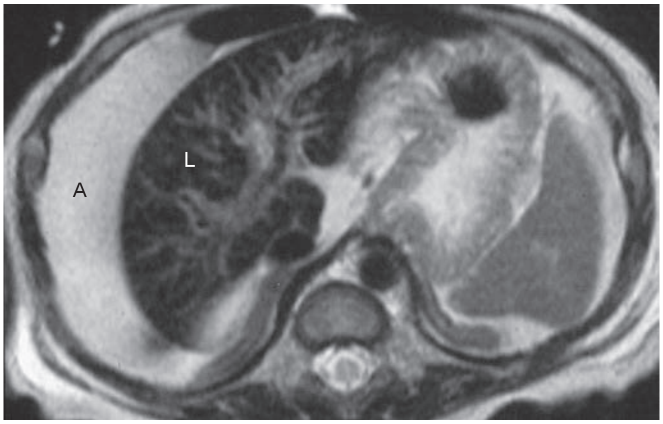

**Figure 89.5. Primary hemochromatosis in an infant with multiorgan system failure.** Axial T2-weighted MR image reveals extensive ascites *(A)* surrounding a liver *(L)* of low signal intensity. *(Courtesy of Lynn Fordham, MD, University of North Carolina–Chapel Hill.)*

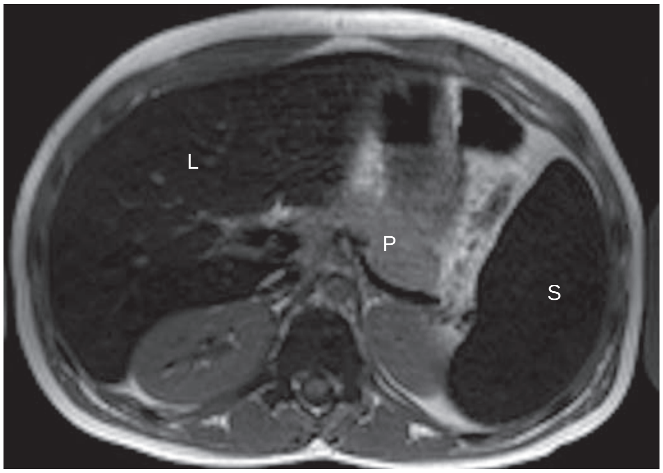

**Figure 89.6. Transfusional iron overload.** T1-weighted MR image of the abdomen in a 13-year-old male with sickle cell disease on chronic transfusional therapy shows marked hypointensity of the liver *(L),* spleen *(S),* and vertebral bone marrow with sparing of the pancreas *(P),* consistent with transfusional iron overload.

(T2 or T2* depending on whether spin echo or gradient echo techniques are used). Reciprocal values of the signal decay constant, R2 or R2*, have also been used as they provide direct correlation with liver iron content (LIC).[33] In general, R2* values are more sensitive for low levels of iron and are faster to acquire (performed with GRE techniques) but are inaccurate at higher iron levels, while R2 values are less susceptible to artifact or hardware/scanner differences but take longer to perform.[33] R2 and R2* methods of estimating LIC are statistically equivalent in children when LIC is less than 20 mg/g.[37]

***Treatment.*** Treatment aims to reduce iron levels and relies on either scheduled phlebotomy or chelation therapy, depending on the etiology.[38] MR quantification of liver iron concentration may be used to follow treatment regimes, obviating the need for liver biopsies.

## GLYCOGEN STORAGE DISEASE

***Overview.*** The GSDs are autosomal recessive disorders with abnormal storage or utilization of glycogen.[39] In the postprandial period, glucose is stored in the liver and muscle in the form of glycogen, which can then be released for energy during periods of starvation or high energy demand. Mutations in genes resulting in deficiencies of the enzymes involved in glycogen synthesis, degradation, or regulation result in GSDs.[40] GSDs are a heterogeneous group of disorders with varying time of onset, severity of disease, and pattern of organ involvement. Fifteen types of GSD have been identified. The most common forms of GSD are types I (von Gierke), type III (Cori), and type IV (Andersen disease or amylopectinosis).

***Clinical Presentation.*** Enzyme deficiencies that affect the liver impair hepatic gluconeogenesis and glycogenolysis and cause hypoglycemia. Of these, type I GSD (von Gierke disease) is the most common. Patients with type I GSD have a deficiency of the enzyme glucose-6-phosphatase and usually present with hypoglycemia around 3 months of age.[41] While hypoglycemia is the dominant clinical finding in liver-related GSDs, these patients may also present with hepatomegaly, lethargy, and seizures related to hypoglycemia. GSDs affect muscles causing exercise intolerance, with weakness, cramps, and rhabdomyolysis.

Complications of GSD affecting the liver include steatosis and the development of hepatic adenomas,[42] which may be associated with poor metabolic control.[39] Hepatic adenomas in patients with GSD-I may be multiple and can be seen in 25% to 50% of patients.[42] Spontaneous intraperitoneal bleeding is a known complication due to rupture of a hepatic adenoma. Malignant transformation of hepatic adenomas to HCCs has been described but is rare.[43]

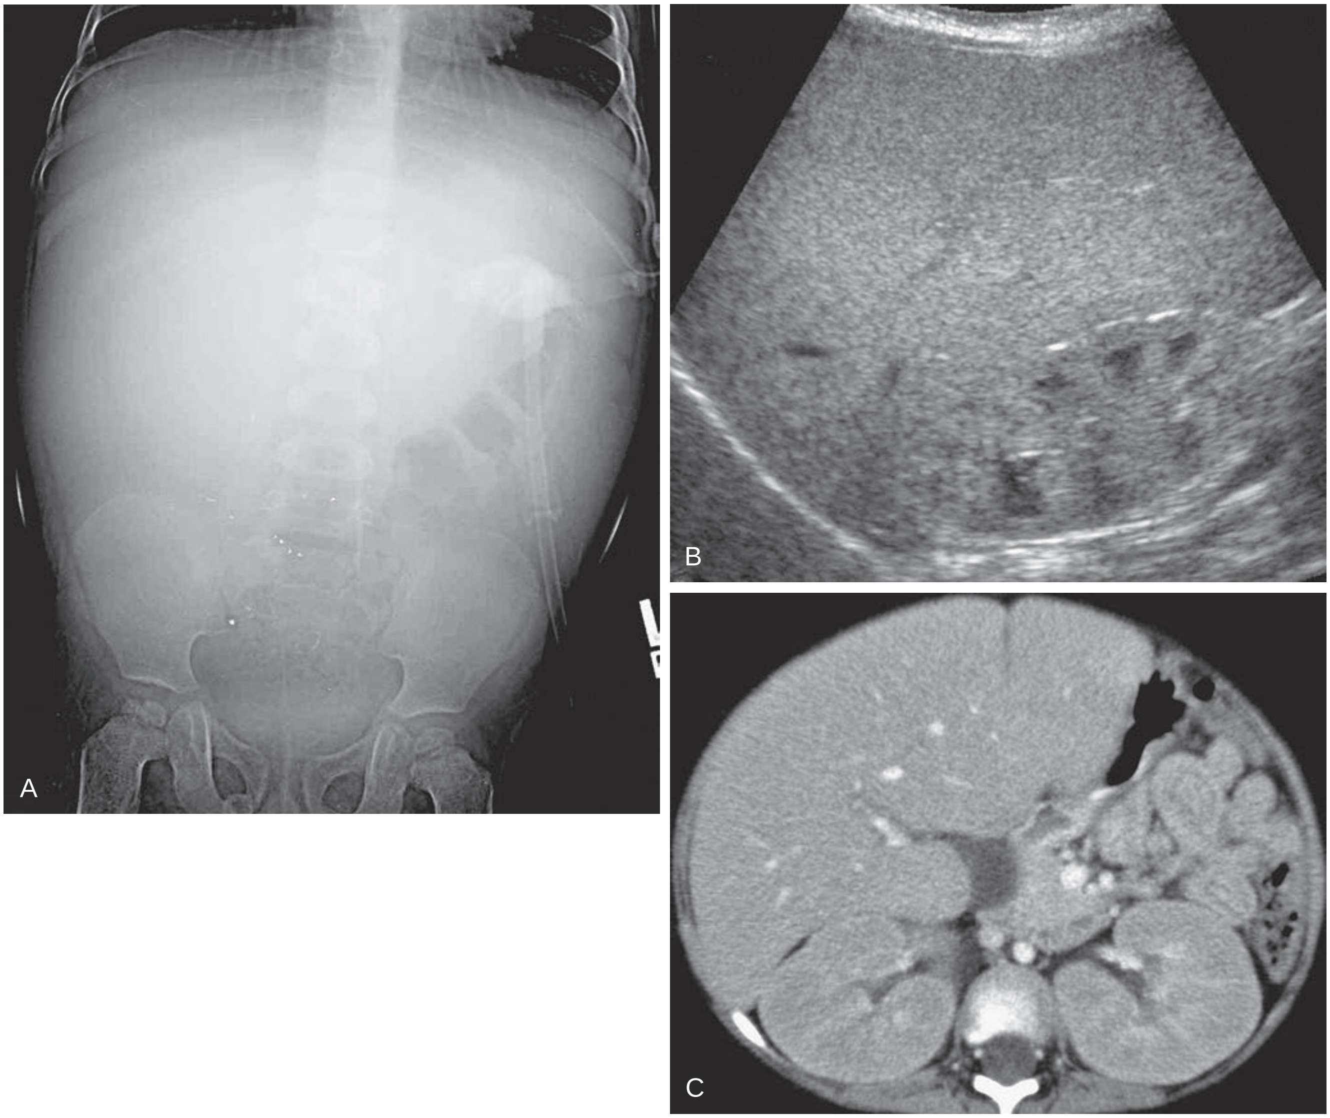
***Imaging Findings.*** Hepatic ultrasound surveillance is recommended every 12 to 24 months until age 16 years. If adenomas are detected, contrast-enhanced hepatic CT or MRI every 3 to 6 months are recommended.[44]

Ultrasound of the liver in patients with GSD-I usually show hepatomegaly and diffusely increased parenchymal echogenicity, which may be related to steatosis or glycogen deposition[45] (e-Fig. 89.7). Likewise, adenomas with varying degrees of echogenicity may also be present (e-Fig. 89.8).[46] It is difficult to distinguish adenomas from HCCs on ultrasound, but rapid enlargement of masses and elevated serum alpha-fetoprotein are worrisome for carcinoma.

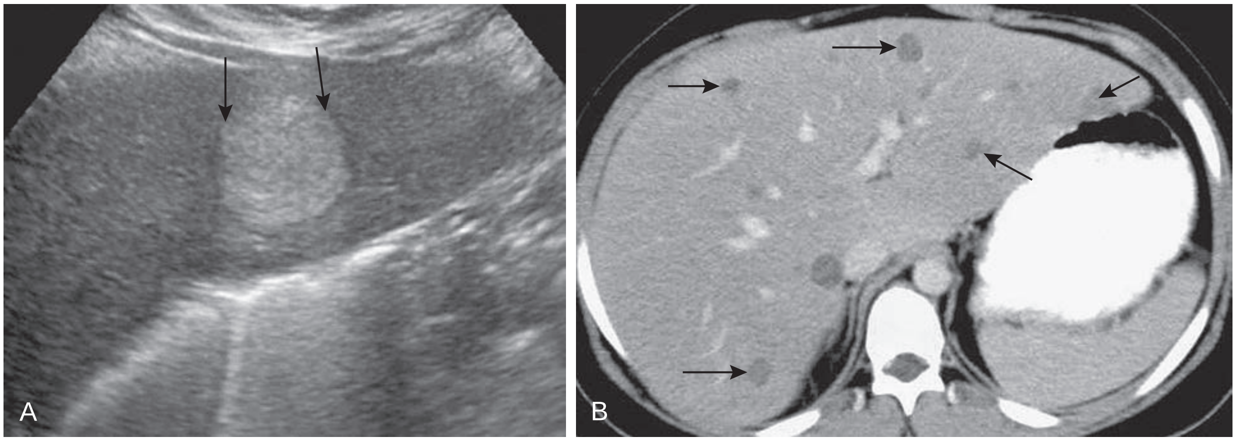
CT shows similar features, with hepatomegaly from glycogen deposition in hepatocytes and low-attenuation related to steatosis. Because hepatic attenuation is increased by glycogen but decreased by fat, the CT findings are variable depending on which factor predominates. In younger patients without steatosis, the liver may actually be hyperdense due to the presence of excess glycogen in liver cells.[47] Masses may be relatively hyperdense on noncontrast CT compared with the background liver parenchyma. Adenomas may contain fat or hemorrhage, and a small number will show areas of coarse internal calcification, presumably related to necrosis. Arterial enhancement and washout on portal venous phases is diagnostic of HCC in the cirrhotic liver on dynamic contrast-enhanced CT but may be seen in some patients with GSD and hepatic adenomas.[48]

On MRI, diffuse hepatic steatosis is readily demonstrable on chemical shift images. Adenomas are of hepatocellular origin, and are usually T1 isointense to mildly hyperintense and hyperintense on T2-weighted images. After Gadoxetate disodium (Gd-EOB-DTPA) administration, adenomas usually enhance during the arterial phase with washout on later phases. During the hepatocyte phase of enhancement, adenomas are typically hypointense to the surrounding liver (Fig. 89.9).[49,50] An enhancing pseudocapsule can be seen in up to a third of hepatic adenomas, and some lesions show heterogeneous internal enhancement with areas of increased T1 signal resulting from hemorrhage or fat.[50]

***Treatment.*** Management of liver-related GSD centers on prevention of severe hypoglycemic episodes with frequent oral glucose polymer/cornstarch administration.[39] Infants may also require continuous feeds overnight via a nasogastric or gastrostomy



**e-Figure 89.7. Glycogen storage disease in a 3-year-old boy with abdominal distension and elevated liver function enzymes.** (A) Abdominal radiograph shows mass effect from diffuse hepatomegaly. Punctate radiodense foci over the lower abdomen were artifactual. (B) Longitudinal ultrasound of the right upper quadrant shows hepatomegaly and diffusely increased hepatic echogenicity. The renal cortex also is hyperechoic. (C) Axial contrast-enhanced CT reveals hepatomegaly and nephromegaly.



**e-Figure 89.8. Glycogen storage disease in a 9-year-old boy with hepatic adenomas.** (A) Longitudinal ultrasound reveals a hyperechoic mass with enhanced through-transmission and refractory shadowing at the margins *(arrows),* typical of a hepatic adenoma. (B) Enhanced axial computed tomography demonstrates numerous scattered, low-attenuation, well-defined hepatic adenomas *(arrows).*

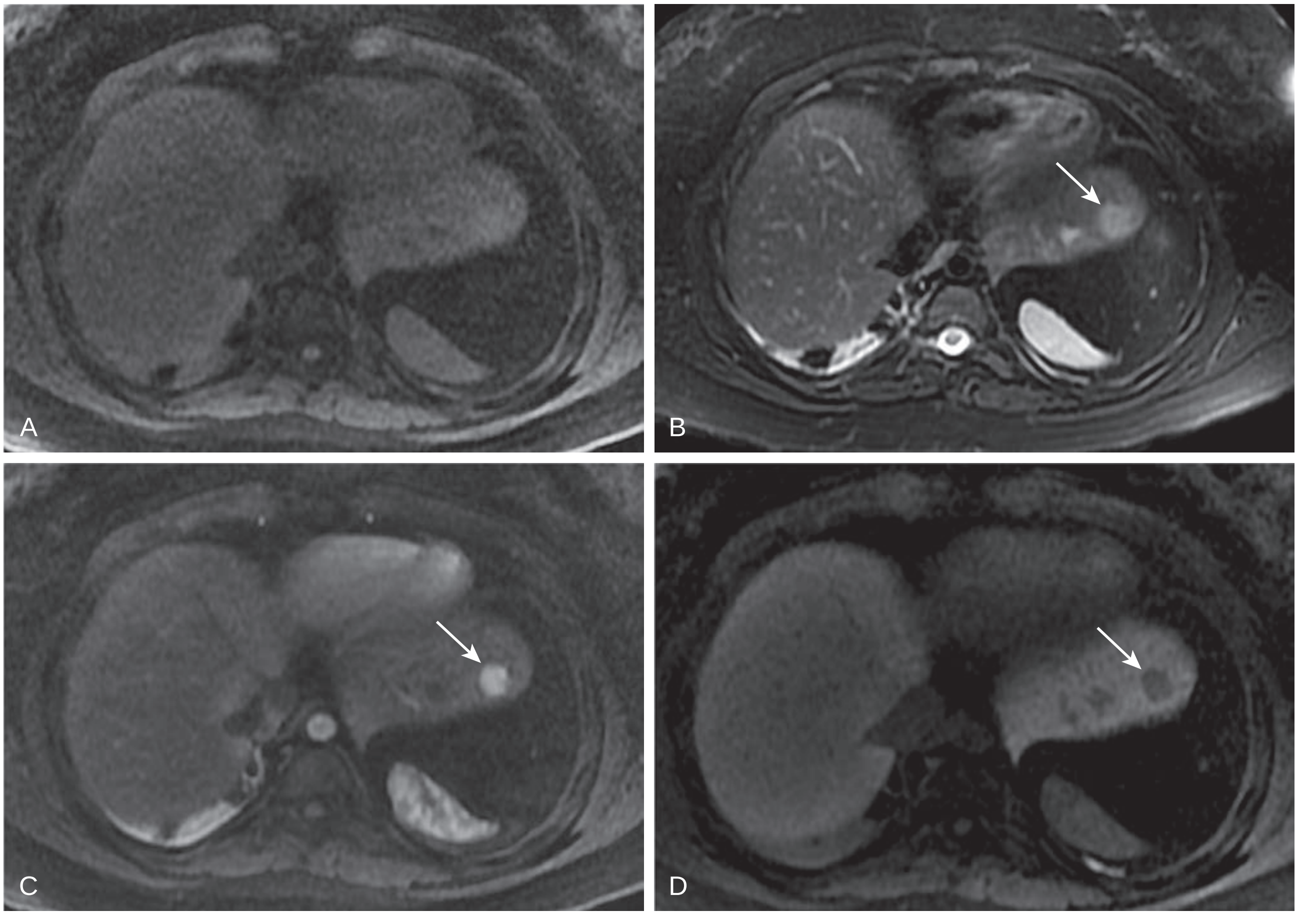


**Figure 89.9. Hepatic adenoma in an adolescent patient.** (A) Axial T1-weighted fat suppressed MR image, (B) axial T2-weighted fat suppressed MR image, (C) axial T1-weighted MR image obtained in the early arterial phase, and (D) axial T1-weighted MR image obtained during the delayed hepatocyte phase after Gd-EOB-DTPA administration show the typical appearance of a hepatic adenoma. There is a T1-isointense, T2-hyperintense round lesion (*arrow* in B, C and D) in the superior left hepatic lobe, which is arterially hyperenhancing compared with the background liver. This lesion shows washout or portal venous hypoenhancement on the delayed images. In a normal noncirrhotic liver, these findings are compatible with a hepatic adenoma.

tube to prevent hypoglycemia.[51] Liver transplantation has been performed for some patients with HCC, liver failure, or poor metabolic control. Transplantation improves glucose homeostasis in some patients.[52]

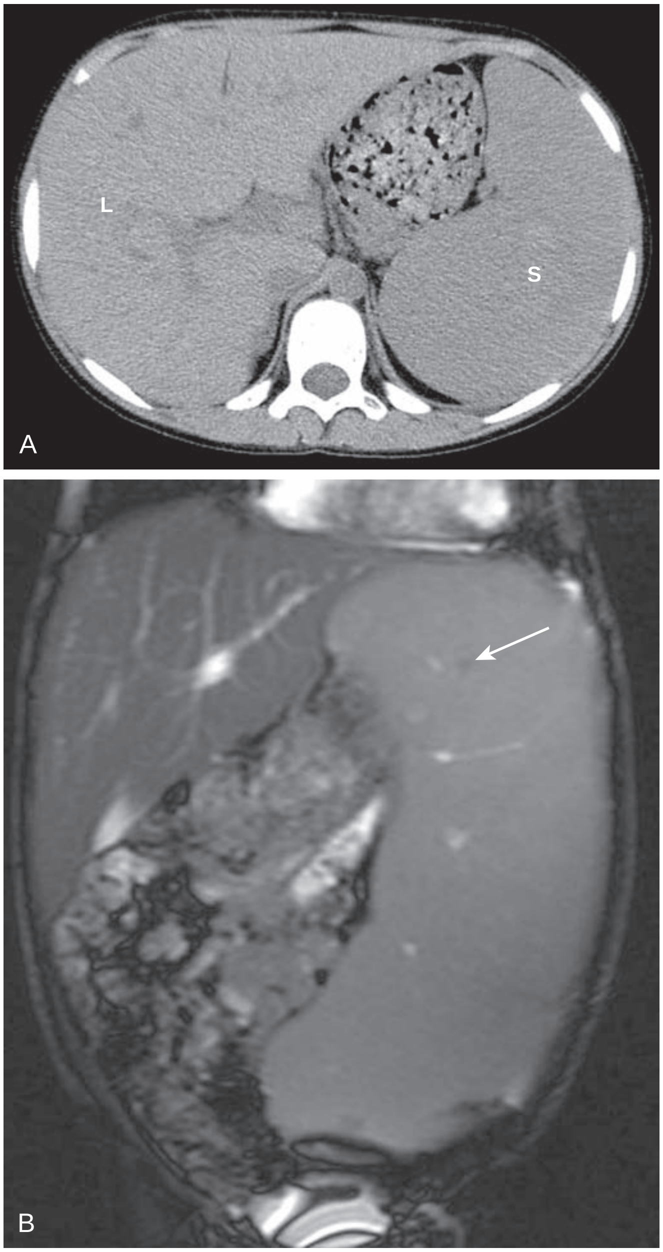
## GAUCHER DISEASE

***Overview.*** Gaucher disease (GD) is an autosomal recessive lysosomal storage disorder resulting from deficiency of the lysosomal enzyme glucocerebrosidase. GD is more common in patients of Ashkenazi-Jewish descent but is seen in other populations as well. There are three main types of GD, but the type I form (nonneuronopathic) accounts for over 90% of cases. Deficiency of glucocerebrosidase results in accumulation of undegraded glucosylceramide in the reticuloendothelial system of the bone marrow, spleen, and liver causing cellular and organ dysfunction.[53,54]

***Clinical Presentation.*** The clinical manifestations of GD include hepatosplenomegaly, anemia, thrombocytopenia, and bone disease. Thrombocytopenia and clinically significant bleeding may result from splenic sequestration of platelets. Bone disease is the most important cause of long-term morbidity, and poorly controlled disease is characterized by episodes of acute crises with bone infarcts and avascular necrosis. Patients also have low bone mineral density, which puts them at risk for fractures. Over 90% of patients have radiographic evidence of bone disease, and bone crises are more common in patients under 10 years of age.[55] The diagnosis of GD can be made by detecting decreased levels of glucocerebrosidase activity in peripheral leukocytes. Lipid-laden macrophages (Gaucher cells) may also be seen in bone marrow or liver biopsy specimens.

***Imaging Findings.*** Abdominal imaging of GD is nonspecific. Hepatomegaly and splenomegaly are seen in the majority of patients. Liver volumes in GD type 1 patients are usually approximately two times normal.[54] The Gaucher cells may accumulate and form nodules that may be seen with ultrasound or MRI. These nodules may show a variable sonographic appearance. On MRI, these nodules are usually hypointense on T1-weighted and hyperintense on T2-weighted imaging.[54] Areas of fibrosis and fibrous septa are seen in the enlarged liver.

In many cases, the splenic enlargement is out of proportion to hepatic enlargement and dominates the clinical presentation. Splenic volumes in type 1 GD may be enlarged 5 to 50 times (e-Fig. 89.10). Focal splenic lesions are not uncommon and may reflect clusters of Gaucher cells or extramedullary hematopoiesis.[54] Splenic infarcts may occur as a result of the massive splenomegaly and can be seen in up to a third of patients on MRI.[56] Abnormal marrow infiltration by Gaucher cells can be seen on MRI and are usually hypointense on T1-weighted images with corresponding hyperintensity on T2-weighted images and fat-suppressed



**e-Figure 89.10. Gaucher disease in a 10-year-old boy.** (A) CT of the abdomen without contrast demonstrates hepatosplenomegaly. (B) Coronal T2-weighted MR image demonstrates hepatosplenomegaly with small hypointense foci in the spleen suggestive of infarcts or Gaucher cells *(arrow)*. *L,* Liver; *S,* spleen.

fluid-sensitive sequences.[57] Bone marrow edema from acute crises can also be seen, and poor disease control in some patients can cause progression to avascular necrosis.[57]

***Treatment.*** Early treatment of GD with enzyme replacement therapy can improve outcomes.[58] Liver and spleen volumes correlate with disease severity and are used in the initial phenotyping of GD.[59] The abnormal T1 hypointense marrow signal related to marrow infiltration also resolves after enzyme therapy, with conversion back to fatty marrow signal.[60]

## ALPHA-1 ANTITRYPSIN DEFICIENCY

***Overview.*** Alpha-1 antitrypsin (AAT) deficiency is an autosomal recessive disorder caused by abnormal protein folding and accumulation of AAT in hepatocytes. AAT is caused by mutations in the *SERPINA1* gene located in the long arm of chromosome 14.[61] AAT is a protease inhibitor that degrades elastase and other proteolytic enzymes in the body. Uninhibited elastase activity in the lungs causes early-onset emphysema in a basilar-predominant distribution. Accumulation of polymerized AAT in hepatocytes causes liver inflammation, fibrosis, and organ dysfunction. Necrotizing panniculitis is a documented but rare manifestation of AAT deficiency.[62]

***Clinical Presentation.*** Liver manifestations of AAT are more common in the first 3 decades of life, with pulmonary airflow limitation occurring later in the disease course.[63] The disease can present early, with neonatal hepatitis and cholestasis, findings that can be initially concerning for biliary atresia.[64] Hepatomegaly, elevated liver function tests, and conjugated hyperbilirubinemia may be present. Clinically, infants may have dark stools and pale urine. Low serum levels of AAT can suggest the disease, and genetic testing can identify the mutated alleles. Both children and adults can progress to end-stage liver disease and cirrhosis related to AAT deficiency, and some patients develop HCC.

***Imaging Findings.*** Infants presenting in the first months of life with neonatal cholestasis and elevated direct bilirubin levels may undergo scintigraphy with the intention of excluding biliary atresia.[65] However, hepatobiliary scans are not helpful in distinguishing AAT from biliary atresia, as both entities can have radiotracer uptake in the liver without excretion into the bile ducts and bowel as a result of a paucity of intralobular bile ducts in some cases of AAT deficiency (e-Fig. 89.11). Abdominal ultrasound may show hepatomegaly and a normal gallbladder in AAT, but a small number of patients with biliary atresia may also have a gallbladder. Complications of AAT such as cirrhosis and HCC can be seen on ultrasound, CT, or MR.

***Treatment.*** There is no specific treatment for AAT deficiency liver disease, but obesity can contribute to disease severity. The prognosis is extremely variable, depending on disease severity, age at diagnosis, and therapeutic interventions. Liver transplantation has a 5-year survival rate of 85% in patients with AAT associated end-stage liver disease.[66]

## WILSON DISEASE

***Overview.*** Wilson disease or hepatolenticular degeneration is an autosomal recessive disorder localized to chromosome 13 that results in impaired biliary excretion of copper. Copper accumulation leads to chronic liver disease ranging from steatosis, hepatitis, and eventually cirrhosis eventually in untreated patients.[67] The brain is also affected, particularly the basal ganglia and midbrain, with neuropsychiatric and parkinsonian syndromes seen in older patients.

***Clinical Presentation.*** Patients with Wilson disease can present acutely with fulminant liver failure (encephalopathy, coagulopathy) or Coombs-negative hemolysis, or chronically with neuropsychiatric symptoms and chronic liver disease. Movement disorders are common due to involvement of the extrapyramidal pathway. Laboratory tests can suggest the diagnosis, with many patients having low serum ceruloplasmin levels and elevated serum and 24-hour urinary copper. Slit-lamp examination of the eyes may reveal Kayser–Fleischer rings or sunflower cataracts. Kayser–Fleischer rings are seen in over 90% of patients with neurologic disease, but only about half of patients with liver disease. Biopsy allows for measurement of hepatic copper concentration, which is considered the single most important test for diagnosing hepatolenticular degeneration.[67] Hepatic copper levels over 250 ug/mg dry weight of liver are diagnostic.[67]

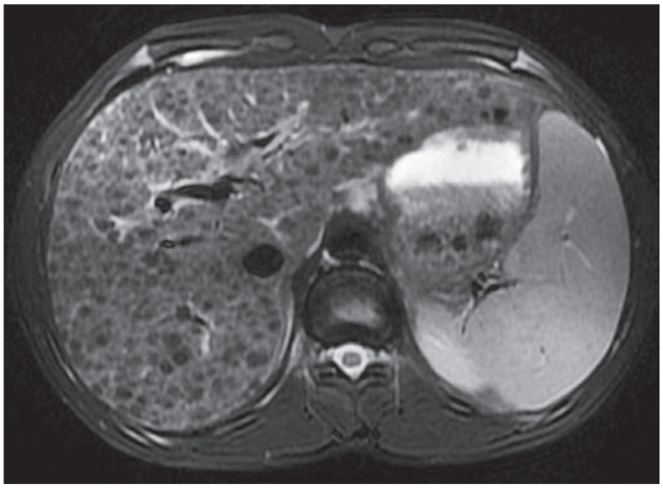


**Figure 89.12. Wilson disease in a 17-year-old male.** Axial T2-weighted MR image shows a cirrhotic liver with innumerable, subcentimeter, hypointense nodules, which are typical of cirrhotic regenerative nodules. Imaging findings of the liver in patients with Wilson disease are typically nonspecific and only show the sequelae of liver inflammation caused by copper deposition.

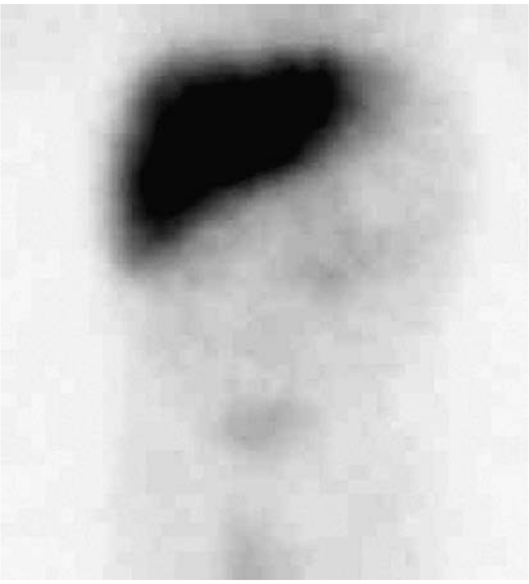
***Imaging Findings.*** Imaging findings in patients with liver-predominant Wilson disease are nonspecific and range from fatty deposition to inflammation and fibrosis/cirrhosis (Fig. 89.12). Noncontrast CT may show increased attenuation of the liver, which has been attributed to copper deposition in hepatocytes.[68] However, this finding is infrequent and nonspecific. On occasions, focal liver lesions may be seen.[69] In patients with neurologic symptoms, brain MRI may show abnormal hyperintensity in the basal ganglia and midbrain on T2-weighted images.[70] Intrinsic T1-weighted hyperintensity may be seen in these areas as well in other patients with Wilson disease, but this finding has been attributed to the hyperammonemia/encephalopathy syndrome which sometimes accompanies liver-predominant Wilson disease.

***Treatment.*** The introduction of copper chelators into clinical practice radically changed medical therapy for Wilson disease. Many patients today can be medically managed with copper chelators (penicillamine, trientine) and zinc.[67] Patients with fulminant liver failure or medically-resistant disease are candidates for liver transplantation.

## CIRRHOSIS

***Overview.*** Cirrhosis is end-stage liver disease resulting from repeated liver injury and inflammation. It is characterized by parenchymal fibrosis and the development of regenerative nodules which distort the normal liver architecture. Once considered an irreversible process, it is now known that early fibrosis and cirrhosis are potentially reversible. While cirrhosis represents the end result of any chronic liver injury, a specific cause or etiology can be found in over 85% of cases, which has implications for treatment and screening of family members.[71] Some imaging patterns of cirrhosis are suggestive of an underlying etiology (for example, marked caudate hypertrophy in patients with Budd–Chiari syndromes), but are not specific enough to serve as stand-alone



**e-Figure 89.11. AAT deficiency in a 6-week-old girl with poor weight gain and hyperbilirubinemia.** Biliary scintigraphy shows liver uptake of radiopharmaceutical without excretion into the biliary tree.

**BOX 89.2** Causes of Cirrhosis in Children

- Viral hepatitis
- Hepatic fibrosis
- Biliary atresia
- Primary biliary cirrhosis
- Cystic fibrosis
- Budd–Chiari syndrome
- Iron overload
- Chronic biliary obstruction
- $\alpha_1$-antitrypsin deficiency
- Glycogen storage disease
- Tyrosinemia
- Wilson disease
- Galactosemia
- Autosomal recessive polycystic kidney disease (hepatic fibrosis)
- Hereditary hemorrhagic telangiectasia

diagnostic criteria. Cirrhosis traditionally has been classified into three main categories depending on the size of the regenerative nodules: micronodular (Laënnec), with equal-sized nodules up to 3 mm; macronodular (postnecrotic), with variable-sized nodules ranging from 3 mm to 3 cm; and mixed cirrhosis.[72,73]

***Clinical Presentation.*** In children, cirrhosis is the result of many different disease processes, including biliary, postnecrotic, and metabolic causes (Box 89.2). Many patients with cirrhosis are asymptomatic, other than vague nonspecific complaints. When acutely symptomatic, the clinical presentation is determined by the complications of portal hypertension (encephalopathy, ascites, spontaneous bacterial peritonitis, variceal bleeding, HCC). On physical examination, the liver may be enlarged with a nodular edge. Other signs of portal hypertension and altered metabolic homeostasis may be seen including jaundice, spider nevi, palmar erythema, hypogonadism, gynecomastia, caput medusa, and esophageal varices on upper endoscopy.

***Imaging Findings.*** Ultrasound of the cirrhotic liver shows a heterogeneous echotexture with surface irregularity. Contrast-enhanced CT and MR show heterogeneous enhancement of the liver parenchyma and a nodular surface (Fig. 89.13). Fibrous bands may also be seen, which can be striking in some patients. Other morphologic changes include right lobe atrophy, with caudate and left lateral segment hypertrophy. There may also be widening of the gallbladder fossa. In patients with decompensated cirrhosis and portal hypertension, ascites, splenomegaly, and portosystemic collaterals are also seen.

Regenerative nodules are common in cirrhotic livers and represent a reparative process in the liver in response to chronic injury.[74] Regenerative nodules reiterate normal hepatic parenchymal signal and enhancement characteristics. Regenerative nodules are usually hypointense to background cirrhotic liver parenchyma on T2-weighted MR images, without arterial hyperenhancement (Fig. 89.14). Dysplastic nodules (low-grade and high-grade) and siderotic nodules are also common findings in cirrhotic livers. Dysplastic nodules harbor hisologically abnormal cells. Low-grade dysplastic nodules are isointense to hyperintense on T1-weighted images when compared with the background liver, without arterial hyperenhancement. Low-grade nodules are usually isointense to the liver on T2-weighted images but may be hypointense in the case of iron accumulation.[74] High-grade nodules are hyperintense to liver on T2-weighted images and may be difficult to distinguish from HCC on imaging alone. The term *siderotic nodule* refers to iron deposition in regenerative or dysplastic nodules. The Liver Imaging-Reporting and Data System (LI-RADS) is used in cross-sectional imaging of cirrhotic livers in an attempt to standardize the degree of certainty regarding findings seen on imaging, however, it is not categorically used for pediatric liver lesion characterization at this time.[74] Lesions are classified from LI-RADS 1 to 5, with LI-RADS 1 being definitely benign and LI-RADS 5 representing definite HCC. Findings concerning for HCC include masslike configuration, arterial hyperenhancement, portal venous washout, tumor thrombus, and growth by more than 1 cm over a 12-month interval. Focal iron sparing in a siderotic liver or nodule is also concerning for the development of HCC. MRE is useful in patients with chronic liver disease. Early identification of at-risk patients can result in earlier treatment, potentially averting progression to late-stage fibrosis and cirrhosis (e-Fig. 89.15).

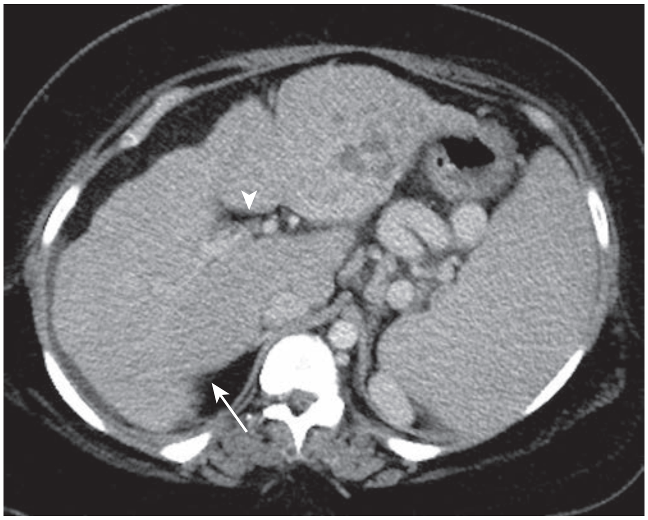


**Figure 89.13. Cirrhosis in a 16-year-old male.** Contrast-enhanced CT of the liver shows a shrunken, nodular liver, consistent with cirrhosis. Linear hypoattenuating lesions in the left hepatic lobe reflect mild intrahepatic biliary ductal dilatation. There is evidence of portal hypertension, with splenomegaly and perisplenic collaterals. Notice the "hepatic-notch" sign *(arrow),* the result of right lobe atrophy, and the relative prominence of the hilar periportal space *(arrowhead)* due to medial segment atrophy.

***Treatment.*** Treatment for cirrhosis depends on the cause and extent of liver damage. The goals of treatment are to slow the progression and to prevent or treat symptoms and complications of cirrhosis. Chemotherapy and ablative therapies can be used as a bridge to transplant or in patients who are not candidates for liver transplantation.

## KEY POINTS

- NAFLD is the most common cause of chronic liver disease in childhood.
- MR can be used to quantify hepatic steatosis and MRE is useful for monitoring the development of hepatic fibrosis in patients with NAFLD.
- Pancreatic iron deposition is a characteristic feature of primary or hereditary hemochromatosis. Splenic iron deposition is seen in transfusional iron overload.
- Patients with alpha-1 antitrypsin deficiency (AAT) may present in a fashion similar to patients with biliary atresia, with similar findings on hepatobiliary scans. Abdominal ultrasound performed in patients with AAT usually shows a normal gallbladder.
- Arterial hyperenhancement and portal venous phase washout of a mass in a cirrhotic liver is HCC until proven otherwise.
- Focal iron sparing in a siderotic liver or siderotic nodule should be viewed with suspicion for HCC, as tumor cells do not usually take up iron to any significant degree.

# Infectious Causes of Liver Disease

Melissa A. Hilmes

## INTRODUCTION

A wide range of viruses, bacteria, fungi, and parasites can infect the liver. The liver can be the primary organ of infection (as seen with viral hepatitis), or the liver can be secondarily involved as part of a systemic infection (such as with bacterial or fungal infections). The agents can cause a wide range of disease, ranging from subclinical infection, jaundice and cholestasis, diffuse hepatitis, microabscesses, focal abscess, or necrosis. Immunocompromised patients are affected differently than immunocompetent patients.

## VIRAL INFECTIONS OF THE LIVER

***Overview.*** Viral hepatitis presents a spectrum of clinical severity, which can range from subclinical infections to fulminant hepatitis with further evolution to cirrhosis.

***Etiology.*** In the neonatal period and in early infancy, patients are more likely to show signs and symptoms from viruses that cause perinatal and congenital infections, such as cytomegalovirus (CMV), herpes simplex virus (HSV), rubella virus, and parvovirus rather than the hepatotropic viruses.[1] They can become seriously ill with hepatitis and present with massive hepatocellular necrosis. It is important in these infants to exclude biliary atresia as a cause for cholestasis.

In childhood, viral hepatitis is most commonly caused by the hepatitis A, hepatitis B, and hepatitis C viruses, which are viruses that target the liver.[2] A number of other viruses have been implicated in childhood hepatitis, including mumps, measles, varicella-zoster virus, HSV, CMV, adenovirus, Coxsackie virus, and Epstein–Barr virus (EBV). These viruses cause systemic or disseminated illness, with hepatitis a part of the illness.[3]

Most affected patients have a short-lived acute disease with complete recovery. Complications include subacute and chronic active hepatitis, evolution into cirrhosis, and development of hepatocellular carcinoma. Chronic hepatitis B and C viral infections are linked directly to hepatocellular carcinoma development.[4,5]

***Imaging.*** Nuclear scintigraphy may be performed in infants with cholestasis to differentiate biliary atresia from other causes, collectively known as neonatal hepatitis. In neonatal hepatitis, liver function is decreased, and there is poor uptake of radiopharmaceutical with delayed excretion through the biliary tree into the small bowel and vicarious excretion through the kidneys (Fig. 90.1). The test has high sensitivity (98%–99%) but lower specificity (70%).[6] More accurate specificity is obtained when using premedication with phenobarbital to induce the hepatocytes, radiotracers with higher hepatic extraction (such as trimethylbromo-iminodiacetic acid [BrIDA] and diethyl iodophenyl-carbamoylmethyl-iminodiacetic acid [IODIDA]), dosing by body weight, and use of booster doses.[6]

In children and adults, diagnosis of a viral hepatitis infection is made clinically and on the basis of laboratory data. If imaging is performed during the acute phase of the illness, the liver may be enlarged or normal in size. On ultrasound (US), the liver echotexture may be normal or sonography may demonstrate increased parenchymal echogenicity and heterogeneity.[7] The "starry sky" pattern describes an edematous liver that is diffusely hypoechoic, allowing the portal triads and portal venous walls to appear bright; this imaging finding has limited sensitivity and specificity, and may be present in other forms of liver disease other than viral hepatitis[8] (Fig. 90.2). Computed tomography (CT) scans may show heterogeneous changes in attenuation but more commonly show hepatomegaly, gallbladder wall thickening, and periportal low attenuation (Fig. 90.3).

If the course of the viral infection progresses to hepatocellular necrosis, the areas of necrosis can mimic pyogenic microabscesses or diffuse hypoattenuating nodules on contrast-enhanced CT, as in reported cases of fulminant herpes-simplex virus hepatitis.[9,10]

In patients with fulminant hepatitis and subsequent hepatic regeneration, imaging differences have been described between necrotic areas and regenerating nodules. Regions of necrosis have central low attenuation on precontrast CT relative to regions of regeneration. After intravenous contrast administration, areas of necrosis and regeneration may enhance similarly such that they become indistinguishable, or the regenerating nodules may show hyperenhancement, which can simulate a neoplastic lesion. Similarly, magnetic resonance (MR) imaging may show nonspecific periportal high intensity on T2-weighted images and hepatomegaly.[7] On MR, areas of nodular regeneration show high signal on T1- and low signal on T2-weighted images relative to adjacent necrotic parenchyma.[11]

Measuring liver stiffness with US and MR elastography techniques is proving useful for detecting development of liver fibrosis and cirrhosis associated with hepatitis B and C infection.[12–14] Children have special considerations, as the liver stiffness changes over normal development from childhood to adolescence to adulthood, as demonstrated on MR elastography.[15]

***Treatment and Follow-up.*** Treatment of viral hepatitis varies from symptomatic treatment to antiviral medication or transplant depending on the type and severity of the disease. Fulminant hepatitis may be fatal without hepatic transplant.[11]

## BACTERIAL INFECTIONS OF THE LIVER

***Overview.*** Bacterial infections of the liver have a wide range of manifestations, including cholestatic jaundice, hepatitis, hepatomegaly, abscess formation, and fulminant hepatic necrosis. Many of the bacterial infections that have liver involvement do not require the aid of imaging for diagnosis and treatment, and lack specific imaging findings. Patients with prolonged fever without a source or patients with unexplained hepatomegaly often come to imaging for assistance in identifying the source of infection, and liver findings, such as identification of complications such as abscess, can aid in the diagnosis.

***Etiology.*** Because of the wide range of bacteria that can cause infection with liver involvement, identification of the specific organism causing the patients' symptoms is the key to diagnosis and treatment. Table 90.1 lists prominent bacterial infections that involve the liver, including spirochetes, rickettsial organisms, and tuberculosis.

Neonates are at risk for sepsis, jaundice with a urinary tract infection, and disseminated listeriosis and syphilis.[19–22] Patients with immune deficiency such as chronic granulomatous disease have special considerations such as infections with actinomycosis and nocardiosis.[23] Important to note is a history of animal exposure, especially in the case of bartonellosis, leptospirosis, and Q fever, or tick exposure with Lyme disease or Rocky Mountain spotted fever.

## Abstract:

A wide range of viruses, bacteria, fungi, and parasites can infect the liver. The liver can be the primary organ of infection (as seen with viral hepatitis), or the liver can be secondarily involved as part of a systemic infection (such as with bacterial or fungal infections). Patients can be affected at any age, from the newborn period to adulthood. The agents can cause a wide range of disease, ranging from subclinical infection, jaundice and cholestasis, diffuse hepatitis, microabscesses, focal abscess, or necrosis. Immunocompromised patients are affected differently than immunocompetent patients. Diagnostic imaging can help differentiate infectious conditions from other causes of liver inflammation, such as biliary atresia, identify abscesses that would be amenable to therapeutic interventions, and identify the source of fever and infection in immunocompromised patients.

Hepatic abscess
Hepatic microabscesses
Schistosomiasis
Amebiasis
Echinococcosis

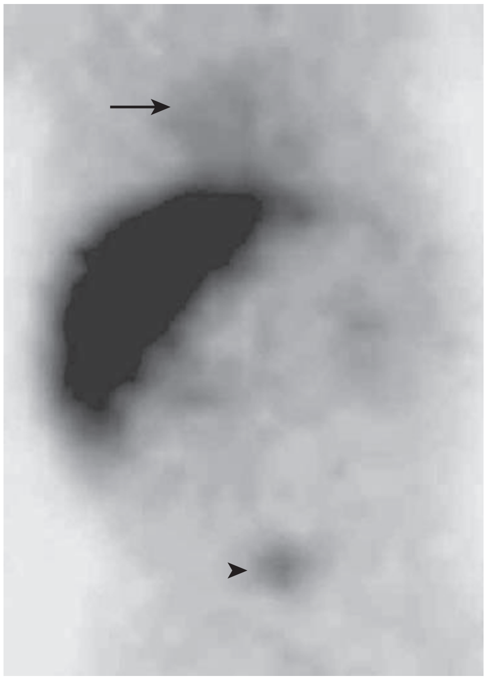

**Figure 90.1. Hepatitis in a 7-week-old boy with persistent jaundice.** Technetium-99m-labeled hepatoiminodiacetic (HIDA) scan shows poor uptake within the liver with large amount of background activity in the heart *(arrow)* and vicarious excretion through the genitourinary tract *(arrowhead)*.

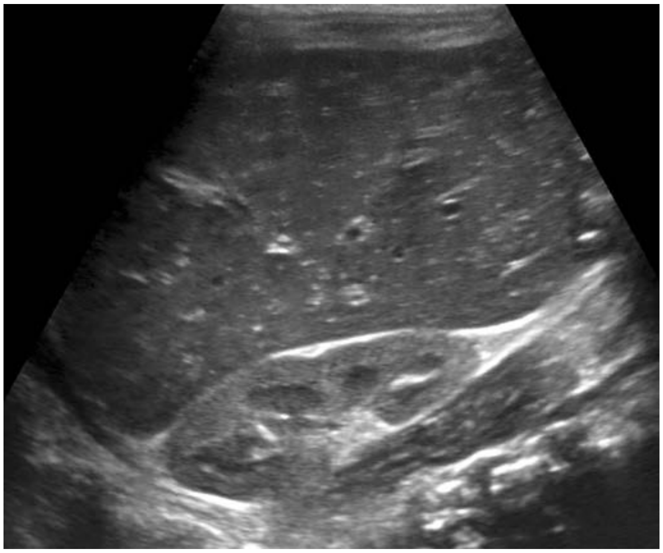

**Figure 90.2. Hepatitis B in a 5-month-old boy with persistent elevation of liver function tests.** Longitudinal sonogram of the liver shows an enlarged, diffusely hypoechoic liver which is decreased in echogenicity when compared with the kidney. The liver shows a “starry sky” appearance, as the portal venous triads and portal venous walls appear bright against the edematous liver. (Image courtesy of Dr. Gabriella Crane, Nashville, TN.)

**TABLE 90.1** Bacterial Pathogens and Their Manifestations in the Liver

| Disease | Causative Organism | Patient Population | Liver Disease Manifestations |
|---|---|---|---|
| Sepsis syndrome with cholestatic jaundice[1,21,59] | Gram positive organisms *(Staphylococcus aureus, Group B Streptococcus, pneumococcus)*<br>Gram negative bacteria (such as *Pseudomonas*, *E. coli, Klebsiella*) | Infants, children, adults | Immune response to bacterial endotoxins create cholestasis and jaundice; hepatomegaly |
| Urinary tract infection in neonates[1,22,60] | mainly *Escherichia coli;* also *Enterobacter, Klebsiella, Enterococcus* | Neonates | Prolonged jaundice and indirect hyperbilirubinemia |
| Actinomycosis[23,61] | *Actinomyces israelii* and other species | Mostly reported in immunocompetent adults; children with chronic granulomatous disease | Hepatic abscess formation |
| Bacille Calmette-Guerin (BCG) vaccination[62] | Live attenuated vaccine against tuberculosis disease | Immunodeficiency disorders such as severe combined immunodeficiency (SCID) | Multiple liver lesions; enlarged lymph nodes |
| Bacillus cereus[63] | *Bacillus cereus* | Immunocompetent patient; food borne illness | Fulminant hepatic failure from emetic toxin |
| Bartonellosis[64-66] | *B. henselae* and *B. quintana* | Children more so than adults; bite or scratch from infected cat or infected fleas | Granulomatous lesions with microabscesses; can calcify late |
| Brucellosis[67] | *Brucella* | Humans in contact with infected animals or their products | Hepatic abscess (necrotizing granuloma), possible calcification |
| Listeriosis[21,68,69] | *Listeria monocytogenes* | Fetal infection; immunocompetent and immunocompromised | Abscesses or granulomas in fetal infections (part of granulomatosis infantiseptica)<br>Hepatitis; solitary abscess; multiple liver abscesses (in adults) |
| Leptospirosis (spirochete)[70,71] | *Leptospira* species | Children exposed to infected animals, contaminated soil or water | Fever and jaundice; can lead to liver failure (Weil disease) |
| Lyme disease (spirochete)[72] | *Borrelia burgdorferi* | Tick bite | Subclinical hepatitis, abnormal liver function tests, hepatomegaly |

*Continued*

**TABLE 90.1** Bacterial Pathogens and Their Manifestations in the Liver—cont'd

| Disease | Causative Organism | Patient Population | Liver Disease Manifestations |
|---|---|---|---|
| Nocardiosis[23,73] | *Nocardia* species | Immunocompromised patients especially with chronic granulomatous disease; some immunocompetent patients | Mainly pulmonary and CNS disease; hematogenously disseminated disease affects liver |
| Q fever (Rickettsia)[74,75] | *Coxiella burnetii* | Children and adults exposed to infected animals and drinking raw milk | Hepatomegaly, jaundice and granulomatous hepatitis; fibrosis and cirrhosis in chronic form |
| Rocky Mountain spotted fever[72] | *Rickettsia rickettsia* | Tick bite | Jaundice, elevation of liver function tests |
| Syphillis (spirochete)[1,76] | *Treponema pallidum* | Fetal infection; neonatal and congenital infection | Cholestasis, hepatosplenomegaly, ascites, intrahepatic calcifications |
| Tuberculosis[25,26,77] | *Mycobacterium tuberculosis* | | Miliary dissemination with caseating granulomas and hepatomegaly; focal or nodular tuberculosis; hepatic abscess; enlarged lymph nodes |

*CNS,* Central nervous system.

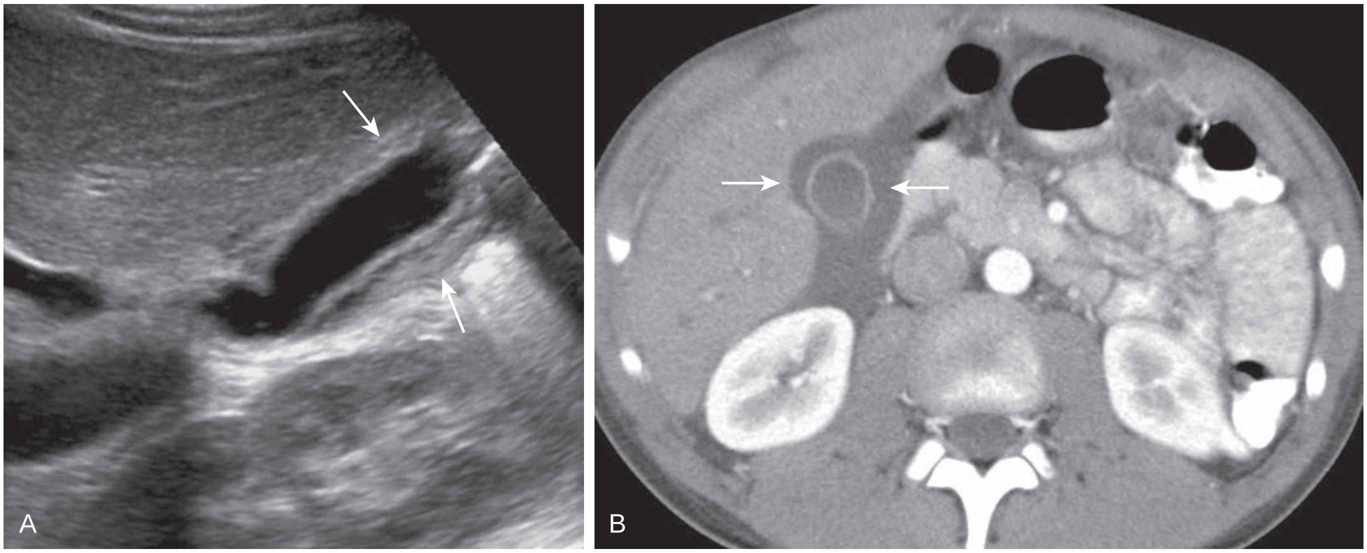

**Figure 90.3. Gallbladder wall thickening in a 10-year-old boy with viral hepatitis.** (A) Longitudinal sonogram shows a thick, hyperechoic gallbladder wall *(arrows)*. (B) Contrast-enhanced CT image confirms gallbladder wall thickening *(arrows)* and periportal edema.

## LIVER ABSCESS

In neonates, common bacterial pathogens causing liver abscess are *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Escherichia coli*. Other organisms such as *Klebsiella* and *Pseudomonas* have been identified, as well as fungal species like *Candida albicans*. Up to half of the reported abscesses are polymicrobial.[24]

***Hepatic Abscess Formation.*** In neonates, hepatic abscess are rarely reported, but risk factors include prematurity, umbilical vein catheterization, sepsis, total parenteral nutrition, and necrotizing enterocolitis (Fig. 90.4).[16] Worldwide, liver abscess in children is more frequent in developing countries than in developed countries.[17] Risk factors include intraabdominal infection such as perforated appendicitis and inflammatory bowel disease such as ulcerative colitis.[17,18] Immunocompromised patients are at particularly high risk for liver abscesses, and the risks include acquired immunodeficiency such as with chemotherapy and bone marrow transplantation, and congenital immunodeficiency like chronic granulomatous disease.[17]

The most common bacterial cause of liver abscess in children is *S. aureus;* the most common parasitic cause is *Entamoeba histolytica*.[17] In endemic areas, tuberculosis is a significant cause of liver abscess, regardless of the presence or absence of active disease elsewhere.[25] The occurrence of multiple hepatic abscesses in a child should raise concern for underlying immunodeficiency.

***Imaging.*** The identification of an hepatic abscess or multiple microabscesses are specific imaging findings in bacterial infection, often found while working up abdominal pain, prolonged illness, or unexplained fever. Other imaging findings of hepatitis or hepatomegaly are nonspecific.

The hepatic abscess can take on multiple appearances. They can appear as multiple microabscesses less than 2 cm scattered throughout the liver. These lesions can appear on US as discrete hypoechoic foci in the liver with little or no posterior acoustic enhancement. On contrast-enhanced CT, they appear as hypoattenuating lesions. Rim enhancement help to differentiate from simple cysts.[26]

The lesions in hepatosplenic cat-scratch disease are an example of a granulomatous infection common in children and adolescents that produces microabscesses/granulomata with multiple lesions in the liver and spleen in association with enlarged abdominal lymph nodes and organomegaly[26,27] (Fig. 90.5). The disease mimics malignancy such as lymphoma, and the lesions are FDG avid at 18F-FDG PET imaging.[28] Calcifications can occur with healing, especially in granulomatous disease such as hepatosplenic catscratch disease or in children with chronic granulomatous disease.[29,30]

Larger abscesses on US range from hypoechoic to hyperechoic and can have internal debris and gas, which causes strong shadowing (Fig. 90.4). With CT, they are largely hypoattenuating, with or without septations, and may be unilocular or multilocular. The variable protein content of a hepatic abscess gives them a variable appearance on MR. There may be perilesional edema with increased signal on T2-weighted imaging.[26]

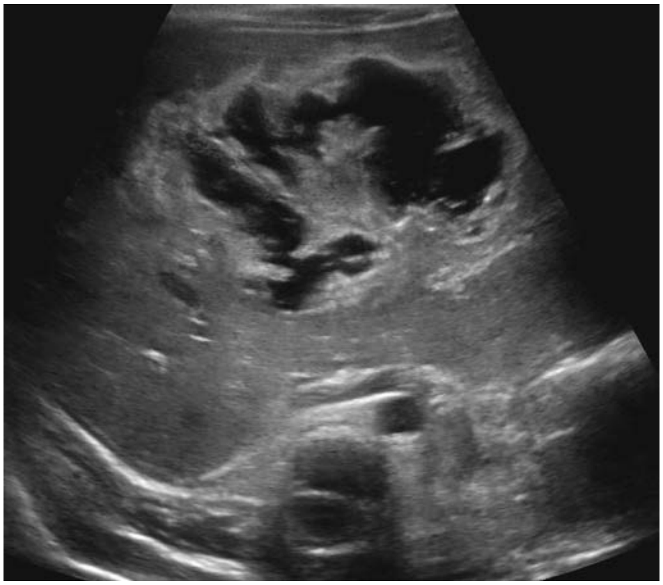

**Figure 90.4. Liver abscess.** Liver sonogram in an 8-day-old girl born prematurely who had an umbilical line placement and persistent fevers shows an irregularly shaped fluid collection with echogenic rim. Patient was treated with percutaneous drainage and antimicrobials. *(Image courtesy of Dr. Gabriella Crane, Nashville, Tennessee.)*

***Treatment and Follow-up.*** Treatment of bacterial infections is the appropriate antimicrobial therapy targeted to the specific organisms causing disease.

Hepatic abscess, if left untreated, can be fatal due to sepsis and rupture into pleural, peritoneal, and retroperitoneal spaces. Treatment of small pyogenic abscesses, less than 5 cm, is usually successfully managed with appropriate antimicrobials alone. Lesions that appear liquefied on imaging can be managed with percutaneous needle aspiration in combination with antimicrobials. Percutaneous catheter drainage may be required for larger lesions. Open surgical drainage is a less common management approach but may be required for patients with peritonitis or peritoneal rupture, or failure of percutaneous drainage.[17,31]

Diffuse liver microabscesses can be successfully treated with appropriate antimicrobial therapy, such as a combination of doxycycline and rifampin for hepatosplenic cat-scratch disease.[32] The occurrence of multiple hepatic abscesses in a child should raise concern for underlying immunodeficiency.

## FUNGAL INFECTIONS OF THE LIVER

***Overview.*** Fungal infection of the liver is often from dissemination of systemic disease and occurs frequently in the setting of immune compromise, such as neutropenia with hematologic malignancies, or stem cell or solid organ transplants; patients with AIDS and chronic granulomatous disease are at an increased risk.[33,34] In vulnerable patient populations, such as those listed, a high index of suspicion in patients with prolonged fever is essential, as is early detection. Mortality rates are approximately 30%.[34]

***Etiology.*** The majority of disseminated hepatic fungal infections are caused by *Candida* species, *Aspergillus* species, and *Cryptococcus neoformans*, with *Candida* species predominating.[34] Other possible fungal species include *Histoplasma* and *Mucor*. Emerging pathogens include *Trichosporon*, *Blastoschizomyces*, and *Fusarium*.[34] The specific cause can be hard to detect, as blood cultures are often only positive 50% of the time.[34]

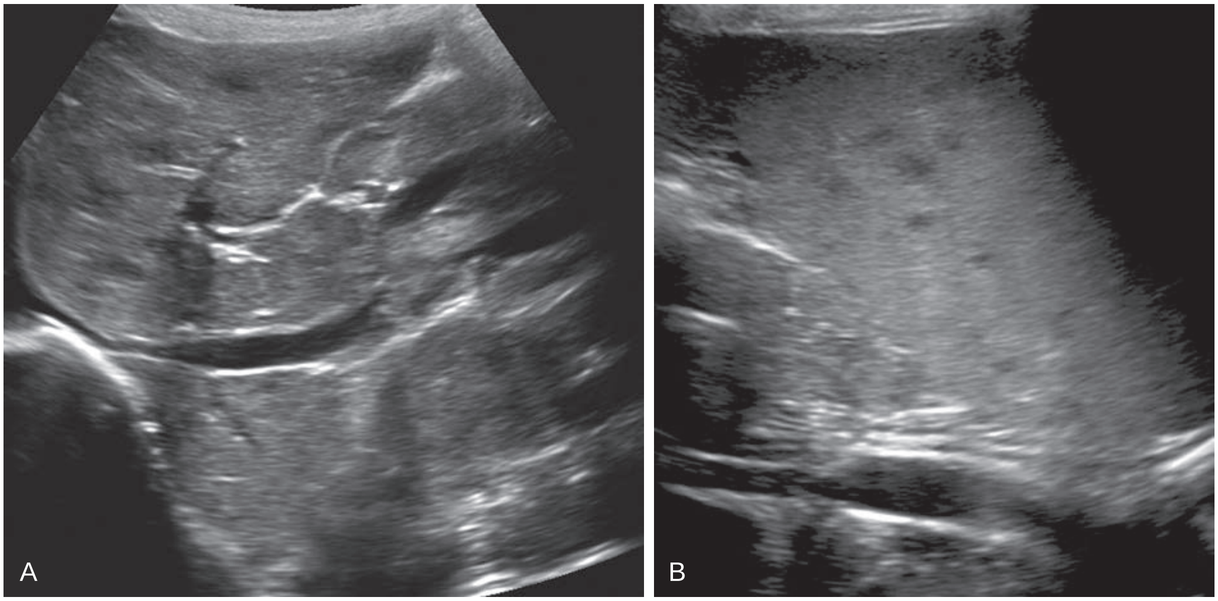

**Figure 90.5. Cat-scratch disease in a 6-year-old girl with 3 weeks of fevers, organomegaly, and diffusely enlarged lymph nodes.** (A) Sagittal sonogram of the liver show ill-defined hypoechoic lesions. (B) Sagittal sonogram of the spleen shows splenomegaly and multiple hypoechoic lesions. *(Images courtesy of Dr. Gabriella Crane, Nashville, Tennessee.)*

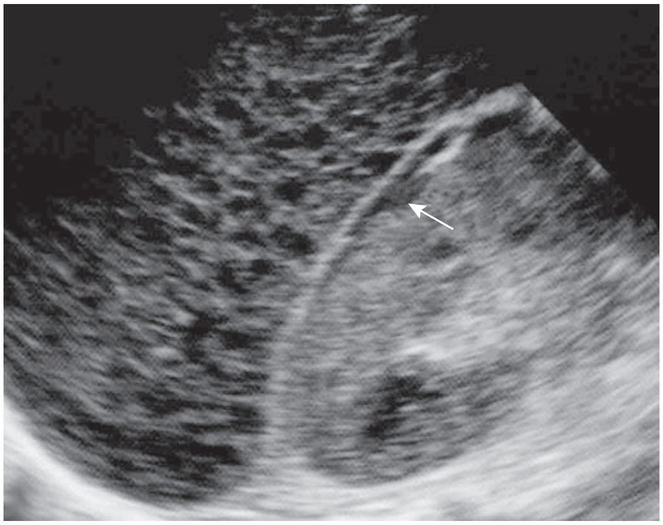

**Figure 90.6. Hepatic candidiasis in a 7-month-old immunodeficient boy.** Longitudinal sonogram shows diffuse, homogeneous, hypoechoic foci consistent with microabscesses throughout the liver. Tiny amount of fluid in Morrison pouch is noted *(arrow)* adjacent to the right kidney.

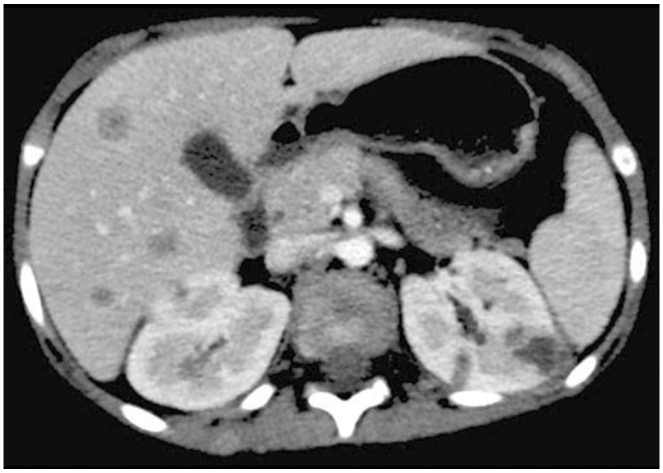

**Figure 90.7. Disseminated candidiasis in a 6-year-old boy undergoing treatment for acute lymphocytic leukemia.** Contrast-enhanced CT image shows multiple lesions in the liver, as well as disease in the kidneys. *(Image courtesy of Dr. Gabriella Crane, Nashville, Tennessee.)*

*Histoplasma capsulatum* is a dimorphic fungus with two varieties, one commonly found in the eastern United States and Latin America, and another in sub-Saharan Africa.[35] Histoplasmosis is a common infection in immunocompetent patients. Most often it is an asymptomatic, self-limiting infection, but the infection can disseminate and can cause life-threatening infection, including hepatitis.[36] Histoplasmosis can also infect immunocompromised patients, such as those receiving solid organ transplant[37] and individuals with AIDS; it is now considered an AIDS-defining illness.[35]

***Imaging.*** Imaging may be useful to detect the typical presence of disseminated fungal disease with diffuse microabscesses. Sometimes only hepatomegaly with or without splenomegaly without focal lesions may occur. Imaging findings generally cannot distinguish among causative organisms. The imaging features are similar across US, CT, and MR.[34]

MRI is the modality of choice when evaluating suspected fungal infection of the solid organs in pediatric patients, as the sensitivity is high and no ionizing radiation is involved.[35,38,39] Disseminated disease usually manifests are diffuse microabscesses. The lesions are hyperintense on T2-weighted imaging and minimally hypointense on T1-weighted imaging. With diffusion-weighted imaging, the lesions may show restriction.[40]

These numerous microabscesses have multiple patterns described on US, including wheel-within-a-wheel, bull's eye, hypoechoic nodule, and echogenic focus of calcification that occurs with resolution[41] (Fig. 90.6). CT may show multiple small low attenuation lesions throughout the liver and spleen, with peripheral enhancement possible as well as calcifications, especially in the healing stage[33] (Fig. 90.7). Arterial phase CT is more sensitive for lesion detection.[42]

Invasive aspergillosis has been reported manifesting as liver abscesses, with multiple large hypoechoic lesions, easily identified on imaging.[43]

***Treatment and Follow-up.*** Clinical practice guidelines exist for invasive candidiasis and invasive aspergillosis in neutropenic and nonneutropenic patients.[44,45] Various antifungal treatments include echinocandins, a group of antifungal drugs that include caspofungin, micafungin, and anidulafungin.[46] These drugs are more expensive but have lower infusion related effects and nephrotoxicity compared with amphotericin B. Hepatotoxicity is their main adverse effect.[46] Other options include fluconazole and amphotericin B. Recommendations for chronic disseminated hepatosplenic candidiasis include amphotericin B, followed by oral fluconazole.[44] For hepatic aspergillosis, voriconazole or the lipid formulation of amphotericin B is recommended.[45] For severe histoplasmosis, amphotericin B is preferred; itraconazole is used for moderate disease.[34]

## PARASITIC INFECTIONS OF THE LIVER

Parasitic infections are a worldwide problem, usually affecting the less developed regions of the world. With travel and immigration, these diseases may be encountered unexpectedly. Major groups of parasites that infect or involve the liver include protozoans and flatworms of the phylum *Platyhelminthes*. The flatworms can be divided into the cestodes, tapeworms such as *Echinococcus* species, and trematodes, flukes such as *Schistosoma*.[47]

Malaria is caused by plasmodium protozoa, and is one of the most devastating diseases in the world. A WHO report in 2014 estimated 200 million people were infected in 2013, with nearly 1 million deaths.[47] The infection can cause hepatosplenomegaly and other nonspecific abdominal findings such as periportal edema, ascites, and gallbladder wall thickening.[47]

Other parasitic infections preferentially involve the biliary tree, such as ascariasis, clonorchiasis, and fascioliasis, and are not covered in this section.

### Amebiasis

***Overview.*** Amebiasis is widespread worldwide but is more common in tropical areas with poor sanitation. In a study from 2007 to 2011, most travelers diagnosed with *Entamoeba histolytica* had returned from touring India, Indonesia, Mexico, and Thailand.[48]

***Etiology.*** *Entamoeba histolytica* is the main amebic protozoan that infects the gastrointestinal tract. Infection occurs after drinking contaminated water or eating contaminated food. The most common extraintestinal complication is a liver abscess.[47] Studies suggest that amebic abscess is rare in children.[17]

***Imaging.*** Amebic liver abscesses are usually unilocular; septa are present less commonly. The majority of lesions are solitary and in the right lobe of the liver, near the liver capsule. They appear similar to pyogenic abscesses (discussed earlier) and appear as a hypoechoic mass on US. The lesion appears as a

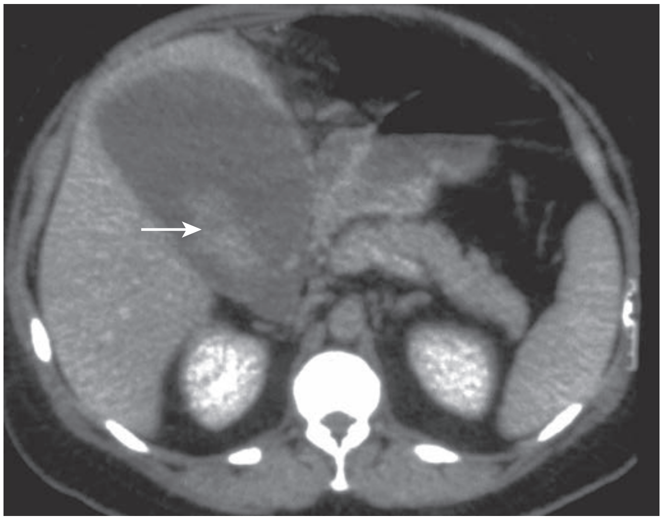

**Figure 90.8. Amebic abscess.** Axial contrast-enhanced CT image shows a large, exophytic low-attenuation cyst with hyperdense central debris *(arrow)*.

well-defined lesion with rim enhancement on a contrast-enhanced CT (Fig. 90.8). At MR, the abscesses appear as low-signal intensity on T1-weighted imaging and high-signal intensity on T2-weighted imaging.[34] Diaphragmatic disruption and direct extension into the thorax is highly suggestive of this disease and may manifest as a pleural effusion.[47]

***Treatment and Follow-up.*** Once the infection is confirmed with culture, serology, or immunofluorescence on biopsy specimens, treatment with metronidazole or ketoconazole is recommended.[47] Most studies suggest that amebic abscess can be managed with medical therapy without aspiration.[17] If a secondary bacterial infection occurs, addition of antibiotics should be considered as well as abscess drainage.[17]

## Echinococcosis or Hydatid Disease

***Overview.*** Echinococcosis is a worldwide infection. Affected areas are slightly different for the cystic and alveolar forms, but affected areas are mostly where herding and grazing are prevalent, as dogs are the definitive hosts and sheep and goats are intermediate hosts. Affected areas include the Mediterranean, central Europe, Russia, central Asia, China, southern South America, Australia, northwest Canada, western Alaska, and parts of Africa.[49]

***Etiology.*** These infections are mainly caused by the tapeworm *Echinococcus granulosus*, which causes cystic echinococcosis. *E. multilocularis* causes alveolar echinococcosis, a much less common infection. After ingesting the worm eggs in contaminated food, water, or soil, humans become accidental intermediate hosts. The embryonic form of the worms, onchospheres, settle into the liver and lungs, and then progress into the larval stage, forming hydatid cysts.[47]

***Imaging.*** There are several classification systems of hepatic hydatid cysts and the appearance on US, including a radiologic classification,[50,51] WHO classification of 2003,[52] and the oldest system, the Gharbi classification of 1981.[53] The WHO classification can also apply to MR. The classifications describe degeneration of the hydatid cysts from unilocular cysts, confused with other simple cysts, to lesions with daughter cysts, to chronic hydatid cysts with complete calcification[47] (Figs. 90.9 and 90.10). Some unique imaging features of this disease include "falling snowflakes," a description of denser material inside the unilocular cyst on US or higher attenuation material on CT. The "rosette" describes a cyst that contains daughter cysts; the mother cyst has more dense content and has higher attenuation on CT than the daughter cysts. The "water lily" sign describes a rupture of the cyst with internal floating membranes.[34]

The lesions of *E. multilocularis* are multiloculated and mimic large tumors, infiltrating surrounding tissues and displacing intrahepatic structures. Central necrosis and calcifications are common.[54]

***Treatment and Follow-up.*** Traditionally, the standard treatment is removal of the cysts and antiparasitic treatment such as albendazole or mebendazole.[47]

## Schistosomiasis

***Overview and Etiology.*** Schistosomiasis is a blood fluke parasitic disease endemic to tropical and subtropical regions.[34] These waterborne parasitic flatworms are found in freshwater and aquatic snails that serve as the intermediate hosts. Worldwide, there are 252 million cases, and 90% are in Africa.[55] Schistosomiasis takes on two main forms: the genitourinary form caused by *S. hematobium*, (representing two-thirds of cases worldwide) and the intestinal form caused by *S. mansoni* (one-third of cases worldwide) and *S. japonicum* (1% of cases worldwide, mainly East Asia).[55]

The secondary larvae of these blood flukes leave the intermediate hosts, aquatic snails, and swim to invade final hosts, human beings. They penetrate skin, enter blood and lymphatics, and then lodge into liver sinusoids to copulate. The adult worms then migrate into venous plexus and venules where they live and produce eggs. In intestinal schistosomiasis, rectal and mesenteric venules are involved; in the genitourinary form, the pelvic and paravesical plexus is infested. The eggs migrate through bowel or bladder wall, and then are passed in stool or urine.[47,55]

Chronic infection in children can lead to anemia, chronic pain, malnutrition, growth failure, and cognitive deficits.[55]

***Imaging.*** Acute infection, known as Katayama fever, is sometimes observed in travelers. Although rarely imaged, imaging can demonstrate hepatosplenomegaly, hypoechoic liver lesions corresponding to granulomata, and enlarged portal nodes.[47,56]

Chronic infection is a result of egg deposition in tissues causing fibrosis, inflammation, bleeding, and end organ damage.[55] Imaging findings of chronic hepatic infection include fibrosis and signs of portal hypertension, such as hepatofugal flow and splenomegaly. Other findings include periportal fibrosis, irregular or nodular liver surface, heterogeneous parenchyma, atrophy of right lobe, and hypertrophy of caudate of left lobe.[47]

The differences in egg size and distribution accounts for the different appearances on imaging. The larger *S. mansoni* eggs are deposited along the large portal branches from the liver hilum, producing a central distribution of periportal fibrosis. The smaller eggs of *S. japonicum* are deposited along the small portal radicles at the periphery of the liver, producing periportal fibrosis along the peripheral part of the liver.[57] Fibrotic tracts in patients with *S. japonicum* form a "polygonal network" with a honeycomb or tortoise shell appearance and are likely to calcify. Fibrotic tracts in patients with *S. mansoni* do not tend to calcify and form a "Symmers' pipe-stem" fibrosis.[57] Sonography reveals hyperechoic septa outlining polygonal areas which may resemble a "fish scale network." On CT, dense fibrous and calcific septa distributed at right angles to the hepatic surface produce the classic CT appearance of "turtle back calcification" in *S. japonicum* infection. MR imaging may show isointense periportal bands on T1-weighted images, which are bright on T2-weighted images and enhance after gadolinium contrast administration.[26,58]

***Treatment and Follow-up.*** Schistosomiasis is treated with praziquantel, although up to 20% of patients will develop fibrosis even with treatment. Current control strategies include mass drug administrations of praziquantel, although most children do not receive their needed regular treatment. Vaccine development is underway.[55]

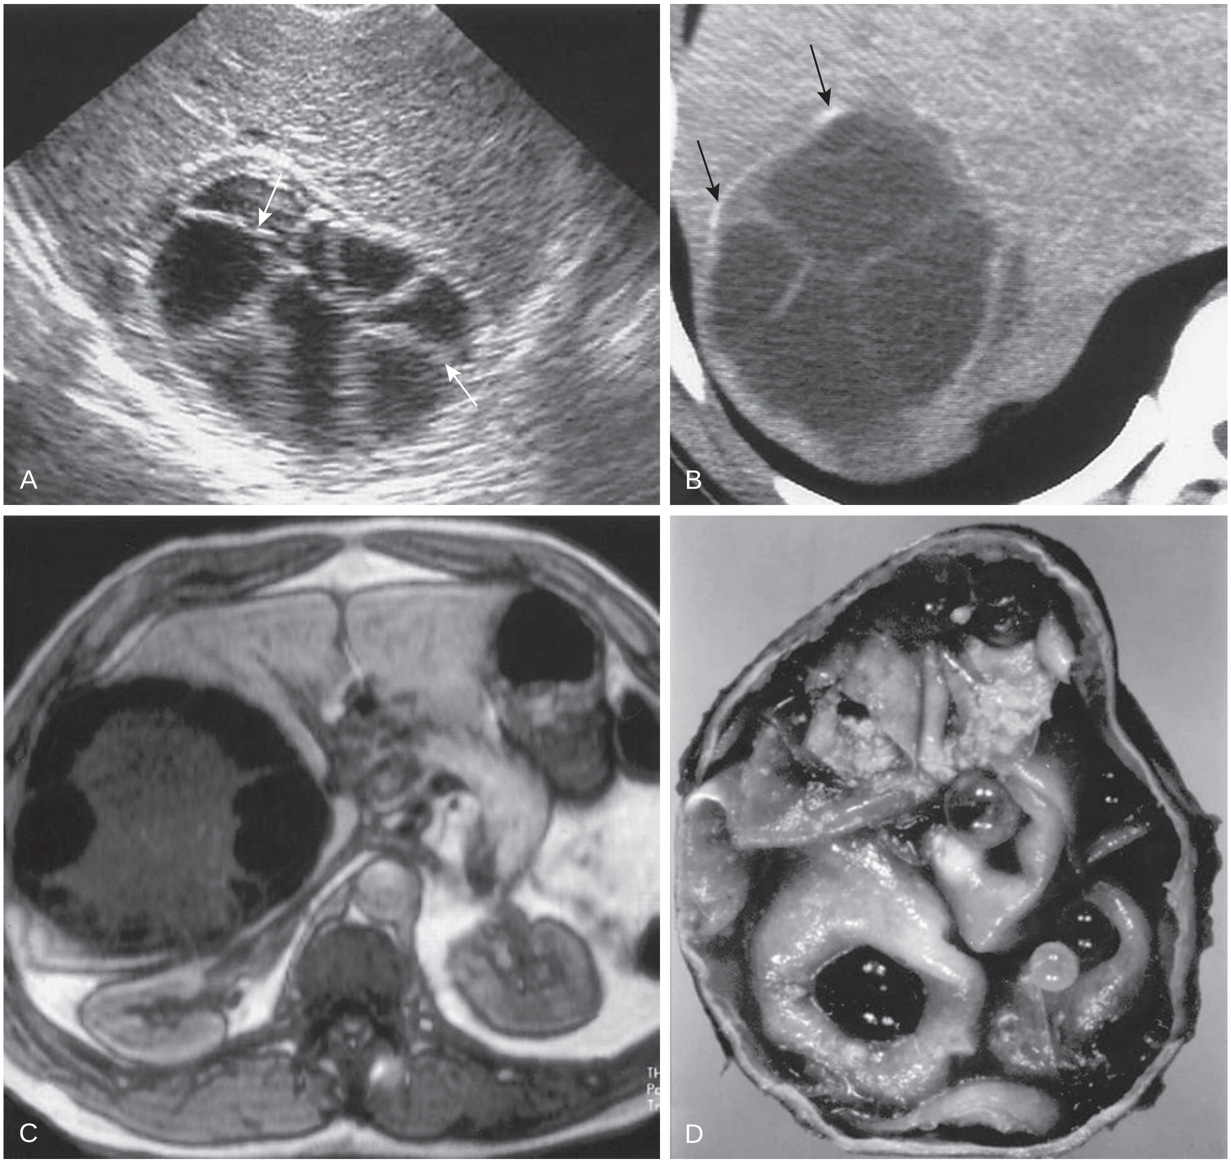

**Figure 90.9. Echinococcal (hydatid) cyst.** (A) Longitudinal hepatic sonogram shows a type II well-defined *(arrows),* multilocular lesion with a “spoke wheel” appearance. (B) Axial unenhanced CT image confirms a mass with multiple septations and peripheral daughter cysts. (C) Axial T1-weighted gradient echo MR image shows a hepatic hydatid cyst with a hypointense fibrous pericyst and extensive peripheral low-signal-intensity daughter cysts surrounding central intermediate-signal-intensity matrix that was bright on T2-weighted images *(not shown)*. (D) Gross specimen of resected hydatid cyst reveals numerous daughter cysts. *(From Mortele KJ, Segatto E, Ros PR. The infected liver: radiologic-pathologic correlation.* Radiographics *2004;24:937–955.)*

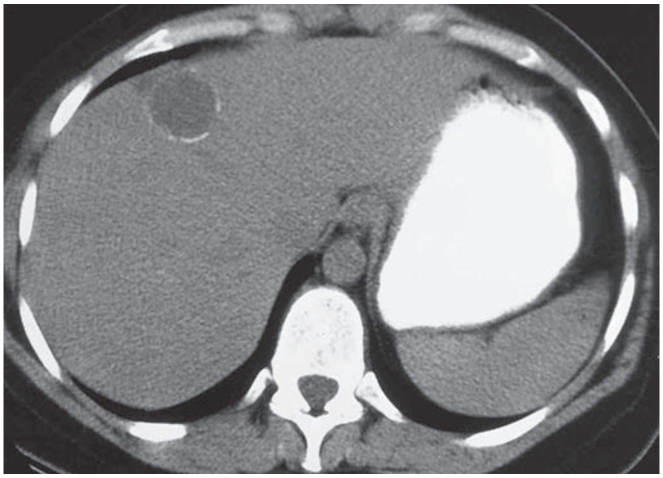

**Figure 90.10. Echinococcal (hydatid) cyst.** Axial unenhanced CT images show peripheral calcification in a hepatic echinococcal cyst.

## KEY POINTS

- Imaging of hepatitis can be nonspecific, no matter the causal pathogen. Imaging can help to find complications of disseminated infections, such as diffuse microabscesses or focal abscesses.
- Viruses that cause neonatal hepatitis are from congenital or perinatal infection, rather than the heterotropic viruses of childhood and beyond. Biliary atresia should be excluded as a cause in neonatal cholestasis.
- Fungal infections involving the liver tend to occur in immunocompromised patients, with *Candida* and *Aspergillus* as the main pathogens.
- Parasitic infections that involve the liver are prevalent worldwide and may be seen in tourists who have traveled to endemic areas. Chronic parasitic infections negatively affect the health of children worldwide.

*Josée Dubois and Michael Ditchfield*

## OVERVIEW

Hepatic neoplasms constitute approximately 2% of all childhood tumors, approximately 6% of pediatric abdominal neoplasms, and are the third most common intra-abdominal tumors in children after Wilms tumor and neuroblastoma. Two-thirds of liver tumors in children are malignant and most of these are hepatoblastomas. The remaining malignant tumors in order of frequency are: hepatocellular carcinoma (HCC) including the fibrolamellar variant, undifferentiated embryonal sarcoma (UES), and angiosarcoma.[1] The benign hepatic tumors in pediatrics include those specific to children, such as vascular tumors and mesenchymal hamartomas, as well as entities that are also seen in adults, such as focal nodular hyperplasia (FNH), hepatocellular adenoma (HCA), and nodular regenerative hyperplasia (NRH). The most common benign pediatric tumors are infantile hemangiomas and FNH.

Some pediatric hepatic tumors may be discovered incidentally, however, the majority present with abdominal pain or a mass.

A differential diagnosis of liver tumors can be obtained based on the age of the patient, clinical setting, laboratory findings such as serum alpha fetoprotein (AFP) levels, and some characteristic imaging findings in some tumors as illustrated in Table 91.1. However, serum AFP levels can be confusing in the first few months of life, being normally elevated at birth (25,000–50,000 ng/mL) and do not reach the normal adult level (<25 ng/mL) until 6 months of age.[2,3]

All standard imaging modalities are used in the evaluation of liver masses, including plain radiographs, ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), radionuclide scintigraphy, and positron emission tomography (PET). US is the initial study of choice to confirm the organ of origin, characterize the lesion, and decide on the most appropriate subsequent imaging. Additional imaging with CT, MRI, nuclear scintigraphy, and, rarely, angiography, may be required to fully characterize a hepatic lesion before biopsy and treatment.

New developments in US and MR contrast have improved the diagnostic capabilities of these modalities in the investigation of focal liver masses; however, there is little data available of their use in pediatrics and their use remains off-label in children.[4,5]

Currently, the most commonly used liver specific contrast agents in adult practice are gadobenate dimeglumine (MultiHance, Bracco) and gadoxetate disodium (Gd-EOB-DTPA, gadoxetic acid, Eovist or Primovist, Bayer HealthCare). Gadobenate dimeglumine demonstrates weak and transient binding with serum albumin in the intravascular space and therefore remains within the intravascular space for a longer time than do other gadolinium chelates. This improves evaluation of vascular structures. In addition, up to 5% of the administered dose has hepatobiliary excretion. Gadoxetate disodium has 50% hepatobiliary excretion in the setting of normal renal and hepatic function and can therefore provide both a functional and anatomic magnetic resonance cholangiopancreatography (MRCP) examination. Gadoxetate disodium has higher T1 relaxivity and allows adequate first-pass hepatic imaging, and delayed phase postcontrast imaging can demonstrate the relationship of the tumor with the portal and hepatic veins and identify intrahepatic satellite lesions.[6]

## MALIGNANT HEPATOBILIARY TUMORS

### Hepatoblastoma

Hepatoblastoma is the most common primary malignant liver tumor in infants and children. Sixty-eight percent of cases are seen in the first year of life and 90% in patients younger than 5 years of age, with a male predominance of 2 : 1.[3] Four percent of cases are congenital.[1,3,7–9] Predisposing conditions include Beckwith–Wiedemann syndrome, familial adenomatous polyposis, type 1A glycogen storage disease, Gardner syndrome, fetal alcohol syndrome, Wilms tumor, and trisomy 18. It is also reported in premature and low birth weight infants and in infants born of mothers taking oral contraceptives. There is a strong association with low birth weight, raising the issue of a potential contribution by a variety of iatrogenic exposures in the neonatal intensive care unit.[10]

Hepatoblastoma usually presents as a palpable mass. Infrequently, it can present with jaundice and precocious puberty related to the secretion of chorionic gonadotropins. Serum AFP is markedly elevated in approximately 90% of patients and can be used to monitor therapy and detect recurrence.

***Pathology.*** Hepatoblastoma is classified into two histologic types: the more common epithelial type and the mixed epithelial mesenchymal type.[1–3] Hepatoblastoma is usually solitary and is most commonly located in the right hepatic lobe (60%).[11] It may also be multifocal or, less commonly, diffusely infiltrating. Multifocal disease may consist of a dominant mass with satellite nodules or multiple small masses. Vascular compression or invasion is important to identify. The portal vein is most commonly affected. When the hepatic veins are involved, extension to the inferior vena cava and right atrium can also occur.

Distant metastases are present in less than 10% of cases at diagnosis, most commonly to the lungs, followed by lymph nodes, bone, brain, eye, and ovary.

***Imaging.*** Sonographically, hepatoblastomas are most often well-defined and hyperechoic relative to adjacent liver (Fig. 91.1). Epithelial type hepatoblastomas are more homogeneous, whereas mixed tumors are more heterogeneous often containing areas of calcifications, necrosis, or hemorrhage.[12–14] Infiltrative hepatoblastomas show diffuse heterogeneous echogenicity.[12–14] Intravascular tumor thrombus may be seen within the hepatic or portal veins. Flow within the thrombus on color Doppler imaging aids in differentiating neoplastic from nonneoplastic thrombus.

Unenhanced CT typically shows a well-circumscribed low density mass with speckled or amorphous calcifications (50%).[12] It enhances heterogeneously with contrast and may be hyperdense compared with liver parenchyma in the early arterial postcontrast phase and usually iso- or hypodense on delayed images. Peripheral enhancement can be seen. The routine use of multiphase CT imaging is, however, not recommended in suspected hepatoblastomas.

On MRI, epithelial type hepatoblastomas are homogeneously hypointense on T1- and hyperintense on T2-weighted images relative to adjacent liver and enhance with intravenous gadolinium contrast.[12] Mixed-type tumors show more heterogeneous signal intensity with areas of calcifications, necrosis, hemorrhage, and septation.[12–14] Vascular invasion is demonstrated with gradient-echo sequences; tumor thrombus appears as high signal on T1-weighted

## Abstract:

Hepatic neoplasms constitute approximately 2% of all childhood tumors, approximately 6% of pediatric abdominal neoplasms, and are the third most common intraabdominal tumor in children after Wilms tumor and neuroblastoma. Two-thirds of liver tumors in children are malignant and most of these are hepatoblastomas. The remaining malignant tumors in order of frequency are: hepatocellular carcinoma (HCC) including the fibrolamellar variant, undifferentiated embryonal sarcoma, and angiosarcoma. The benign hepatic tumors in pediatrics include those specific to children, such as vascular tumors and mesenchymal hamartomas, as well as entities that are also seen in adults, such as focal nodular hyperplasia (FNH), hepatocellular adenoma, and nodular regenerative hyperplasia. The most common benign pediatric tumors are infantile hemangiomas and FNH.

All standard imaging modalities are used in the evaluation of liver masses. Ultrasound (US) is the initial study of choice to confirm the organ of origin, characterize the lesion, and decide on the most appropriate subsequent imaging. Additional imaging with computed tomography, magnetic resonance imaging (MRI), nuclear scintigraphy, and, rarely, angiography, may be required to fully characterize a hepatic lesion before biopsy and treatment.

New developments in US and MRI contrast have improved the diagnostic capabilities of these modalities in the investigation of focal liver masses. Currently, the most commonly used liver specific MR contrast agents in adult practice are gadobenate dimeglumine and gadoxetate disodium; however, there is little data available of their use in pediatrics and their use remains off-label in children.

**TABLE 91.1** Summary for Differential Diagnosis of Liver Tumor

| Tumor | Age Group | Clinical Features | Imaging Features |
|---|---|---|---|
| Hepatoblastoma | <5 y | AFP levels: elevated | Calcifications: coarse, chunky<br>Solid mass<br>Invasion veins<br>Enhancement: less than adjacent liver |
| Hepatocellular carcinoma | 10–14 y | AFP levels: elevated<br>Underlying liver disease | Solid, focal, multifocal<br>Heterogeneous, hemorrhage, necrosis<br>Invasion veins |
| Fibrolamellar carcinoma | Adolescent | AFP levels: normal<br>No liver disease | Fibrous scar: hypointense T2-weighted imaging, no enhancement<br>Homogeneous<br>Solitary mass |
| Undifferentiated embryonal sarcoma | 6–10 y | AFP levels: normal | Cystic on CT and MRI<br>Solid on ultrasound<br>Enhancement: solid portion and septa |
| Embryonal rhabdomyosarcoma | <5 y | AFP levels: normal | Often located near porta hepatis with intraductal growth pattern |
| Liver hemangioma | <1 y | AFP levels: normal<br>Cardiac heart failure<br>Coagulopathy<br>Hypothyroidism | Calcifications (50%): fine, granular<br>Enhancement: more than adjacent liver |
| Mesenchymal hamartoma | <5 y | AFP levels: normal | Cystic lesion<br>Enhancement: septa and solid portion enhancement<br>No calcification |
| Focal nodular hyperplasia | Young children<br>Adolescents | AFP levels: normal<br>Strong predilection girls | Vascular, myxoid scar: hyperintense T2-weighted imaging, delayed enhancement<br>Homogeneous lesion enhancement |
| Adenoma | >10 y | AFP levels: normal<br>Oral contraceptive or androgenic steroid use<br>Glycogen storage disease | No central scar<br>Heterogeneous: fat/hemorrhage<br>Opposed-phase T1-weighted gradient echo or fat suppressed: evidence of fat and glycogen |
| Metastases | | | Multifocal |
| Hydatid cyst | | History travel | Cystic lesion |
| Simple cyst | | | No enhancement |
| Choledochal cyst | | | Location in porta hepatis with communication with biliary tree |

*AFP,* Alpha fetoprotein; *CT,* computed tomography; *MRI,* magnetic resonance imaging.

images and signal void on gradient-echo images. On postgadolinium arterial and venous phase images, the tumor thrombus respectively enhances and then becomes a filling defect.

Hepatic scintigraphy may demonstrate increased activity on the initial angiographic phase due to tumor vascularity, and photopenia on the delayed images. Rarely, increased uptake of the radiopharmaceutical may be seen on delayed images, a finding more typical of FNH. Catheter angiography is currently rarely performed but usually shows tumor hypervascularity except in avascular areas of necrosis.[12–14]

The International Childhood Liver Tumor Strategy Group (SIOPEL) created the PRETEXT staging system for primary malignant liver tumors in children and is primarily used in hepatoblastoma. It has good interobserver reliability. It divides the liver into four sections (left lateral, left medial, right anterior, and right posterior). A PRETEXT number is designated by subtracting the highest number of contiguous sections not involved by tumor from 4. This system assists with surgical planning and prognosis, and predicts expected surgical difficulty.[15]

***Treatment.*** Where possible, hepatoblastomas are treated with surgical resection. However, about 40% to 60% of cases are unresectable at diagnosis.[16] Treatment with chemotherapy permits up to 85% of these to become resectable.[3] Imaging is crucial in assessing surgical resectability at presentation and after chemotherapy. Disseminated tumors have been successfully treated with chemotherapy and multiple resections of metastases. Radiofrequency ablation may be a promising treatment for recurrence.[17] Liver transplantation is an alternative for lesions that are considered unresectable. The presence of pulmonary metastases is not considered an absolute contraindication to liver transplantation due to their sensitivity to chemotherapy.[12] However, there should be no residual evidence of pulmonary metastasis postchemotherapy and before liver transplantation. The overall survival rate is reported at 65% to 70%.[1,12–14] Poor prognostic factors include AFP levels less than 100 ng/mL or more than 1,000,000 ng/mL, vascular invasion, and aneuploid nuclear content. Factors associated with favorable prognosis include single lobe involvement, pure fetal histologic composition, and AFP levels between 100 and 1,000,000 ng/mL.[12]

## Hepatocellular Carcinoma

HCC, the second most common liver tumor in children after hepatoblastoma, accounts for 35% of primary pediatric hepatic malignancies.[18] It affects two age peaks in childhood: 4 to 5 years, and, more commonly, 12 to 14 years.

In non-endomic areas of the world, approximately half of HCC arise in patients with underlying liver disease. Predisposing conditions

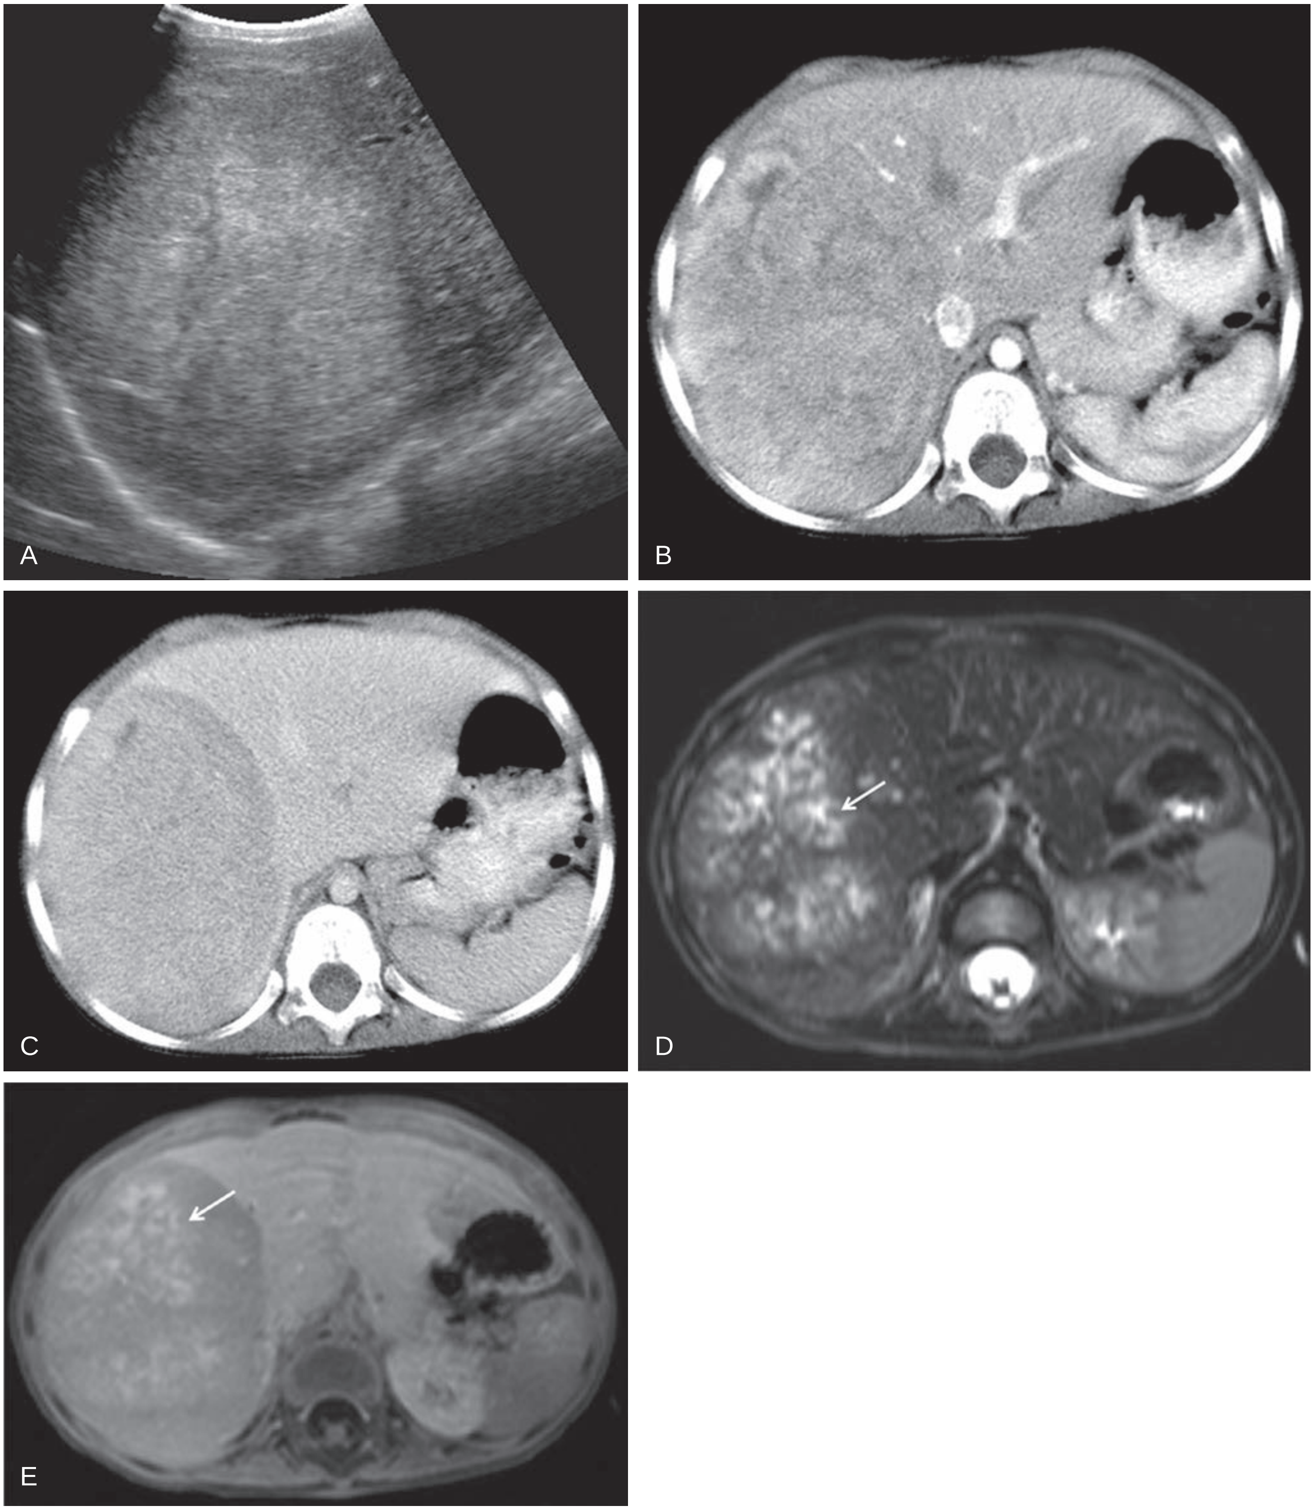

**Figure 91.1. Hepatoblastoma.** (A) Transverse abdominal sonogram in a 3-year-old boy shows a well-defined hyperechoic lesion relative to the liver. (B) CT-scan in early arterial postcontrast phase demonstrates a heterogeneous mass, hyperdense compared with the liver. (C) CT scan in delayed contrast phase shows a hypodense lesion. (D) Axial T2-weighted MR image shows hyperintense nodules with hypointense septa in between *(arrow)*. (E) Axial T1-weighted MR image after intravenous administration of gadolinium demonstrates enhancement of septa and capsule *(arrow)*.

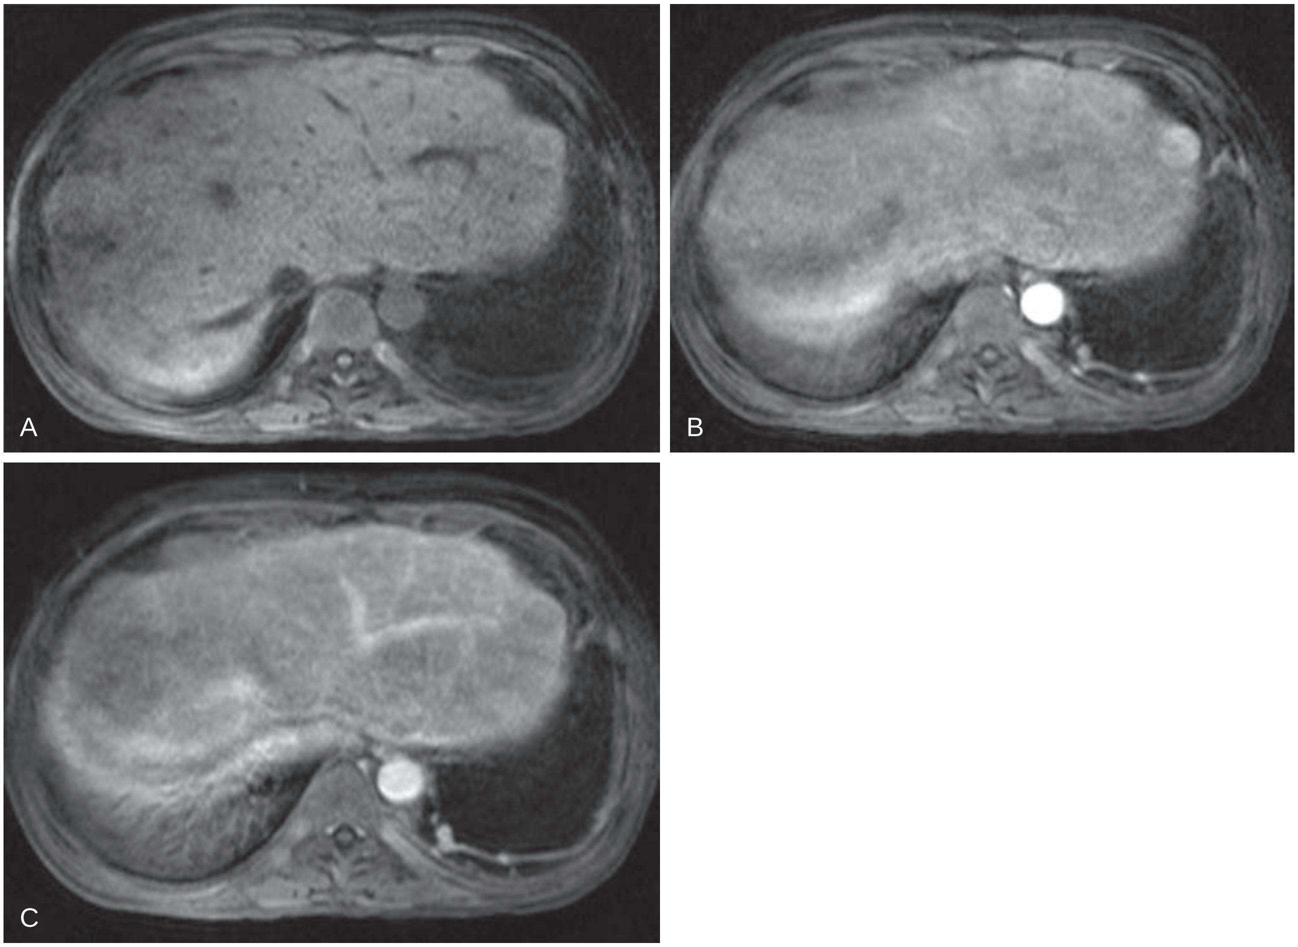

**Figure 91.2. Hepatocellular carcinoma in a 16-year-old male with cardiac cirrhosis secondary to hypoplastic left heart and Fontan circuit.** (A) Axial T1-weighted gradient echo MR image shows a nodular contour to the liver secondary to cardiac cirrhosis. (B) Postcontrast arterial phase image shows an arterial enhancing 2 cm lesion in segment 4a. (C) The lesion demonstrates washout with a peripheral enhancing pseudocapsule seen on portal venous phase images leading to a diagnosis of hepatocellular carcinoma.

include entities leading to cirrhosis such as biliary atresia, infantile cholestasis, Alagille syndrome, hemochromatosis, hereditary tyrosinemia, glycogen storage disorder, $\alpha_1$-antitrypsin deficiency, Wilson disease, galactosemia, and viral hepatitis B and C.

Serum AFP levels, like hepatoblastomas, is markedly elevated in 70% of patients.[18,19]

***Pathology.*** Neoplastic cells vary from very well to poorly differentiated. The most helpful histologic feature in distinguishing HCCs from metastases is the presence of bile canaliculi or bile pigment.[1] Kupffer cells may also be present.[12] HCCs, like hepatoblastomas, have three main growth patterns: solitary, multifocal, and diffuse/infiltrative.[12] The solitary pattern occurs most often in the right lobe of the liver. HCC demonstrates a high propensity for vascular invasion, which is present in approximately 75% of cases. Metastatic disease occurs in the lungs, brain, and skeleton.

***Imaging.*** The US findings of HCC are variable. With respect to liver parenchyma, most are hypoechoic, however, smaller lesions may be iso- or hyperechoic[12–14]; larger lesions are heterogeneous. Internal areas of increased echogenicity may represent acute hemorrhage, fat, or calcifications (less common than in hepatoblastoma), whereas areas of decreased echogenicity may represent necrosis. If a capsule is present, this may be detected as a thin halo of decreased echogenicity. Doppler demonstrates high-velocity arterial flow and is useful to identify vascular invasion by showing blood flow within the substance of the tumoral thrombus.[12]

On unenhanced CT, HCC appears as a solitary mass or as multiple well or poorly defined, hypo- to isodense masses.[14] The tumor shows variable contrast enhancement and may contain low attenuation regions of necrosis. The tumor capsule may also show a rim of low attenuation on unenhanced images that enhances on the delayed phase after contrast injection.[14] Vascular tumor thrombi may be seen as intraluminal filling defects with a surrounding meniscus of contrast. When the tumor arises in a cirrhotic liver, differentiation from regenerating nodules may be difficult.

With MR imaging, the tumor is typically slightly hyperintense on T2-weighted and hypointense on T1-weighted images, although the latter tends to be more variable because fat or hemorrhage may produce regions of hyperintensity. If a fibrous pseudocapsule is present, MR shows low signal intensity on T1- and T2-weighted pulse sequences.[20] After gadolinium, in the early arterial phase, the lesion demonstrates enhancement and washes out during the portal venous phase. The presence of a delayed enhancing pseudocapsule favors the diagnosis of HCC (Fig. 91.2). The presence of "washout" and delayed enhancing pseudocapsule are highly specific features of HCC when using extracellular contrast agents. Though the liver imaging and reporting data system (LI-RADS) is often applied in children for suspected HCC, its use has not been validated in the pediatric population. Vascular invasion appears as lack of a signal on spin-echo images and as an intravascular arterial enhancing mass with a delayed filling defect on dynamic gadolinium-enhanced images.[21]

Nuclear scintigraphy is rarely performed in patients with HCC, and usually shows decreased uptake. Fluorodeoxyglucose (FDG) PET is useful in evaluating the degree of tumor differentiation. Although the uptake of FDG is variable in HCCs, markedly elevated uptake is usually seen in poorly differentiated tumors, and well-differentiated tumors may have normal uptake.

***Treatment.*** The treatment for HCC is complete surgical resection when possible. However, approximately two-thirds of children present with unresectable disease due to multifocal or massive involvement of the liver, major vascular involvement, or metastases. HCC is relatively insensitive to systemic chemotherapy.[22] The impact of chemotherapy is unclear with no evidence that it offers additional benefit in children with resectable localized HCC. Liver transplantation is reported for unresectable tumor but remains controversial.[18]

Radiofrequency and intra-arterial chemotherapy have been reported, but the benefits need further investigation.[23,24] The prognosis is variable and directly related to the resectability and histology of the lesion. In tumors with favorable histology and complete resection, the 2-year survival rate may exceed 97%. However, without complete resection and with unfavorable histology, the 2-year survival rate may be less than 20%.[18] In places where the prevalence of tyrosinemia is especially high, routine neonatal screening and immediate treatment of positive cases by NTBC (2-[2-nitro-4-trifluoromethylbenzoyl]-1,3-cyclohexanedione) has resulted in a marked decrease in the prevalence of HCC in this population.[25]

## Fibrolamellar Carcinoma

***Overview.*** Fibrolamellar carcinoma (FLC) is a variant of HCC representing approximately 5% to 8% of all cases of HCC. It occurs in patients without underlying hepatic disease and has distinctive clinical and pathologic features. It occurs in younger patients; approximately 85% of patients are less than 35 years of age and can occur in children as young as 10 years.[26]

It has been associated with syndromes including Wilms, Carney, Fanconi anemia, and familial adenomatous polyposis; these associations have been implicated in shared molecular pathways.

Patients present with abdominal symptoms or pain, and sometimes a palpable mass. Uncommon presentations are gynecomastia, jaundice, and venous compression or thrombosis. AFP levels are generally normal.[12,20]

***Pathology.*** In 80% to 90% of patients, FLC is a large, circumscribed, and nonencapsulated mass.[20] Uncommonly, it is multifocal. A central fibrous scar is common and may contain calcifications. Metastatic lymphadenopathy is seen in 70% of cases.[27]

***Imaging.*** US shows a well-defined mass with heterogeneous echotexture containing iso- or hyperechoic areas.[28] The central scar is visualized in 50% of patients, is hyperechoic, and may contain calcifications.

CT shows a low-density, well-defined lobulated mass with calcifications in 30% to 55% of cases and a central scar in 45% to 60% of cases. The central scar is hypoattenuating with little

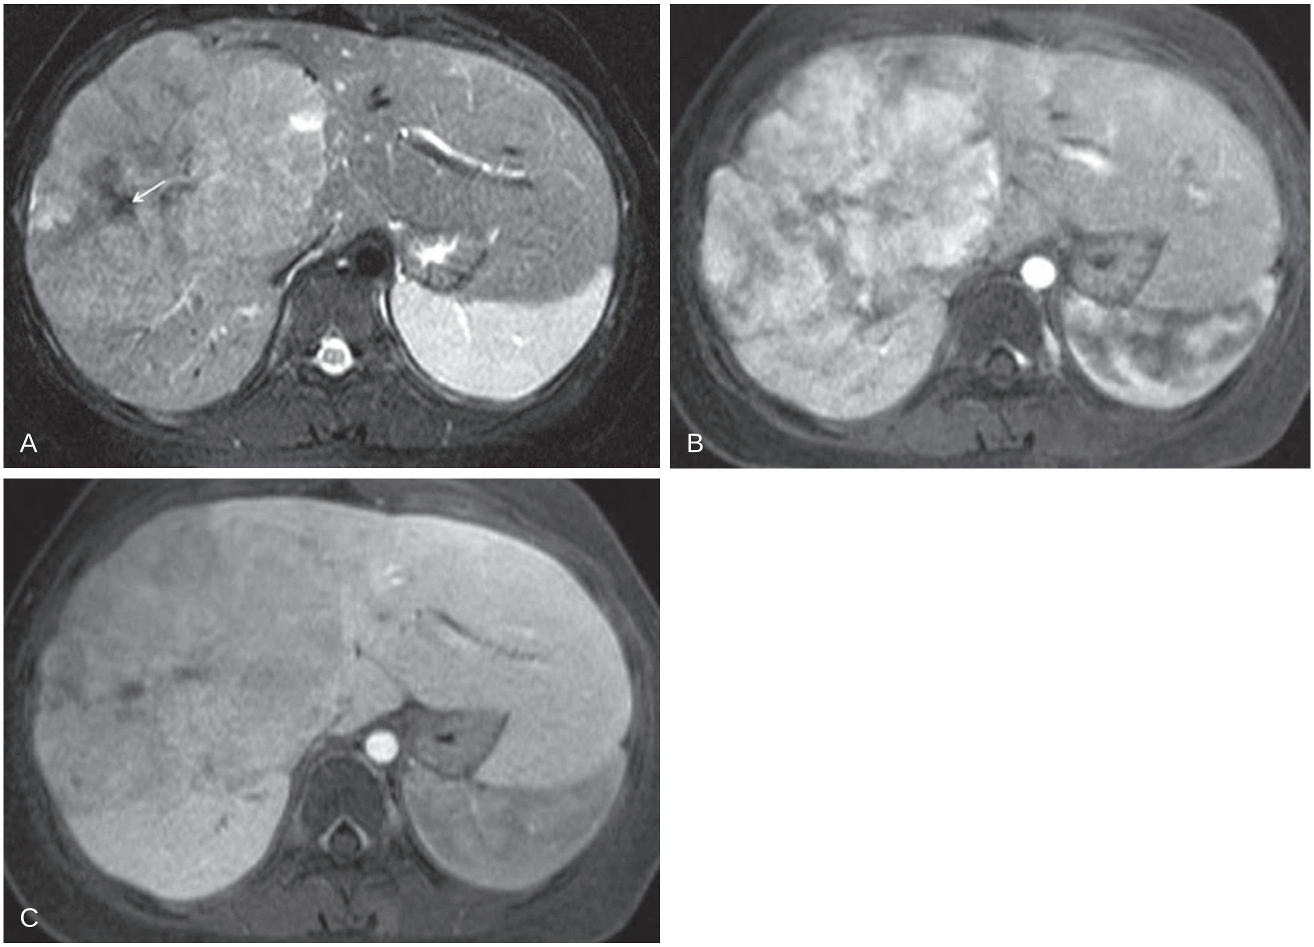

**Figure 91.3. Fibrolamellar carcinoma in a 16-year-old girl.** (A) Axial T2-weighted MR image shows a large mass in the right lobe of the liver with a hypointense *(arrow)* central scar. (B) The mass enhances avidly in the early arterial phase. (C) Portal venous phase demonstrates washout of contrast with the lesion becoming hypointense compared with the normal liver parenchyma.

or no enhancement. Adjacent lymphadenopathy is often present in the hepatic hilum at diagnosis.

On T1-weighted MRI, the tumor is hypo- (86%) to isointense (14%), and slightly hyper- (85%) to isointense (15%) on T2-weighted images (Fig. 91.3).[12–14,16–24,26–29] The fibrous scar is hypointense on T1 and T2 imaging. The hypointensity of the central scar and lack of contrast retention in the mass on hepatocyte phase imaging helps differentiate FLC from FNH.

***Treatment.*** The treatment of FLC is primarily surgical resection, and surgical resectability is therefore the most important prognostic factor.[28] When the tumor is not resectable, liver transplantation, systemic chemotherapy, or hepatic intra-arterial chemoembolization are considered. Recent literature reports no significant difference in the prognosis of FLC compared with HCC in patients without underlying hepatic disease.[26,27] Normal hepatic function, younger age, absence of vascular invasion or thrombosis, lack of lymphadenopathy, and negative surgical margins are favorable prognostic indicators. The 5-year survival rate ranges from 30% to 67%.[23,24,26,27]

## Undifferentiated Embryonal Sarcoma

UES, previously called malignant mesenchymoma, embryonal sarcoma, or fibromyxosarcoma, is a rare, aggressive tumor of mesenchymal origin.

Most commonly, the tumor affects children between 6 to 10 years of age with a slight male predominance.[30] It is the third most common malignant pediatric liver tumor.[3,19,31]

***Pathology.*** On histology, UES shows primitive spindle-shaped, sarcomatous satellite cells, closely packed in sheets or whorls, and scattered throughout a background of loose myxoid tissue, which contains foci of hematopoiesis in 50% of cases.[30] It is usually large at presentation, solitary, and is predominantly solid with occasional cystic, necrotic or hemorrhagic areas and involves the right lobe of the liver (75%).[30] Metastases are usually to the lung and bone. AFP levels are normal.[19]

***Imaging.*** On sonography, the tumor is solid and iso- to hyperechoic relative to normal liver with small anechoic spaces, which correspond to necrosis, hemorrhage, or cystic degeneration.[30,32]

On CT, the tumor reveals predominantly water attenuation correlating with myxoid stroma (88% of tumor volume).[12,30] After IV contrast, a dense enhancing peripheral rim can be seen in relation to the pseudocapsule. Uncommon hyperattenuated regions may indicate hemorrhage and calcifications.

At MR, the tumor is of low intensity on T1- and increased intensity on T2-weighted sequences (Fig. 91.4). A hypointense rim on T1- and T2-weighted images indicates a pseudocapsule. Bright areas on T1-weighted images correspond to regions of hemorrhage. Fluid levels, internal debris, and septa may be seen on T2-weighted images.[30,32] Heterogeneous enhancement of the tumor is seen after intravenous gadolinium contrast.[33]

***Treatment.*** The treatment is complete tumor resection. As late as three decades ago, the prognosis was poor with death occurring within 12 months in many cases.[31] However, more recent reports of multimodal treatment show markedly improved survival. Patients with unresectable tumors, which are not responsive to chemotherapy, can be treated with liver transplantation.[12]

## Rhabdomyosarcoma of the Biliary Tree

Although rhabdomyosarcoma can be found throughout the body, involvement of the biliary ducts is one of the rarest forms of this mesenchymal tumor. It occurs almost exclusively in the pediatric age group and under the age of 5 years (75% of cases).[12] Jaundice is the most frequent presentation, and it may resemble hepatitis, which can cause a delay in diagnosis.[34] Elevated serum conjugated bilirubin and alkaline phosphatase occur with normal levels of AFP.

***Pathology.*** The tumor arises from beneath the biliary epithelium[35] and grows as a polypoid mass within the biliary tree. It most frequently occurs in the common bile duct but can arise within the intrahepatic bile ducts, gallbladder, and cystic duct. Only the embryonal subtype of rhabdomyosarcoma arises in the biliary tree.[12] Histologically, rhabdomyosarcoma demonstrates undifferentiated blue cells with scant cytoplasm and primitive nuclei that form a firm, lobulated mass with infiltrative margins and a well-defined pseudocapsule.[9,12,16,36]

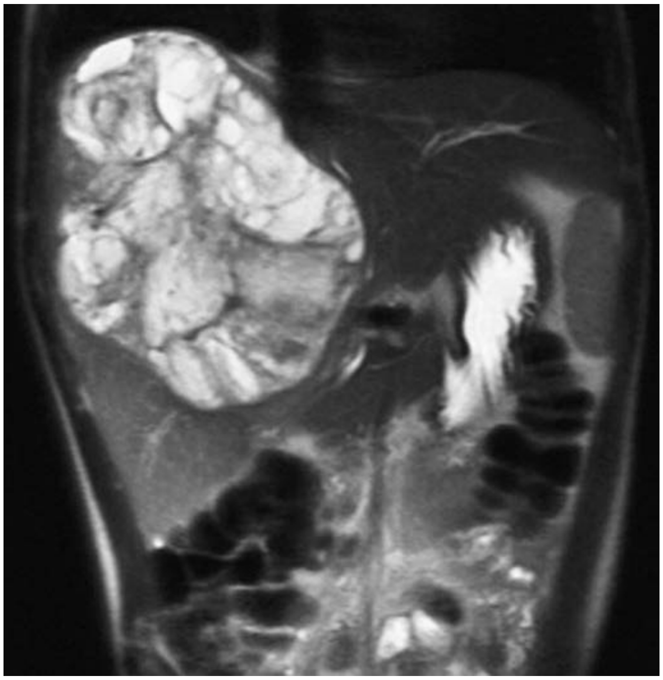

**Figure 91.4. Undifferentiated embryonal sarcoma in a 13-year-old girl.** Coronal T2-weighted MR image shows a multiloculated mass of heterogeneous signal intensity in the right lobe of the liver. *(Courtesy of Lynn Fordham, MD.)*

At diagnosis, metastases are present in 30% of cases,[12] typically to the lung, skeleton, and pericardium, although the tumor has a greater propensity to invade contiguous structures.[35]

***Imaging.*** US usually demonstrates a solitary, heterogeneous, relatively hypoechoic mass or multiple hypoechoic nodules associated with biliary duct dilatation and intraductal extension.[12,37] Portal vein displacement without thrombosis is common.[37]

CT shows a homo- or heterogeneous hypo- or hyperattenuating intraductal mass with variable contrast enhancement associated with biliary dilatation (Fig. 91.5).[37,38] MRI usually shows low-signal intensity on T1- and high-signal intensity on T2-weighted sequences, with intense, heterogeneous enhancement after IV contrast administration.[12,37] MR cholangiopancreatography often demonstrates a partially cystic lesion in the common bile duct and a mass adjacent to the duct causing mural irregularity. Percutaneous cholangiography displays an intraluminal polypoid mass.[37–39] Gallium uptake can help localize metastatic disease.[37]

***Treatment.*** Multimodal therapy, including surgical resection, radiation, and chemotherapy, has improved outcome with 78% survival in local disease.[40] Concurrent internal or external biliary drainage is essential because some chemotherapeutic agents depend on hepatobiliary excretion, and an inability to excrete them may result in significant systemic toxicity.[40]

## Angiosarcoma

Angiosarcoma is a rare, aggressive, malignant vascular tumor. It typically presents in adults with a history of exposure to thorium dioxide (Thorotrast), arsenic, and vinyl chloride[12,41]; however,

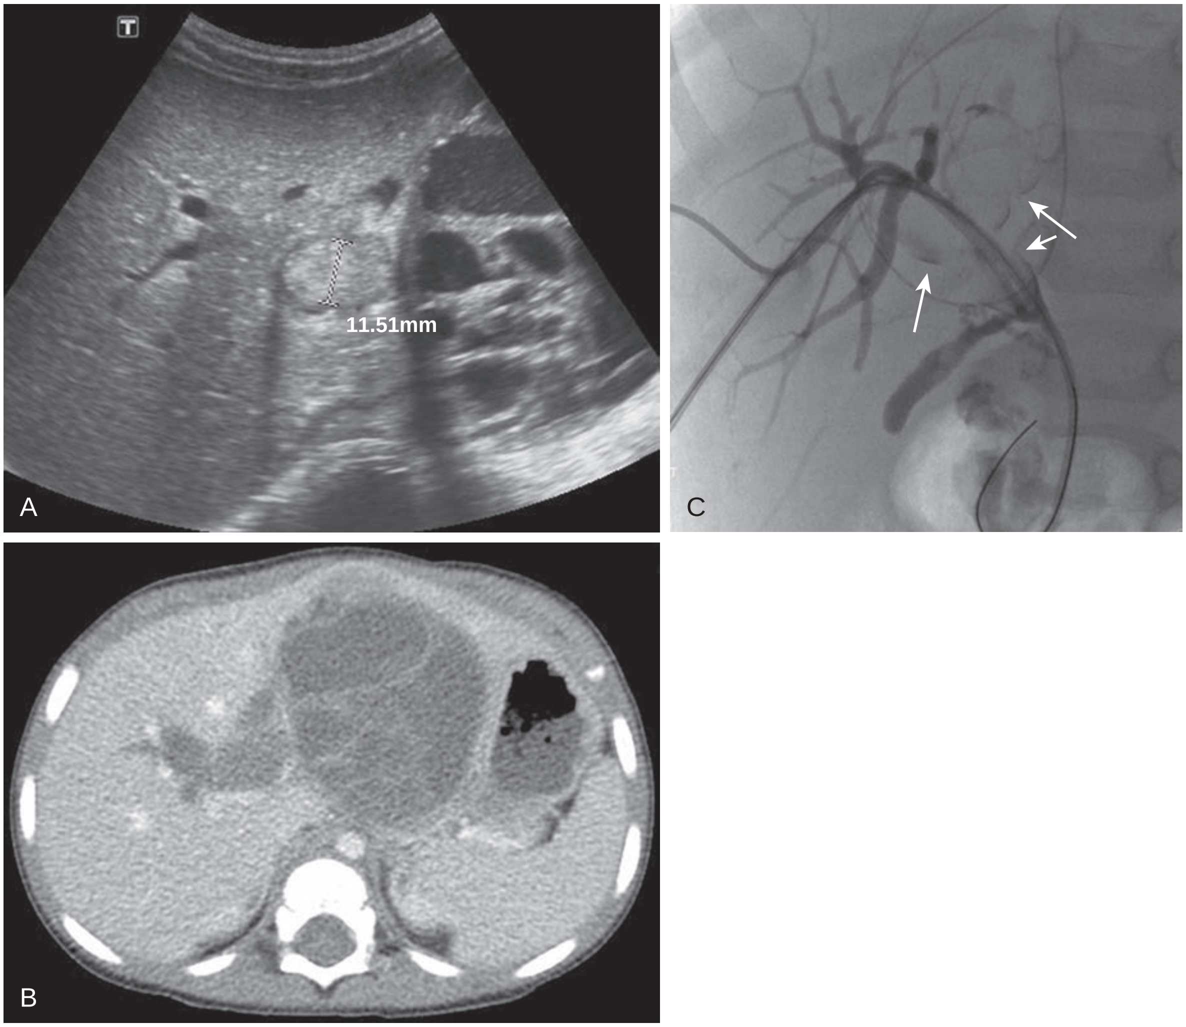

**Figure 91.5. Embryonal rhabdomyosarcoma in a 20-month-old boy.** (A) Transverse sonogram shows a multicystic lesion with a hyperechoic mass in the common biliary tree. (B) CT-scan shows the hypoattenuating tumor in the common bile duct that extends into the intrahepatic and extrahepatic bile ducts. (C) Percutaneous cholangiography reveals multiple filling defect of the common bile duct with extension in the intrahepatic bile ducts *(arrows)*.

exposure to these toxins is now rare. It can arise de novo in adults, in a cirrhotic background, or associated with hemochromatosis and use of anabolic steroids, leading to this tumor being considered the "quintessential example of malignant transformation secondary to environmental exposures."[42,43]

In children, the tumors are very rare, occurring after the age of 1 year. They typically arise without prior history of exposure, with cases reported arising in children with previously diagnosed infantile hemangioendotheliomas.[41,44] Clinical symptoms include hepatomegaly associated with pain, anorexia, and weight loss, as well as thrombocytopenia and consumptive coagulopathy.[43]

***Pathology.*** Histologically, the spindle cell form (hypercellular whorls with intermingled bile ducts and vessels) is especially common in children.[36,41] At the time of diagnosis, 60% of cases have metastatic disease, most commonly to the lungs and spleen.[42,43]

Immunohistochemical studies demonstrate reactivity of tumor cells to factor VIII-related antigen, CD31, and CD34 confirming the vascular nature of the tumor.[45]

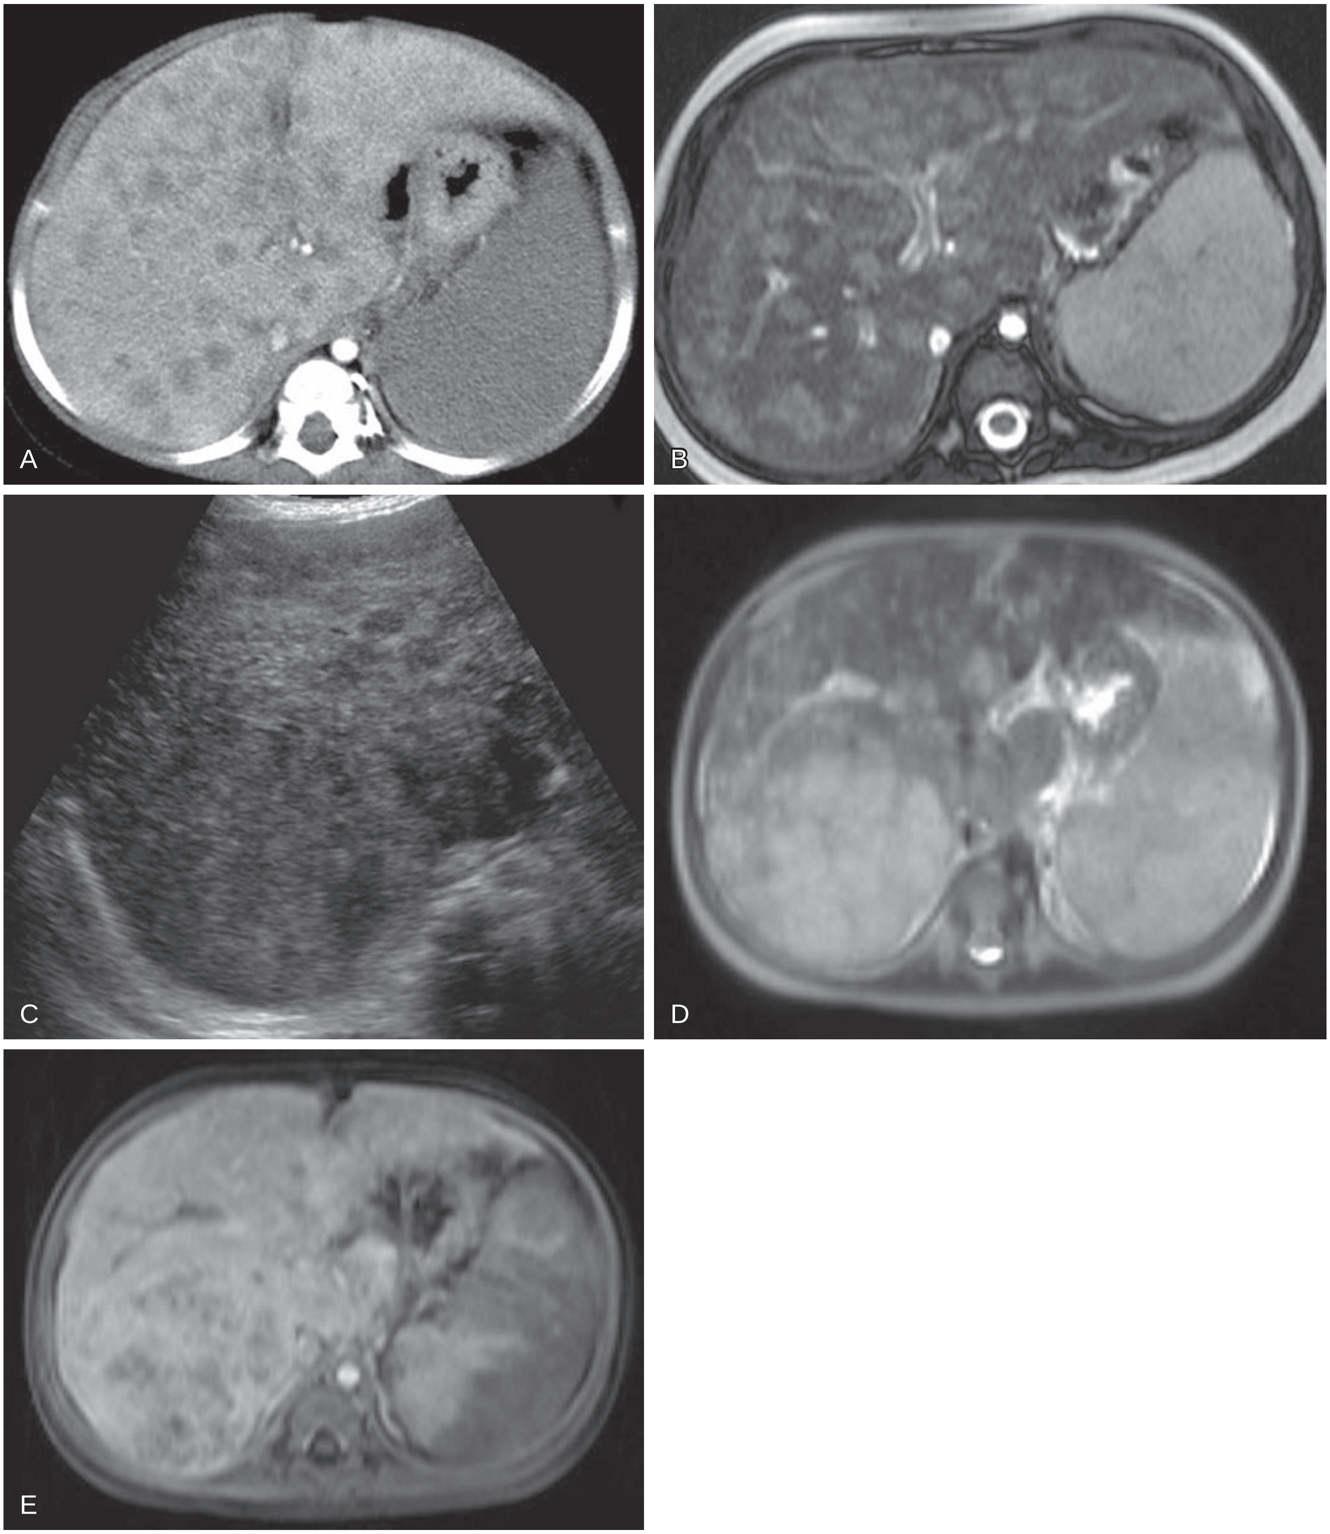
***Imaging.*** Imaging findings are variable. It can be solitary, multifocal, or diffuse.

On US, the lesion is heterogeneous, and the echogenicity varies depending on the amount of hemorrhage or necrosis. At CT, nodules are hypoattenuating and may contain foci of hemorrhage. Contrast enhancement is variable.[42,46] At MR imaging, the masses show low-signal intensity on T1-weighted images with hyperintense foci (related to hemorrhage), and heterogeneous-signal intensity on T2-weighted images (e-Fig. 91.6). Dynamic MR imaging with contrast reveals a heterogeneous pattern of enhancement.[43] FDG PET/CT displays marked uptake in the tumors and is helpful for the detection of metastases.

***Treatment.*** The prognosis is dismal with a rapid deterioration of patients within six months from the diagnosis regardless of treatment.[12,42,45]

## Cholangiocarcinoma

Cholangiocarcinoma is a rare hepatic neoplasm accounting for less than 1% of all carcinomas. It may complicate disorders that affect children, such as choledochal cysts and sclerosing cholangitis, but it usually occurs late in the disease process and thus presents mainly in adults.



**e-Figure 91.6. Angiosarcoma.** (A) A 9-month-old girl with normal US liver at 3 days of life shows numerous hypodense lesions in the liver on CT-scan with contrast enhancement. (B) Axial T2-weighted MR image demonstrates multiple hyperintense nodules diagnosed as infantile hemangioma. Under steroid and interferon, a complete regression of lesions was seen. Eight months later, the patient presented a coagulopathy and abdominal mass. (C) US shows multiple infiltrating nodules associated with a significant lesion in the right lobe. (D) Axial T2-weighted MR image shows a heterogeneous signal intensity. (E) Dynamic MR at 5 minutes demonstrates a heterogeneous pattern of enhancement. *(Courtesy of Lise H. Lowe, MD.)*

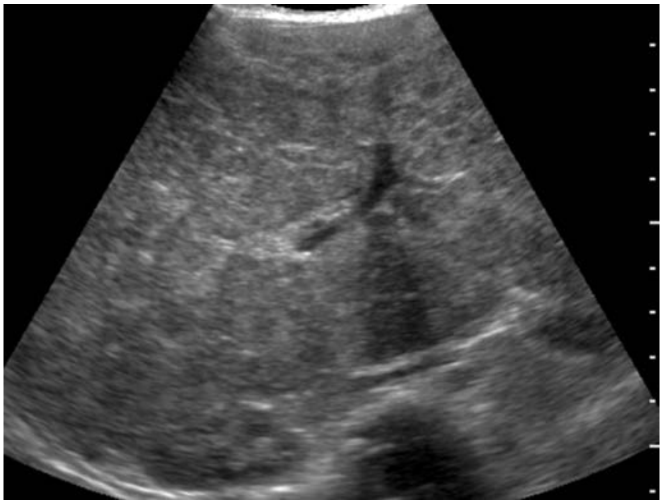


**Figure 91.7. Metastatic infiltrative neuroblastoma in an 8-month-old boy with hepatomegaly.** Transverse sonogram reveals numerous discrete lesions of variable echogenicity and loss of normal architecture.

## Hepatic Metastases

Hepatic metastases in children most often arise from neuroblastoma, lymphoma, and Wilms tumor. The appearance of metastatic disease is highly variable, ranging from one or more focal lesions to a diffuse infiltrative pattern, which is most often seen in neuroblastoma. Most discrete hepatic metastases are multiple; hypoechoic on sonography; low attenuation on CT, with a tendency toward peripheral enhancement; and hypointense on T1- and hyperintense on T2-weighted MRI. Hepatic metastases demonstrate diffusion restriction and lack of contrast retention on hepatocyte phase imaging with hepatobiliary contrast agents. These imaging findings however have to be interpreted in conjunction with patient history and signal intensity on T1- and T2-weighted imaging as benign lesions such as FNH can also demonstrate diffusion restriction.

Metastatic neuroblastoma to the liver has two typical patterns: (1) numerous discrete lesions of variable echogenicity, attenuation, and enhancement; and (2) diffuse infiltration with distortion of the normal hepatic architecture, leading to hepatomegaly (Fig. 91.7). The latter pattern is especially common with stage IV-S disease (primary lesion limited to the organ of origin or primary lesion with regional spread but without extension across the midline, and involvement of the liver, skin, or bone marrow).

Both Hodgkin disease and non-Hodgkin lymphoma involve the liver in more than one-half of patients. Primary hepatic lymphoma is rare. Lymphoma may present with multiple discrete lesions or an infiltrative pattern similar to that of neuroblastoma. In addition, lymphoma is often associated with lymphadenopathy and splenic lesions.

## BENIGN HEPATIC NEOPLASMS

### Liver Hemangioma

Hepatic hemangiomas (HHs) are true benign vascular tumors and can be divided into infantile and congenital hemangiomas. Congenital hemangiomas are divided into rapidly involuting congenital hemangiomas (RICH) and noninvoluting congenital hemangiomas (NICH). These must be differentiated from misnamed adult HHs, which are venous malformations. The literature reports three patterns of presentation of HHs: focal, multifocal, and diffuse.

Usually, focal HHs are RICH diagnosed during in utero. RICH has an equal sex distribution, negative GLUT-1 immunoexpression, and no association with cutaneous infantile hemangiomas. RICH is a significant hypervascular tumor with shunting that may lead to cardiac insufficiency at birth. It may be associated with transient thrombocytopenia and anemia.

Multifocal and diffuse HHs are true infantile hemangiomas with the female:male ratio of 3–5 : 1. Most are associated with cutaneous infantile hemangioma with a positive GLUT-1 immunoexpression.

Most liver hemangiomas are clinically silent and remain undetected. However, they can also present with life-threatening complications, especially in the setting of multifocal lesions with congestive heart failure related to an intralesional shunt, hypothyroidism secondary to overproduction of type III iodothyronine deiodinase, fulminant hepatic failure and/or abdominal compartment syndrome, consumptive coagulopathy related to intralesional thrombosis, hemorrhage, and hemolysis.

***Pathology.*** The differentiation between infantile and congenital hemangiomas (NICH or RICH) is often impossible because: (1) usually there is no biopsy to look for GLUT-1 marker present in infantile hemangioma; and (2) unlike skin lesions, it is usually not known whether or not the hepatic lesion is present at birth.

***Imaging***

*(1) Solitary Lesions.* On US, a well-defined hypo- or hyperechoic lesion is seen. The echotexture is sometimes heterogeneous, related to central hemorrhage or necrosis. Color Doppler US demonstrates a variety of flow patterns depending on the presence of microshunt, portosystemic, or arteriovenous shunt. These shunts are clinically significant only when associated with cardiac failure.

HHs typically appear on CT as low-attenuation masses that may contain calcifications. After IV contrast, there is usually early peripheral and nodular enhancement with variable delayed central enhancement.

On MRI, they are typically hypointense on T1-weighted images and hyperintense on T2-weighted images. The contrast enhancement pattern on MRI is similar to that seen on CT (Fig. 91.8).[47] Heterogeneous signal on all sequences is seen if hemorrhage, thrombosis, and/or necrosis are present. Calcification occurs in approximately 16% of cases.

*(2) Multifocal Lesions.* On US, small multifocal lesions are homogeneous and most are hypoechoic, although hyperechoic nodules may occur. The hepatic arteries and veins generally appear enlarged. Large feeding arteries and draining veins are seen in and around the vascular tumors (Fig. 91.9).

On MR, multiple nodular tumors are T1 hypointense and T2 hyperintense, and demonstrate homogeneous enhancement after gadolinium injection. Flow voids are seen within and/or adjacent to the lesions due to large hepatic arteries or veins. Aortic tapering distal to the celiac trunk is a good indicator of increased hepatic flow, and accordingly is a predictor of cardiac overload risk.[48]

*(3) Diffuse Lesions.* Diffuse lesions present with extensive hepatic involvement, the numerous small lesions in the liver leading to severe hepatomegaly.[49] Despite the size of the lesions, most diffuse liver hemangiomas show no cardiac failure in relation to the shunt. The enlarged infiltrated liver reveals numerous hypoechoic lesions. MR imaging findings are similar to the focal and multifocal lesions.

***Treatment.*** No treatment is required for asymptomatic focal, multifocal, or diffuse HH.

RICH characteristically regresses in an accelerated fashion by 12 to 14 months.[50–53]

Medical treatment can be attempted even though the benefit of medical treatment is unknown.

Patients with multifocal or diffuse infantile HH associated with compartment syndrome, cardiac failure, or hypothyroidism are treated with propranolol (a nonselective beta blocker) and/or systemic glucocorticoid, and control of hypothyroidism. Catheter embolization is recommended for patients with cardiac failure

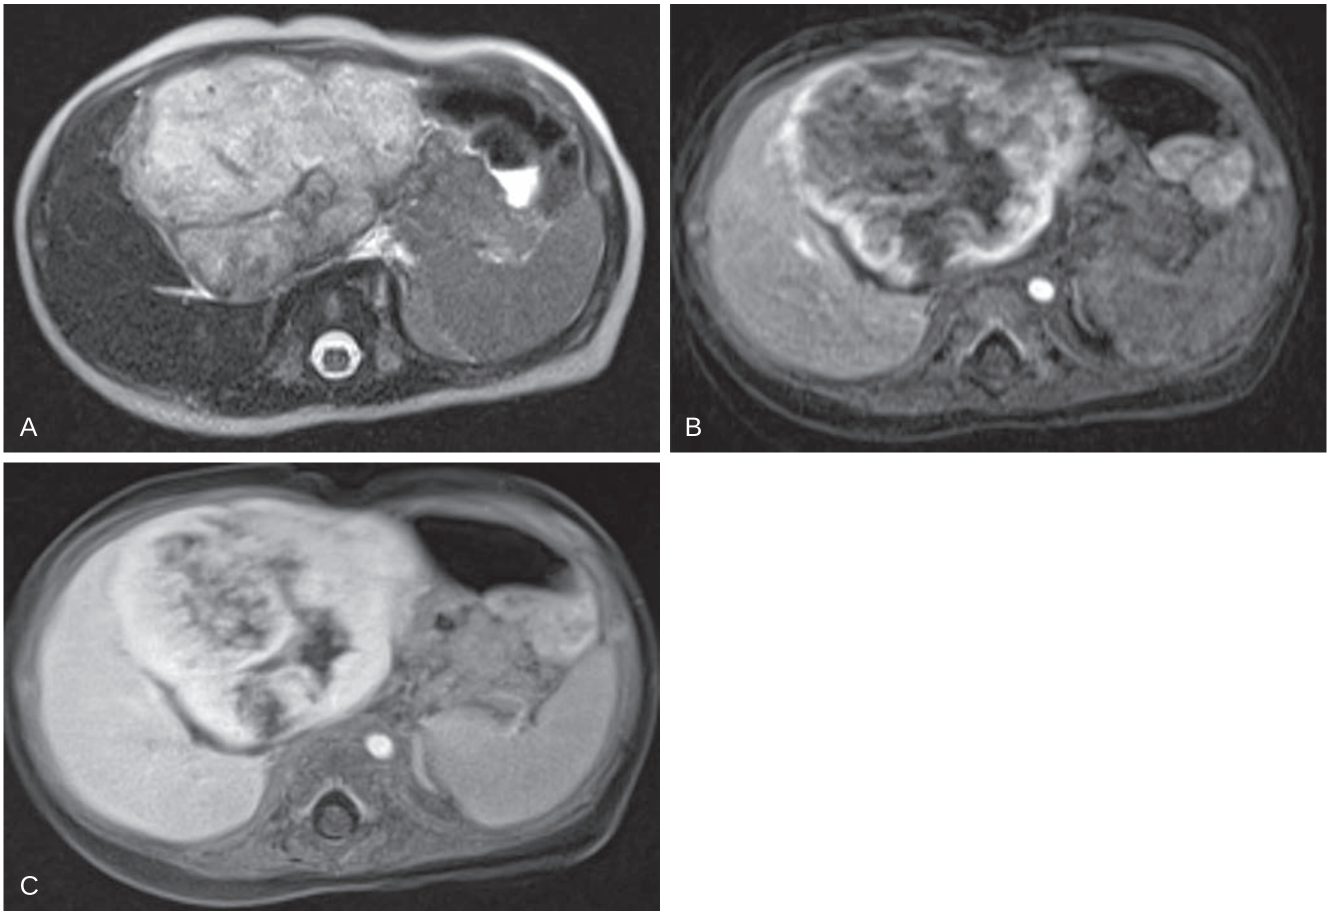

**Figure 91.8. Focal liver hemangioma in a 4-month-old boy.** (A) Axial T2-weighted MR image shows a fairly well-circumscribed T2 hyperintense mass in the left lobe of the liver. (B) Dynamic postcontrast arterial phase image shows peripheral puddling enhancement in the mass. (C) Equilibrium phase image obtained at five minutes postcontrast demonstrates gradual fill in. Note that the intensity of enhancement follows the blood pool closely.

related to arteriovenous or portosystemic shunts when medical treatment has failed.[54] Vincristine is an alternative for patients refractory to beta blockers or steroid treatment.[55] In selected instances, liver transplant may be contemplated.

## Mesenchymal Hamartoma

Mesenchymal hamartoma is the second most common benign liver mass in children after vascular tumors. Most of them are discovered by 5 years of age.[3,56,57] Mesenchymal hamartomas affect boys slightly more often than girls and have been diagnosed on prenatal US. The most common clinical presentation is painless abdominal distension. AFP levels are normal.

***Pathology.*** Histologically, it is composed of disordered, primitive, fluid-filled mesenchyme, hepatic parenchyma, and bile ducts, in addition to stromal cysts of variable size without a capsule. The mass may be pedunculated and attached to the inferior surface of the liver.

***Imaging.*** On US and CT, mesenchymal hamartomas are typically multicystic, heterogeneous masses with septa (Fig. 91.10). They are not typically associated with calcifications or hemorrhage. The cysts are anechoic with thin or thick septa. When the cysts are tiny, the lesion appears as a solid echogenic lesion. Low-level echoes may be seen within the fluid related to gelatinous contents or hemorrhage. On CT, mesenchymal hamartomas are complex cystic masses. Their septations and solid components enhance after IV contrast. On MRI, the cystic regions are hypointense on T1- and hyperintense on T2-weighted images. The signal intensity varies, depending on the stromal content, the amount of protein, and the presence or absence of hemorrhage within the cyst. Septa and solid portions of the lesion are usually of decreased signal on T1- and T2-weighted images.[13,14,58–60] Enhancement occurs within septa and the solid components of hamartomas.

***Treatment.*** The treatment for mesenchymal hamartoma is surgical resection. Observation of mesenchymal hamartoma is not recommended due to rare reports of malignant transformation to UES.[61,62] Long-term survival is 90% even with incomplete resection.[3,57]

## Focal Nodular Hyperplasia

FNH accounts for 2% of all primary pediatric hepatic tumors. It is most commonly diagnosed incidentally in children with a mean age at diagnosis between 8 and 11 years and has a marked female predominance.[3]

Although the exact cause of this lesion is often uncertain, it is generally thought to be due to an underlying hepatic vascular disturbance.[63] Long-term survivors of pediatric malignancy have a higher incidence of FNH believed to be a manifestation of injury sustained to the vascular endothelium secondary to chemotherapy and/or radiotherapy.[64,65] This represents about one-third of children with FNH. Most patients have a history of malignancy or

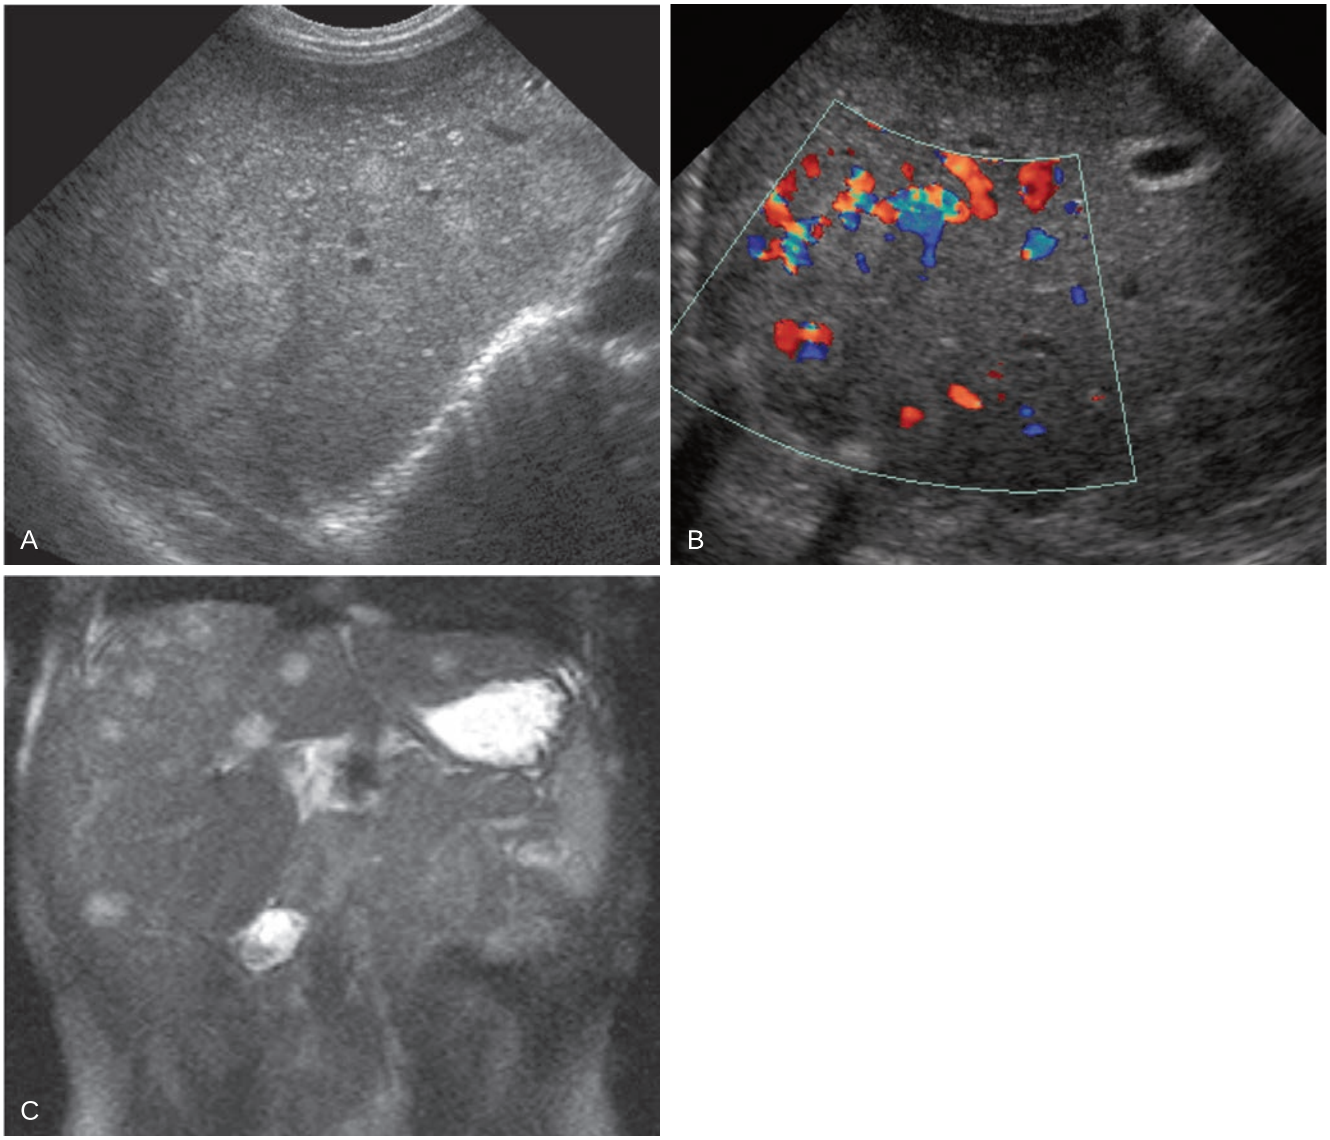

**Figure 91.9. 14-day-old girl with multiple skin infantile hemangiomas with liver hemangioma.** (A) Transverse sonogram shows hyperechoic multiple lesions. (B) Color Doppler US reveals hypervascular nodules. (C) Coronal T2-weighted MR image shows multiple hyperintense lesions.

hematologic disorder requiring stem cell or bone marrow transplant, high doses of alkylating agents that are very hepatotoxic and associated with hepatic veno-occlusive disease and radiotherapy. Oral contraceptives and pregnancy are no longer considered risk factors for the FNH development,[66] however the discontinuation of oral contraceptives is recommended. FNH is also seen in patients with portosystemic shunts and most of them regress after the closure of the shunt.

***Pathology.*** Histologically, FNH is composed of hepatocytes (filled with fat, triglyceride, and glycogen), Kupffer cells, malformed blood vessels, and radial fibrous septa with bile ducts unconnected to the biliary tree. Foci of necrosis and hemorrhage are rare compared with HCA.[66] It usually contains a central vascular scar. FNH is most common in the right hepatic lobe and is multiple in 20% of cases.

***Imaging.*** On imaging, FNH is composed of a single, well-defined, often subcapsular mass with a characteristic vascular myxomatous central scar. However, atypical imaging features are common and necessitate multiple studies to obtain the diagnosis. FNH in pediatric cancer survivors tend to be multiple as opposed to the solitary lesions seen in healthy individuals.

On US, FNH is a well-defined homogeneous mass.[67] The central scar, seen in approximately 33% of cases on US, appears hyperechoic relative to the remaining mass.[66,67] On color Doppler US, increased blood flow is seen in the central scar extending to the periphery in a spoke-wheel pattern.[68,69] The flow is arterial compared with intratumoral venous flow seen in an adenoma.

On unenhanced CT, the mass and central scar are hypo- to isodense in comparison with liver. A central scar is found in up to 60% of cases. After the administration of contrast material, the mass enhances brightly, with delayed enhancement and washout of the central scar.[70]

On MRI, FNH is iso- to slightly hypointense to liver on T1- and iso- to slightly hyperintense on T2-weighted images. The scar is hypointense on T1- and hyperintense on T2-weighted images. Dynamic intravenous contrast imaging shows uniform enhancement, during the arterial phase and mild to absent enhancement on delayed images.[67,71,72] When using a MRI hepatobiliary contrast

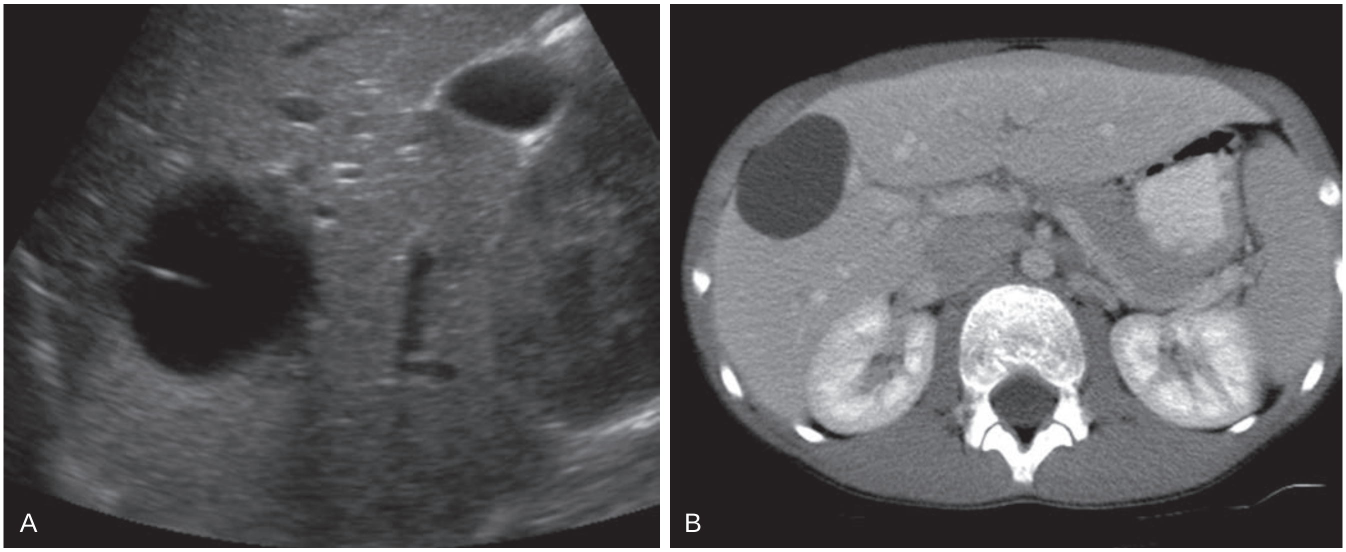

**Figure 91.10. Mesenchymal hamartoma in an 11-year-old male with an abdominal pain.** (A) Transverse sonogram demonstrates a well-defined, lobulated anechoic mass with a septation. (B) Axial contrast-enhanced CT image confirms the well-defined fluid attenuation lesion.

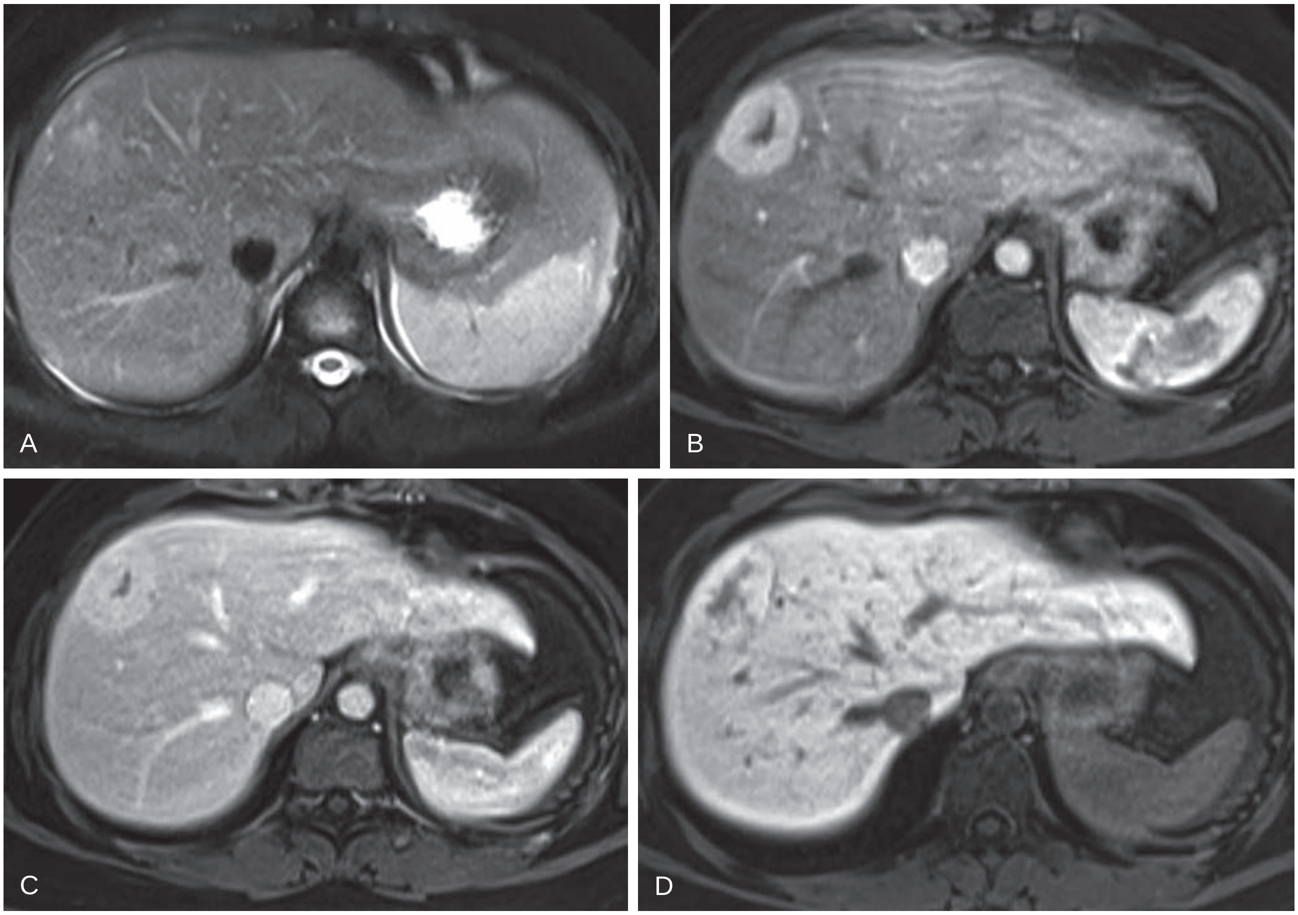

**Figure 91.11. 14-year-old girl with incidentally detected focal nodular hyperplasia.** (A) Axial T2-weighted MR demonstrates a lesion in segment 8 of the liver. The lesion is essentially isointense to the liver parenchyma and has a central T2 hyperintense scar. Dynamic postcontrast imaging was performed with hepatobiliary contrast agent. (B) The lesion demonstrates intense peripheral enhancement on arterial phase imaging. (C) Portal venous phase image shows the lesion is becoming isointense to the liver parenchyma. (D) Hepatocyte phase imaging demonstrates retention of contrast within the lesion leading to a diagnosis of FNH.

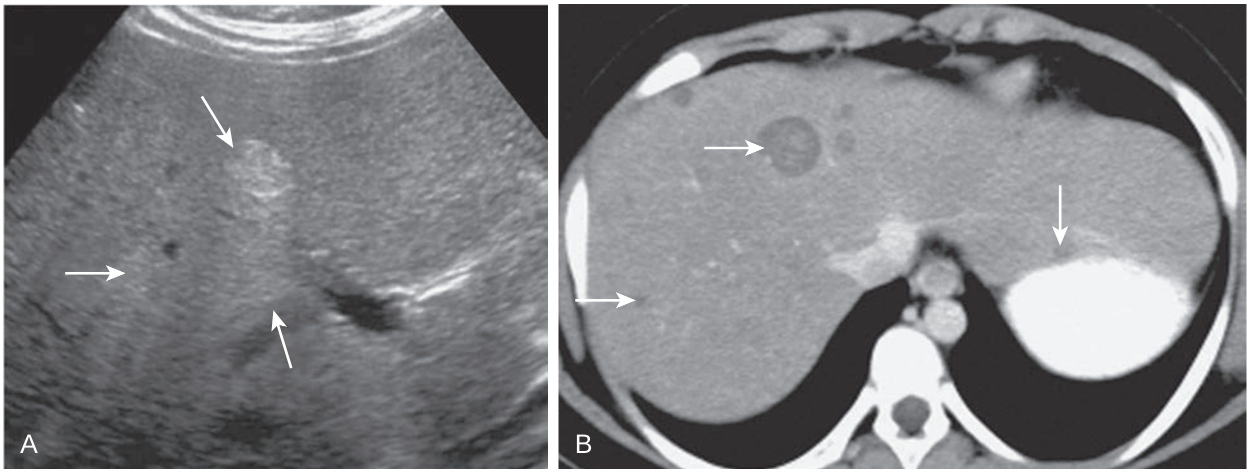

**Figure 91.12. Hepatocellular adenoma in a 9-year-old girl with glycogen storage disease.** (A) Axial sonogram reveals hyperechoic foci within the liver *(arrows)*. (B) Axial contrast-enhanced CT confirms multiple well-defined, hypoattenuating masses of varied size throughout the liver *(arrows)*. *(Courtesy of Dr. Lisa Hutchison.)*

agent, which is currently off-label in the pediatric population (e.g., Eovist; gadoxetate disodium), FNHs demonstrate retention of contrast on delayed images obtained 20 minutes after contrast material injection (hepatobiliary phase) (Fig. 91.11). The enhancement is often vivid resembling a spoked wheel because of the central scar and radiating fibrous septa. On hepatocyte phase images after Gd-EOB-DTPA, it usually appears iso- or hyperintense relative to the surrounding liver parenchyma, showing the classic popcorn like enhancement pattern because of the accumulation of Gd-EOB-DTPA and poor biliary drainage unlike an adenoma that typically appears hypointense because of the lack of biliary canaliculi.

Only FNH contains sufficient Kupffer cells to cause normal to increased uptake on technetium-99m TC sulfur colloid scintigraphy, a finding that is nearly pathognomonic. Sulfur colloid scans may be utilized to distinguish between FNH and HCA.[9,67–69]

In the group of children with a history of chemo- and/or radiotherapy, FNH can be confused with tumor recurrence. Strong enhancement at the arterial or early portal phase is important to differentiate FNH from metastases that usually remain hypointense on arterial or early portal phase when compared with the surrounding liver. Even if not presenting the typical diagnostic criteria for FNH, multiple liver lesions strongly enhancing at the arterial phase in a long-term cancer survivor are highly suggestive of the diagnosis.

***Treatment.*** FNH has no malignant potential and rarely hemorrhages or ruptures. Conservative management with serial hepatic US examination is recommended for asymptomatic patients. Recommendations for symptomatic patients include discontinuation of oral contraceptives, surgical resection, ablative therapy, or embolization.[9]

## Hepatocellular Adenoma

HCAs are extremely rare during childhood and occur more often in adult women. Girls over 10 years of age using oral contraceptives are the most frequent pediatric patients with liver adenomas.[19,57] HCAs are also associated with anabolic steroid therapy in men (e.g., Fanconi anemia),[73,74] glycogen storage disease types I and III, galactosemia, and familial diabetes mellitus. An association between hypervascular liver neoplasms, such as HCA and FNH, and patients with congenital or acquired abnormal hepatic vasculature (portal vein absence or occlusion, and congenital portosystemic shunts) has been reported. Malignant transformation of HCA into HCC is rare. Patients are commonly asymptomatic. Liver function is normal with no elevation of AFP levels.[75–76]

***Pathology.*** On histology, HCA consists of a solitary, spherical growth of hepatocytes within a pseudocapsule. The hepatocytes contain an increased amount of fat and glycogen, and are organized in sheets, along with thin-walled vessels, bile ducts, and dysfunctional Kupffer cells. Intratumoral hemorrhage occurs in approximately 10% of patients and results rarely in intraperitoneal hemorrhage and hypovolemic shock.[74] Adenomas are multiple in 20% of cases and are called adenomatosis when four or more are present.

***Imaging.*** Making the diagnosis of HCA by imaging can be challenging. When sporadic, HCA are frequently large solitary masses. In predisposed children, multiple HCA are more frequently observed.

The US appearance of HCA depends on the tumor content, which consists of lipid or hemorrhage. The hyperechoic component can be related to the lipid content or hemorrhage; they may have a surrounding hypoechoic rim, and some may lack a well-defined wall (Fig. 91.12). The lesion may appear hypoechoic especially in the setting of diffuse fatty infiltration and/or glycogen storage.[77] Color Doppler US shows central venous flow, which is different from FNH with a central arterial scar.[78]

On unenhanced CT, HCAs are usually hypodense with a low-attenuation capsule (25%) and a well-defined border; the presence of hemorrhage or fat can result in heterogeneous attenuation (7%). Homogeneous enhancement is seen during the arterial phase of contrast injection, and the mass becomes isodense on delayed CT images.[76–79]

On MRI, most HCAs are mildly hyperintense to liver on T1- and on T2-weighted images.[76,80–82] On fat suppressed or opposed-phase images, the signal drops out relative to the fat content.[76] This finding is not specific to adenomas and can also be seen in HCC. The pseudocapsule is hypointense on T1- and variable signal on T2-weighted images, and may enhance. Experience with hepatocyte-specific agents suggests that the lack of bile ducts can be used to distinguish between HCA and FNH. HCAs lack biliary ducts and therefore do not enhance, and are typically hypointense to liver parenchyma on hepatocyte phase imaging, while FNHs often demonstrate hyperenhancement during that phase.

Common features that distinguish HCA from FNH include: lack of a central scar, T1-weighted gradient recalled echo (GRE), out-of-phase signal loss due to the presence of intracellular lipid, and lack of contrast material retention on delayed imaging when using a hepatobiliary contrast agent.

Gallium uptake in HCAs is decreased, and they do not usually take up sulfur colloid, appearing as photopenic defects on both studies. Rarely, a HCA contains enough Kupffer cells to show uptake of sulfur colloid on scintigraphy, a finding typically associated with FNH.[78] With hepatobiliary scintigraphic agents, HCAs usually have early uptake, which persists on delayed images.[83]

***Treatment.*** Treatment options include discontinuation of oral contraceptives, dietary therapy in patients with glycogen storage, or surgery. Some authors recommend surgery due to the risks of hemorrhage and the fact that HCC has been reported in solitary or multiple adenomas over 4 cm in size.[84] Radiofrequency ablation is an alternative to surgical resection.[85]

## INFLAMMATORY PSEUDOTUMOR OF THE LIVER

Inflammatory pseudotumor of the liver occurs in adults and children. Patients have a typical clinical presentation of low-grade fever, abdominal pain, and weight loss. Single or multiple well-defined hepatic masses occur.

***Imaging.*** The lesion is hypoechoic on sonography and of low attenuation on CT. It is not possible to reliably distinguish inflammatory pseudotumor from hepatic malignancy with imaging (e-Fig. 91.13).

***Treatment.*** In some cases, the lesion may be resected based on a high preoperative probability of neoplasm, although a percutaneous biopsy may be diagnostic. Inflammatory pseudotumor is generally a self-limited condition with an excellent prognosis. Therefore it is important for clinicians, surgeons, and radiologists to be familiar with this diagnosis and consider it in the appropriate clinical setting.[86]

## NODULAR REGENERATIVE HYPERPLASIA

NRH of the liver is a lesion of unknown cause that develops in noncirrhotic livers, rarely in children.[66] It is characterized by regenerative nodules surrounded by atrophic liver in the absence of fibrosis. This entity has been associated with vasculitis, collagen vascular diseases, hematologic disorders, cardiovascular diseases, neoplasms, metabolic disorders, and some drugs. Histologically, regenerative nodules are composed of focal proliferation of cells resembling hepatocytes within a supporting stroma.[66]

***Imaging.*** On imaging, NRH may be confused with FNH, HCA, or metastases. Imaging findings are variable and depend on the size of the nodules. The nodules may bleed or lead to portal hypertension from pressure on portal radicals, and the liver may or may not be enlarged.

On US, the nodules are difficult to detect because they are made of hepatocyte-like cells. Regenerative nodules may show heterogeneous echotexture with distortion of normal architecture. When detected, most nodules are hypoechoic, but they can be hyperechoic.[87,88] On CT, lesions are hypoattenuated compared with normal liver and do not enhance significantly.[87,88] On MRI, regenerative nodules are slightly hyperintense to adjacent liver on T1- and variable on T2-weighted images. A T1 hyper- or hypointense or T2 hyperintense rim can be seen.[89] Due to the presence of fat in the lesion, decreased signal intensity on fat-suppressed T1-weighted images may be seen. After gadolinium injection, enhancement occurs during the portal phase similar to the signal intensity of normal liver.[87]

***Treatment.*** No specific treatment is recommended other than discontinuation of drugs associated with the NRH. Malignant transformation to HCC has been reported.

### KEY POINTS

- The most common liver masses in children <5 years of age are hemangiomas, metastases, and hepatoblastoma. After 5 years, HCC and FNH are more common.
- Hepatic hemangiomas have a characteristic appearance of hypervascular tumors.
- Mesenchymal hamartomas are typically multicystic, heterogeneous masses with septa.
- The typical central scar in FNH has increased T2 signal unlike the scar in FLC, which is hypointense on T1- and T2-weighted MR imaging.
- Only FNH contains sufficient Kupffer cells to cause normal to increased uptake on technetium-99m TC sulfur colloid scintigraphy, and retention of hepatobiliary MR contrast agents in hepatocyte phase imaging.
- Hepatic metastases in children are most often due to neuroblastoma, lymphoma, and Wilms tumor.
- There is an increased incidence of regenerative nodules in pediatric cancer survivors.

# Vascular Abnormalities of the Liver

*Douglas C. Rivard and Patrick N. Bacon*

Vascular abnormalities of the liver discussed in this chapter are divided into the following broad categories: portal hypertension, hepatopulmonary syndrome (HPS), Budd–Chiari syndrome, sinusoidal obstructive syndrome, and congenital vascular anomalies of the liver.

## PORTAL HYPERTENSION

***Overview.*** Portal hypertension is defined as a rise in pressure within the splanchnic venous system above 10 mm Hg. This increase in pressure may result from either increased resistance to hepatic venous drainage (presinusoidal and postsinusoidal) or increase in inflow pressure, such as is seen in persons with an arterioportal fistula.[1] The pathophysiology and clinical presentation of portal hypertension depend on the underlying hepatic disorder.

***Etiology.*** Cirrhosis, the most common cause of portal hypertension, is due to hepatic scarring resulting from chronic liver injury. In pediatric patients, cirrhosis can result from a variety of conditions, including biliary atresia, cystic fibrosis, hemochromatosis, and Wilson disease[2] (Box 92.1).

Extrahepatic portal vein occlusion is a relatively frequent cause of presinusoidal portal hypertension in children. Incidence is increased in cases of complicated umbilical vein catheterization, sepsis, dehydration, hyperviscosity, shock, coagulopathy, portal vein thrombosis, hypercoagulable syndromes, and congenital portal venous webs, but it may occur without an identifiable cause.[2,3] Cavernous transformation of the portal vein is a result of portoportal collaterals that develop along the thrombosed portal vein and that have been observed to occur in as little as 1 to 3 weeks after acute occlusion.[4]

Postsinusoidal obstruction includes primary liver disease with cirrhosis or hepatic vein obstruction, such as Budd–Chiari syndrome or hepatic veno-occlusive disease/sinusoidal obstructive syndrome, as seen in patients who have had bone marrow transplantation.[2]

***Clinical Presentation.*** Children may present with the consequences of portal hypertension, such as gastrointestinal bleeding, unexplained splenomegaly, and hypersplenism without jaundice, ascites, or cholestasis.[5,6] The Child–Turcotte–Pugh classification system provides a severity score that plays a part in treatment decisions.[3] Patients are stratified into grades A through C based on bilirubin elevation, albumin level, prothrombin time, ascites, and severity of encephalopathy.[7,8]

***Imaging.*** Splenic enlargement may be the earliest imaging finding of portal hypertension. As resistance to portal flow increases, portal venous flow slows down, portal vein diameter decreases, and, with high resistance, portal venous flow may become reversed or even arterialized. In persons with a normal liver, the portal vein has a larger cross-sectional area than the splenic vein.[6,9] If instead the portal vein is smaller than the splenic vein, the presence of collaterals diverting portal flow away from the liver must be assumed (Fig. 92.1). Reversal of venous flow in the superior mesenteric and splenic veins also is suggestive of collaterals and spontaneous portosystemic shunting. Hepatopetal flow in the main portal vein (MPV) does not exclude severe portal hypertension when collaterals are present or when lobe-to-lobe shunting occurs; hepatofugal flow is a late finding in persons with portal hypertension.[6,9] Recently, evaluation of liver stiffness by shear wave elastography has shown promise in predicting clinically significant portal hypertension as well as noninvasive monitoring of fibrosis.[10]

The presence of a paraumbilical varix allows decompression of portal venous flow via the left portal vein, thus allowing hepatopetal flow in the MPV even in the presence of extreme portal hypertension. Because the paraumbilical varices are supplied by the left portal vein, intrahepatic portal flow may be directed toward them, causing reversal of flow in the right portal vein despite hepatopetal flow in the MPV. The paraumbilical varices are well seen in the falciform fossa by color and power Doppler imaging, as well as by computed tomography angiography (CTA) and magnetic resonance angiography (MRA). Hepatic decompression by those veins may serve as relative protection against esophageal varices and variceal hemorrhage.

When portal venous pressure increases in the setting of portal hypertension, splanchnic venous return finds alternative drainage pathways connecting the portal circulation to the systemic circulation. Left gastric and splenic vein branches drain into the azygos system through esophageal and gastric varices, which in turn drain into the inferior vena cava (IVC) via the left renal vein. Paraumbilical varices (e-Fig. 92.2) communicate with inferior epigastric and internal mammary abdominal wall venous networks to drain into the inferior and superior vena cava, respectively. These collateral pathways can be examined with cross-sectional imaging.[4]

Additional collateral pathways develop with portal hypertension. Retroperitoneal and peripancreatic collaterals drain through renal and gonadal veins into the IVC and into paraspinal veins, which drain into the azygos system (Fig. 92.3). Inferior mesenteric branches drain into superior, middle, and inferior hemorrhoidal veins that lead to the iliac veins. Portosystemic collaterals also may form at enterocutaneous junctions in fistulas and enterostomies. Surgical anastomoses, such as a Roux-en-Y biliary-enteric anastomosis, may serve as sites of portoportal collaterals (e-Fig. 92.4). Finally, intercostal and phrenic veins also may serve as a means of portosystemic communication across the diaphragm.[4]

In patients with cavernous transformation of the portal vein, key cross-sectional imaging features include a tangle of venous channels in the liver hilum with no identifiable normal portal vein (Fig. 92.5). In most patients (76%), portoportal collaterals extend over a variable distance along the course of the intrahepatic portal branches. In extreme cases, no portal vein branches are demonstrated (e-Fig. 92.6). Preserved intrahepatic portal vein branches may be identified, some of which may demonstrate hepatofugal flow toward the cavernous vessels. Collateral veins may traverse the liver parenchyma to enter hepatic and capsular veins (e-Fig. 92.7). Doppler ultrasound imaging can be used to interrogate flow characteristics within the cavernous collaterals, revealing abnormal flow.[11]

***Treatment and Prognosis.*** Multiple therapeutic options exist for children with portal hypertension, depending on the underlying cause and severity of liver disease. Treatments range from percutaneous transjugular intrahepatic portosystemic shunts to sclerotherapy and variceal ligation to surgical portosystemic shunts.[2,12] Endovascular therapies have become more refined and are used with increasing frequency.[13,14]

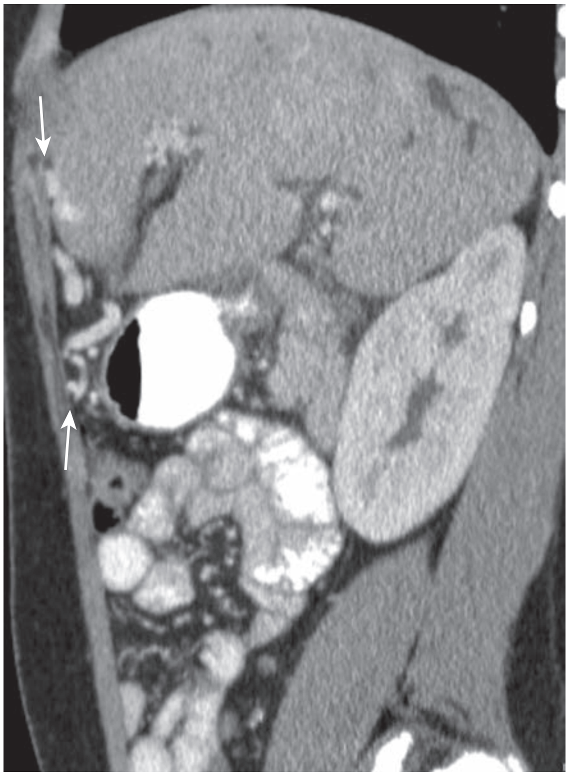
Surgical portosystemic shunts include splenorenal shunts, mesocaval shunts, and the mesoportal (Rex) bypass. In the splenorenal shunt, the distal splenic vein is connected end-to-side to the left renal vein (Fig. 92.8), leaving the superior mesenteric vein connected to the liver. The Rex bypass is used in patients with extrahepatic portal vein obstruction.[15] In this bypass procedure,

## Abstract:

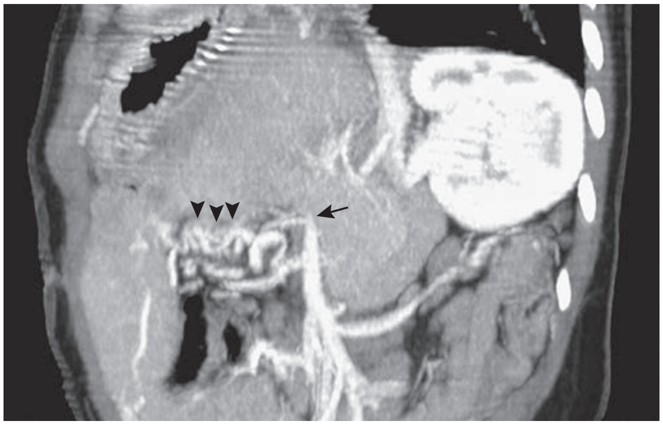
Vascular abnormalities of the liver can be congenital, acquired, or iatrogenic in nature. Knowledge of pertinent anatomy is essential for timely diagnosis. Medical imaging techniques play an integral role in evaluation of these entities and can help guide surgical or minimally invasive image guided therapies.

## Keywords:

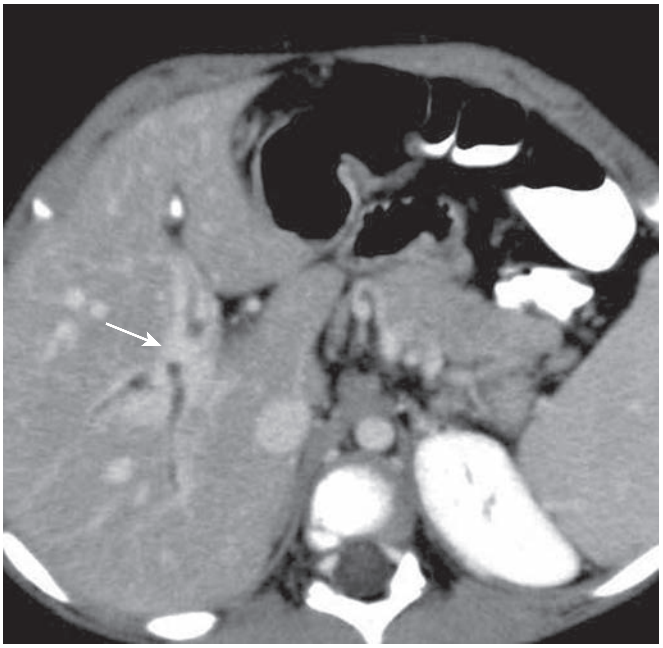
liver vascular abnormalities pediatric imaging congenital treatment



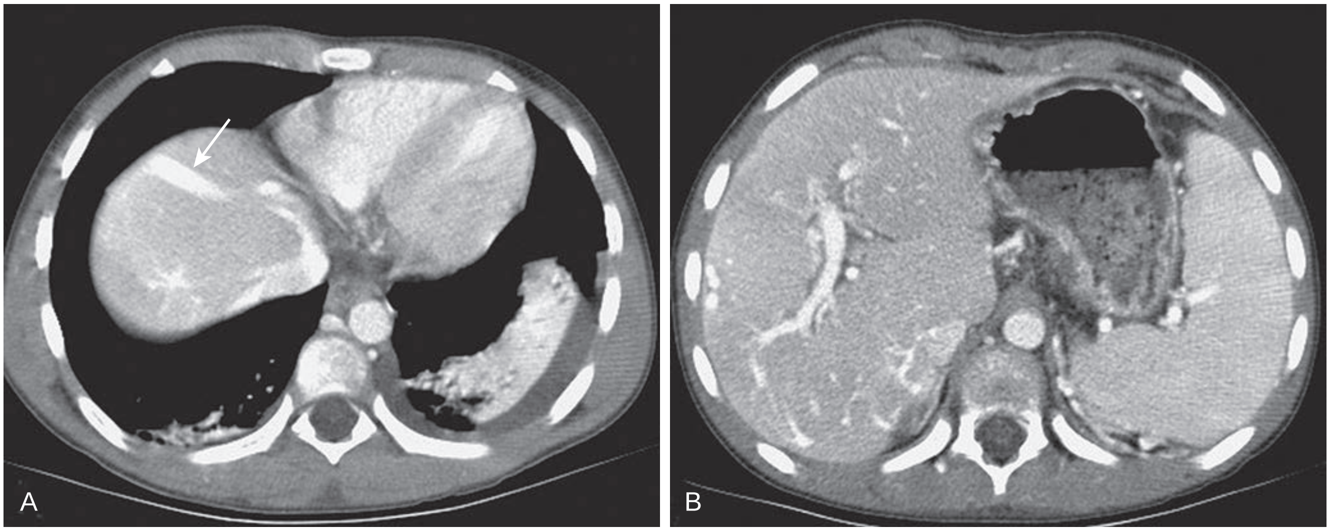
**e-Figure 92.2. Paraumbilical collaterals in a 12-year-old girl with hepatic fibrosis, cirrhosis, and portal hypertension.** Sagittal contrast-enhanced CT image shows enhancing paraumbilical venous collaterals and enhancing internal mammary collateral vessels anterior to the liver *(arrows)*.



**e-Figure 92.4. Nonacute portal vein thrombosis in an 11-year-old boy with a left lateral segment liver transplant.** Oblique sagittal reformat of contrast-enhanced CT image shows an occluded extrahepatic portal vein *(arrow),* and multiple corkscrew collaterals from jejunal branches of the superior mesenteric vein are seen at the Roux-en-Y loop *(arrowheads)* used for the biliary anastomosis. Capsular collaterals are seen at the inferior edge of the liver.



**e-Figure 92.6. Cavernous transformation of the portal vein in a 3-year-old girl with biliary atresia and cirrhosis.** Axial contrast-enhanced CT image shows no visible intrahepatic portal vein branches. Tangles of intrahepatic collaterals *(arrow)* follow the expected course of the entire intrahepatic portal system.



**e-Figure 92.7. Portovenous and transcapsular collaterals in a patient with extrahepatic portal vein obstruction. Portovenous and transcapsular connections are present across the liver parenchyma.** (A) Axial contrast-enhanced CT image at the liver dome shows a large peripheral collateral vein *(arrow)* communicating with the left hepatic vein. (B) A more inferior image shows numerous transcapsular venous collaterals that communicate with the intrahepatic portal vein branches.

**BOX 92.1** Causes of Portal Hypertension in Children

**INCREASED INFLOW PRESSURE OR VOLUME**

- Hepatic artery to portal vein fistula
- Total anomalous pulmonary venous return below the diaphragm
- Pulmonary sequestration with portal venous drainage

**PRESINUSOIDAL VENOUS OBSTRUCTION**

- Splenic vein occlusion (sinistral portal hypertension)
- Extrahepatic portal vein thrombosis/cavernous transformation of portal vein
- Posttransplantation portal vein stenosis, thrombosis, and occlusion
- Congenital hepatic fibrosis
- Schistosomiasis

**INCREASED SINUSOIDAL RESISTANCE**

- Biliary atresia
- Cirrhosis
- Hepatitis: C, non-A, non-B, autoimmune, neonatal
- Sclerosing cholangitis

**POSTSINUSOIDAL OBSTRUCTION**

- Budd–Chiari syndrome
- Glenn, Fontan systemic to pulmonary venous shunts
- Medications: 6-thioguanine

**IDIOPATHIC PORTAL HYPERTENSION**

a venous graft is interposed between the superior mesenteric vein (inferior to the pancreas) and the left portal vein, restoring portal venous flow into the liver (Fig. 92.9). The Rex shunt may be definitive therapy for children with extrahepatic portal vein obstruction.[16] The collapsed intrahepatic portal system, which may be difficult to image before surgery because of exuberant intrahepatic collaterals that dominate portal flow, has been shown to distend rapidly and accommodate the large volume of flow from the shunt. The shunt can be seen by all vascular imaging modalities and should demonstrate hepatopetal flow.[17]

Because the Rex shunt is a bypass graft, portal flow is hepatopetal. Portal vein flow is hepatofugal in patent mesocaval and proximal splenorenal shunts; it may be hepatopetal in the more selective distal splenorenal shunts, which are designed to decompress esophageal varices and preserve some portal venous flow. These shunts provide short- and long-term palliation in children with portal hypertension to prevent gastrointestinal hemorrhages and improve hypersplenism. In children with severe underlying liver disease, these shunts are temporizing procedures before liver transplantation.[18]

## HEPATOPULMONARY SYNDROME

***Overview.*** HPS is defined as an elevated age-adjusted alveolar-arterial oxygen gradient that often leads to hypoxemia and pulmonary vascular dilation in patients with liver disease.[19] It can be acute or chronic and can occur with or without portal hypertension.[20]

***Etiology.*** HPS is associated with hepatic vascular abnormalities (such as portal hypertension or Abernethy malformation) that alter the normal portosystemic circulation, leading to right to left intrapulmonary shunting. The pathophysiology of HPS has not been fully elucidated but is thought to involve increased pulmonary expression of endothelin B receptor, leading to nitric oxide overproduction. Endothelial and arterial wall changes produce either (1) ventilation-perfusion mismatch through vasodilatation and arteriovenous shunting or (2) pulmonary hypertension.[21]

***Clinical Presentation.*** The characteristic clinical features of HPS are orthodeoxia and platypnea in the presence of liver disease. The clinical presentation can range from relatively asymptomatic to the presence of cyanosis and clubbing.[19] Pulmonary manifestations may precede the clinical presentation of the liver disease.

***Imaging.*** Plain radiographs may demonstrate increased vascular markings and cardiomegaly (Fig. 92.10). Computed tomography (CT) may outline enlarged vessels, predominantly in the lung bases. Contrast echocardiography may show microbubbles in the left atrium in three to five cardiac cycles as a result of intrapulmonary arteriovenous shunting and is considered the gold standard for diagnosis of HPS.

***Treatment and Prognosis.*** The treatment of HPS is aimed at the underlying disease, which affects prognosis. In patients in whom the syndrome is a consequence of a portovenous shunt, occlusion of the shunt can lead to regression of the intrapulmonary shunts and resolution of symptoms.[13,19,22]

## BUDD–CHIARI SYNDROME

***Overview.*** Budd–Chiari syndrome is characterized by obstruction of hepatic venous outflow in the absence of constrictive pericarditis or right heart failure, by occlusion of the hepatic veins and/or suprahepatic IVC. This results in severe liver congestion, ascites, and portal hypertension.[23] As sinusoidal pressure increases, the pressure gradient between the portal venous system and the sinusoidal system is reversed, causing the portal vein to become a draining system for the hepatic artery. In complete Budd–Chiari syndrome, blood supply to the liver is solely from the hepatic artery. Because the caudate lobe has separate venous drainage, it is spared in most patients with Budd–Chiari syndrome.

***Etiology.*** The causes of Budd–Chiari syndrome include a caval web, thrombosis in hypercoagulable states, tumor extension into the IVC, external compression, or liver transplantation; the syndrome also may be idiopathic.[23–25]

***Clinical Presentation.*** Clinically, collateral venous drainage develops in some patients, and they may be relatively asymptomatic. Other patients present with intractable ascites, liver failure, or gastrointestinal hemorrhage. Children who experience hepatic vein or IVC obstruction after liver transplantation may experience recurrence of portal hypertension.[26]

***Imaging.*** On cross-sectional imaging, hepatomegaly with ascites and poorly or nonvisible hepatic veins are characteristic.[24,27] Reversal of portal venous flow usually is found in complete cases; however, in patients with partial hepatic vein occlusion, the flow may shunt from higher resistance segments into lower resistance segments, such as the caudate lobe. Intrahepatic portal-to-systemic collaterals may occur via transcapsular and paraumbilical veins, and extrahepatic collaterals occur via esophageal and gastric varices. These hemodynamic changes can be well demonstrated by Doppler ultrasound, CTA, and magnetic resonance imaging (MRI).[9,24,27]

On CT and CTA (Fig. 92.11), the liver parenchyma may demonstrate patchy, abnormal, wedge-shaped areas of attenuation with the apex pointing to the IVC. A heterogeneous, reticular, or mosaic pattern in the hepatic arterial phase that persists during the portal phase also may be observed. The caudate lobe retains a normal appearance and may be hypertrophied. The portal vein may fill before its tributaries as a result of intrahepatic flow reversal. Similar findings are visible on MRI and MRA.

***Treatment and Prognosis.*** Treatment consists of medical control of ascites, percutaneous angioplasty when feasible, surgical creation of a diverting shunt, and liver transplantation in severe cases.[25,28] Prognosis of Budd–Chiari syndrome is highly variable depending on the timeliness of diagnosis and the ability to treat the underlying causes.[23]

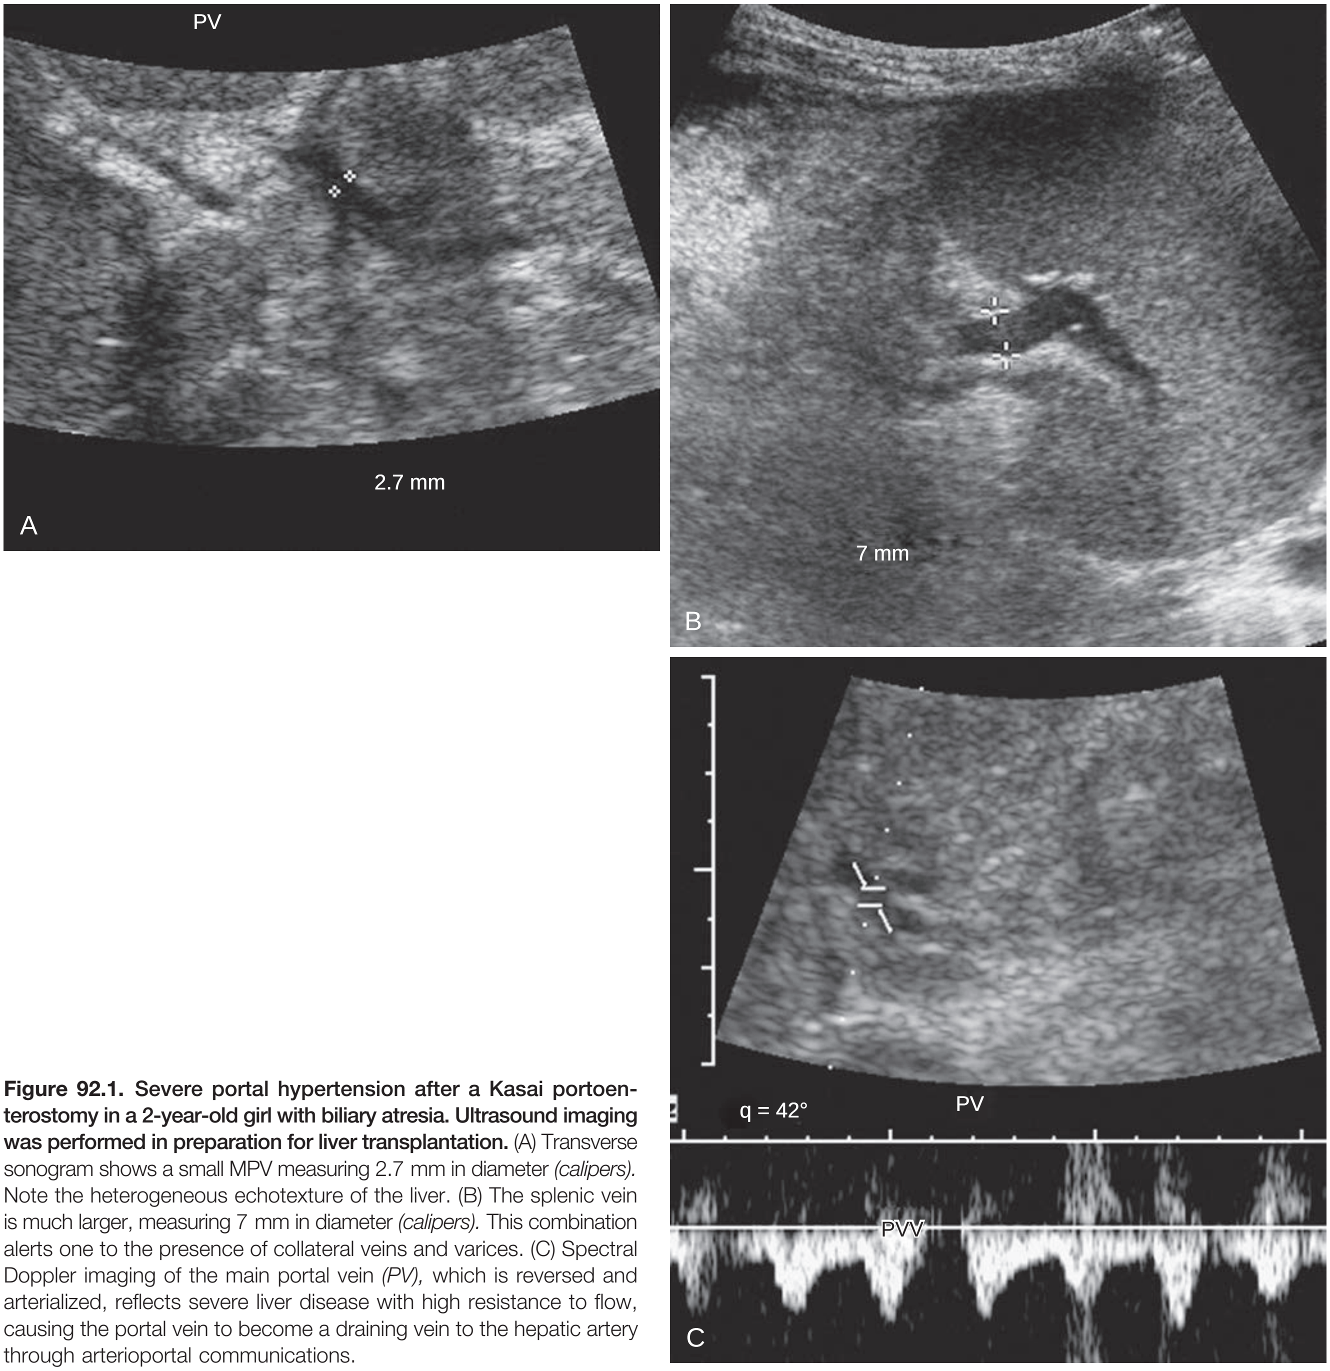


**Figure 92.1. Severe portal hypertension after a Kasai portoenterostomy in a 2-year-old girl with biliary atresia. Ultrasound imaging was performed in preparation for liver transplantation.** (A) Transverse sonogram shows a small MPV measuring 2.7 mm in diameter *(calipers).* Note the heterogeneous echotexture of the liver. (B) The splenic vein is much larger, measuring 7 mm in diameter *(calipers).* This combination alerts one to the presence of collateral veins and varices. (C) Spectral Doppler imaging of the main portal vein *(PV),* which is reversed and arterialized, reflects severe liver disease with high resistance to flow, causing the portal vein to become a draining vein to the hepatic artery through arterioportal communications.

## SINUSOIDAL OBSTRUCTION SYNDROME

***Overview.*** Sinusoidal obstruction syndrome (SOS), previously known as hepatic veno-occlusive disease, is a life-threatening complication that typically occurs within the first 35 to 40 days after myeloablative preparation regimen. It is a primary circulatory disorder characterized by obstruction at the sinusoidal level, which leads to liver dysfunction.

***Etiology.*** Hepatic SOS develops most frequently in patients undergoing myeloablative therapy for hematopoietic stem cell transplantation. The reported frequency in patients who undergo bone marrow transplantation varies wildly (5% to 60%) but has been shown to be higher in patients who are younger (under 1 to 2 years of age), underweight, and treated with actinomycin D.[29–31] Additional risk factors include the presence of previous liver disease or other preexistent conditions such as osteopetrosis, repeat myeloablative procedure beyond second relapse, and specific chemotherapeutic regimens, such as the use of cyclophosphamide in combination with busulfan or total body irradiation.[32] In patients who have not undergone bone marrow transplantation, the entity can occur when the patient has received hepatic radiation or after liver transplantation.

***Clinical Presentation.*** Patients present with fluid retention, abdominal pain, jaundice, and hepatomegaly. SOS is a clinical diagnosis. The Baltimore criteria used for the diagnosis of SOS after hematopoietic cell transplantation are hyperbilirubinemia >2 mg/dL and at least two of the following: hepatomegaly, weight gain ≥5%, and ascites.[33] Based on the course of disease, it can be

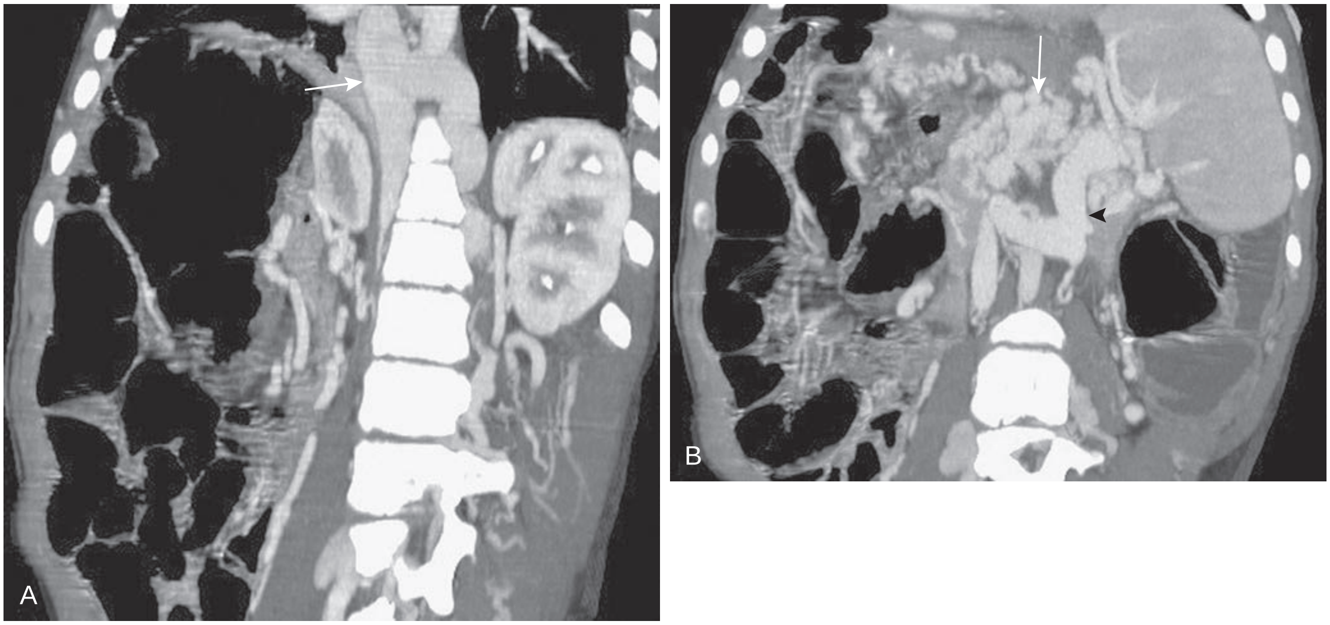

**Figure 92.3. Occluded portal vein and IVC in a liver transplant patient.** (A) Coronal contrast-enhanced CT image shows retroperitoneal, paraspinal, and intraspinal venous collaterals. The azygos and hemiazygos veins are massively enlarged *(arrow)*. (B) Extensive pancreatic *(arrow)* and perisplenic collaterals are present, along with a splenorenal shunt *(arrowhead)*.

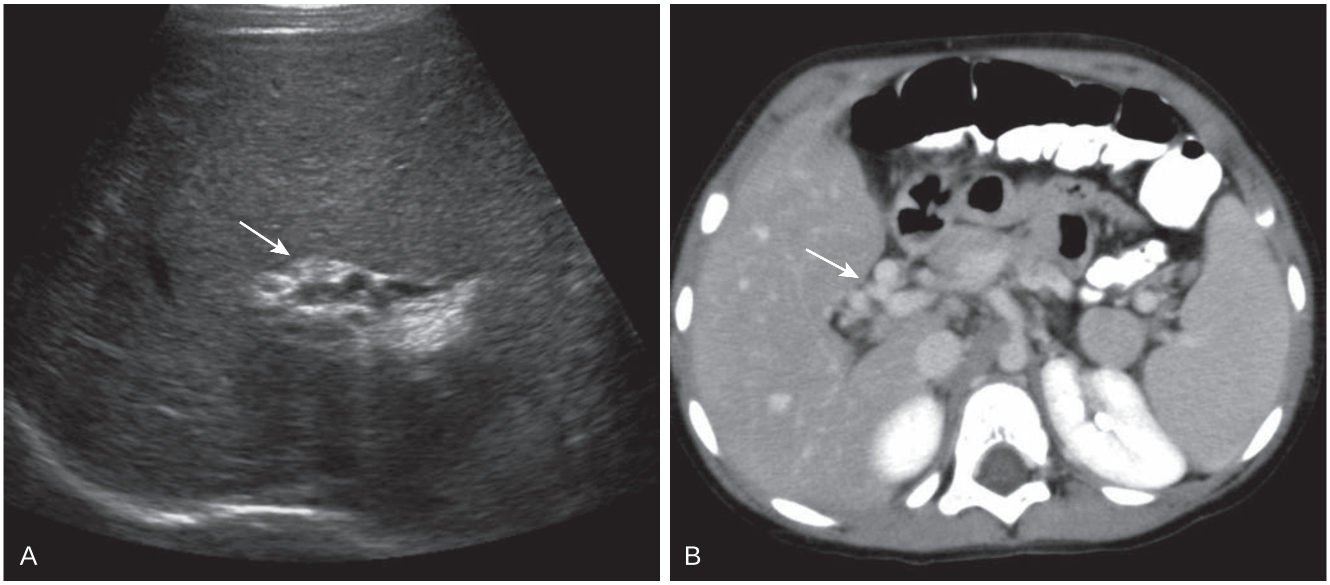

**Figure 92.5. Cavernous transformation of the portal vein in a 3-year-old boy with cirrhosis.** (A) Transverse sonogram shows a tangle of periportal vessels without an identifiable normal portal vein *(arrow)*. (B) Axial contrast-enhanced CT image confirms multiple collateral vessels in the porta hepatis *(arrow)*.

classified as mild (self-limiting), moderate (requiring intervention for fluid excess and pain management), and severe (not resolving by day 100 or leading to death).[34]

***Imaging.*** On ultrasound imaging, hepatomegaly, ascites, and thickening of the gallbladder wall are common findings. On Doppler imaging, decreased or reversed flow in the portal vein, increased resistive index of the hepatic artery, attenuation of hepatic venous flow, and the appearance of hepatofugal flow in paraumbilical varices have been described (Fig. 92.12). In some early cases, partial hemodynamic involvement may be present, resulting in flow reversal in only one segmental or lobar portal vein branch.[35] The full gamut of findings is seldom present, and in many patients, no specific ultrasound findings may be observed.[36]

MRI findings include hepatomegaly, abnormal periportal cuffing, and gallbladder wall thickening with intense wall signal on T2-weighted sequences, ascites, and pleural effusion. Since these findings are nonspecific, they do not necessarily aid in the differential diagnosis.[37] The gold standard for diagnosis is measurement of wedged hepatic venous pressure and transjugular liver biopsy. A hepatic venous pressure gradient of ≥10 mm Hg in a patient without previous liver disease allows an exact diagnosis with a high specificity.[38]

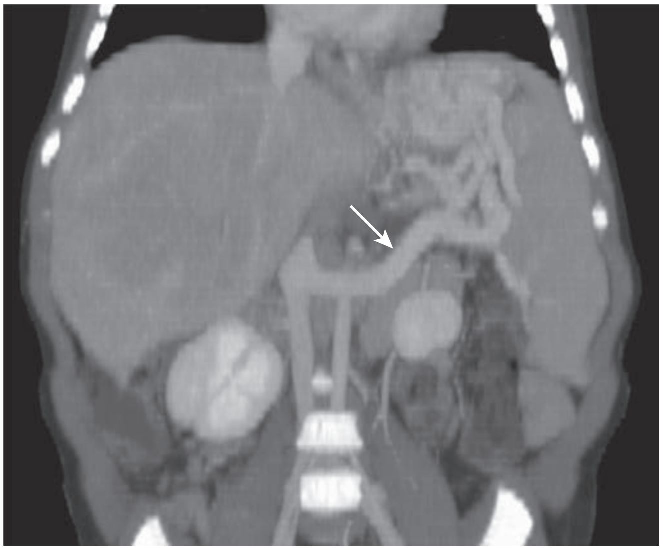

**Figure 92.8. Distal splenorenal shunt in an 8-year-old boy.** Coronal reconstructed CTA image shows the splenic vein connected end to side *(arrow)* to the left renal vein draining into the IVC.

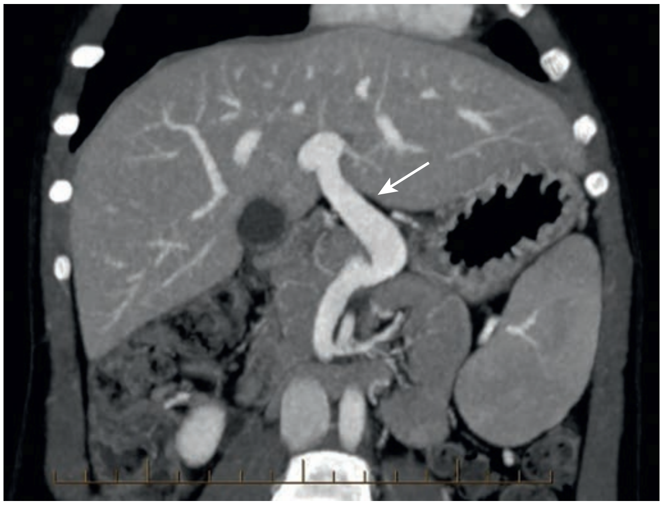

**Figure 92.9. Rex bypass (superior mesenteric to left portal vein).** Angled coronal maximum intensity projection (MIP) image from a contrast-enhanced CT shows the patent Rex shunt *(arrow)* connecting the superior mesenteric vein to the left portal vein.

***Treatment.*** Treatment consists of supportive care and controlling the inflammation and the deposition of fibrin. Agents that have been used include antithrombotic agents such as prostaglandin E1 and heparin, which are of limited value. More promising is defibrotide, which is derived from porcine tissue and has antithrombotic and antiischemic properties, with complete resolution seen in 35% to 55% of patients in reported uncontrolled clinical trials.[32,39,40]

## CONGENITAL ANOMALIES OF LIVER VASCULATURE

### Anomalies of the Portal Vein

#### Preduodenal Portal Vein

***Overview.*** Preduodenal portal vein is a rare anomaly in which the portal vein courses ventral to the duodenum and pancreatic head.

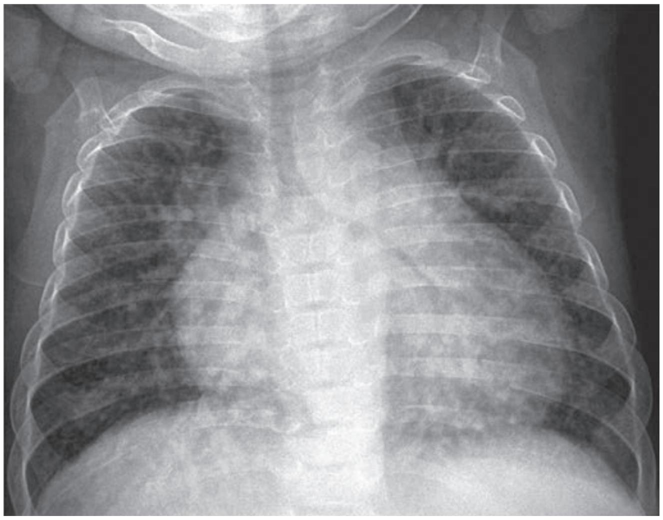

**Figure 92.10. Hepatopulmonary syndrome in an 8-month-old boy with portal vein occlusion and cyanosis.** Chest radiograph shows cardiomegaly and extensively increased pulmonary vascularity, representing diffuse pulmonary arteriovenous shunts.

***Etiology.*** The proposed embryology is nonregression of the caudal anastomotic vein that connects the two vitelline veins ventral to the duodenum, where it then contributes to the formation of the portal vein.[41,42]

***Clinical Presentation.*** The anomaly is closely associated with the heterotaxy syndromes, particularly polysplenia[43] and malrotation, as well as splenic, pancreatic, cardiac, and duodenal anomalies. In approximately 50% of patients, an associated duodenal obstruction is present; however, the anomaly may be asymptomatic and discovered incidentally, particularly during workup of patients with heterotaxy or biliary atresia. Approximately 10% of patients with biliary atresia have associated heterotaxy/polysplenia.[42–45]

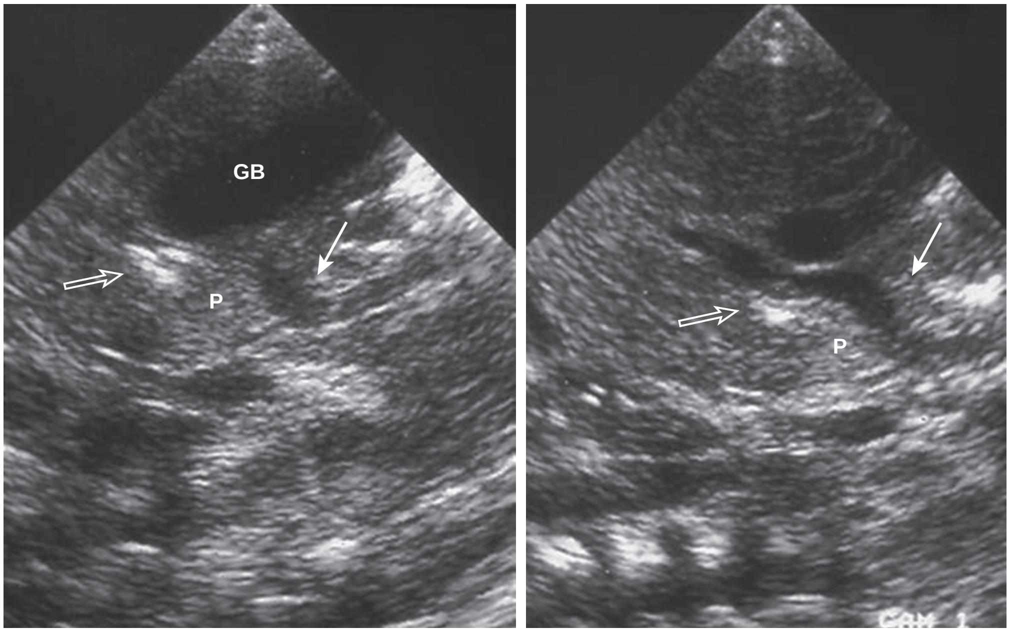
***Imaging.*** The preduodenal portal vein is seen as a vein anterior to the duodenum and pancreas, which is visible on cross-section imaging including ultrasound, CT, and MRI; it is particularly well seen on sagittal images (e-Fig. 92.13).[42,43]

***Treatment.*** Treatment addresses correction of the underlying duodenal obstruction, if present. Awareness of this anatomic abnormality is necessary because it can pose a surgical hazard during other hepatobiliary or proximal intestinal surgical procedures, particularly in patients with concomitant heterotaxy/polysplenia and biliary atresia.[41,45]

#### Extrahepatic Congenital Portosystemic Shunts

***Overview.*** Abernethy[46] first described an extrahepatic portosystemic connection in 1793, and this malformation is now known as the Abernethy malformation. These malformations are classified as type 1 or 2.[47] Type 1 involves a complete shunt; no portal blood reaches the liver, as in congenital absence of the portal vein. In type 1a, the superior mesenteric and splenic veins do not join, and in type 1b, the superior mesenteric and splenic veins join before draining into the systemic circulation. Type 2 involves a partial shunt to the hepatic vein or IVC.[47,48]

***Etiology.*** Extrahepatic portosystemic shunts result from maldevelopment of the coordinated preservation and atresia of the left and right vitelline veins in the abdomen. Such maldevelopment could arise de novo, such as in patients with heterotaxy in whom orderly right-left processes are affected, with secondary hypoplasia of the portal venous system, or they may be a result of hypoplasia of the portal venous system with redirection of portal venous flow through extrahepatic channels.[49]



**e-Figure 92.13. Preduodenal portal vein in an infant with polysplenia.** Transverse sonograms show the superior mesenteric vein *(solid arrow)* courses anterior to pancreas *(P)* and duodenum *(open arrow)* to enter the liver. *GB,* Midline gallbladder. *(Courtesy of Marta Hernanz-Schulman, MD, Nashville, TN.)*

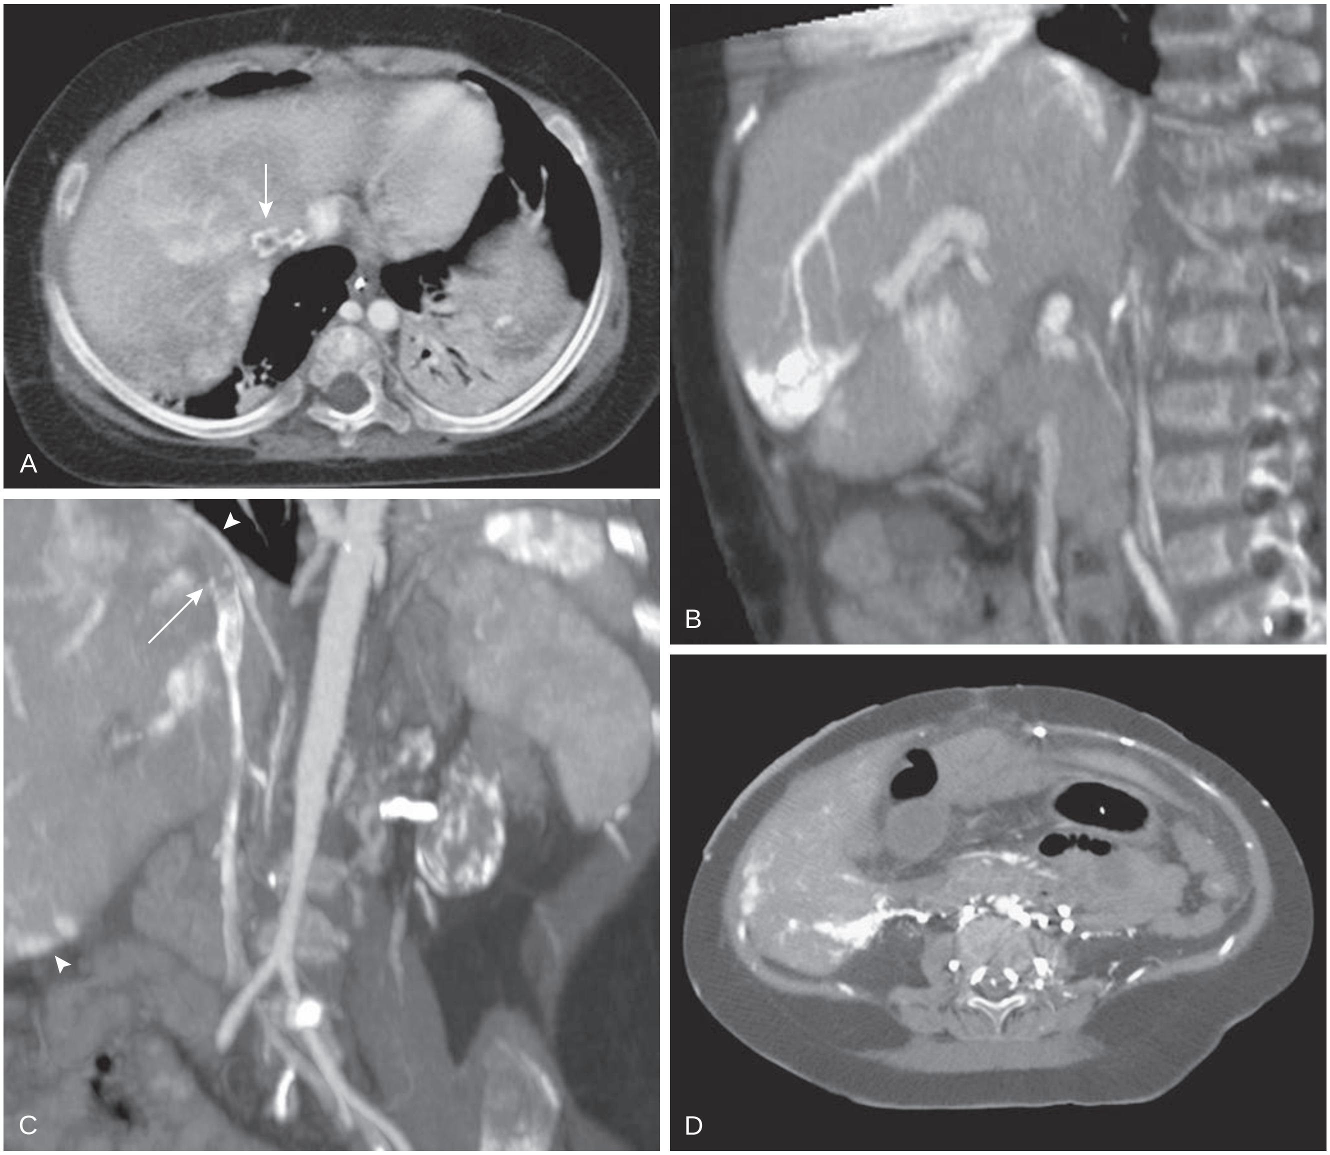


**Figure 92.11. Budd–Chiari syndrome due to IVC thrombosis.** (A) Axial CTA image shows a filling defect within the intrahepatic IVC *(arrow)*. Note the patchy, inhomogeneous enhancement of the liver. (B) Sagittal reformatted CTA shows intense contrast retention peripherally in the territory of the obstructed hepatic vein and transcapsular collateral. (C) Thrombus is visible in the intrahepatic IVC *(arrow)* with transcapsular collaterals at the liver dome and lower lateral edge *(arrowheads)* in this coronal reconstruction. (D) Axial CT image more inferiorly shows extensive retroperitoneal, paraspinal, and transcapsular collaterals enhancing brightly.

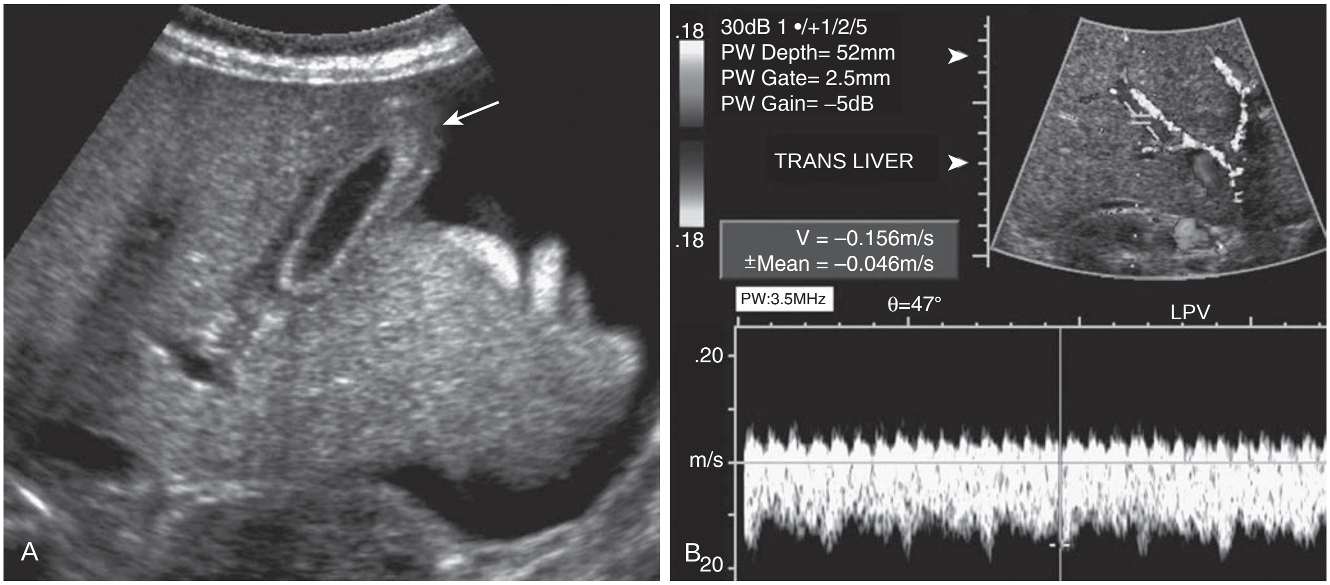

**Figure 92.12. Hepatic veno-occlusive disease.** (A) Longitudinal sonogram shows thickening of the gallbladder wall *(arrow)* and ascites. (B) Doppler image shows reversal of portal venous flow.

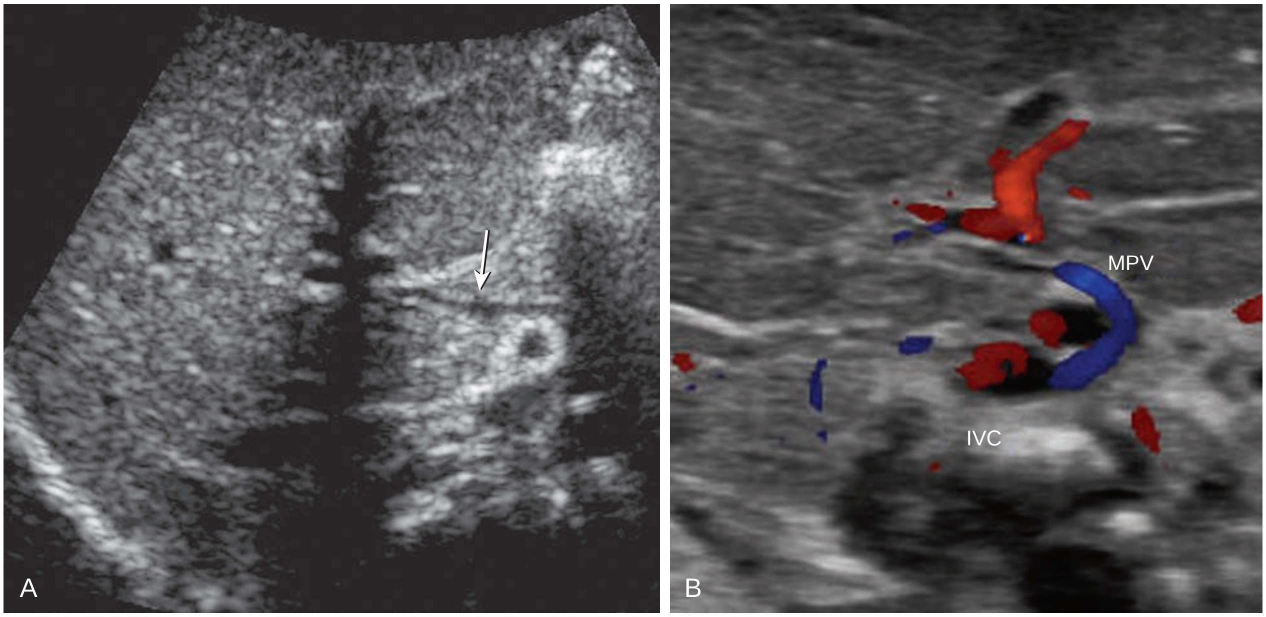

**Figure 92.14. Congenital extrahepatic portosystemic shunt.** (A) Transverse sonogram shows a diminutive MPV is present *(arrow).* (B) Transverse Doppler image in another infant shows the *MPV* draining into the *IVC.*

***Clinical Presentation.*** Extrahepatic portosystemic shunts are associated with other anomalies, such as polysplenia, biliary atresia, and cardiac and renal anomalies. They also are associated with the development of liver lesions, including focal nodular hyperplasia. Malignancies, including hepatoblastoma, hepatocellular carcinoma, and sarcoma, also have been reported in these patients. With the bypass of the hepatic circulation, systemic hyperammonemia also can be present, although hyperammonemic encephalopathy is more typically seen in older and adult patients, dependent in part on the volume of the shunt; increased circulation of galactose and bile acids also occurs.[49–52]

***Imaging.*** Absence of the portal vein may be noted prenatally, with congenital agenesis of the ductus venosus and umbilical vein drainage into the IVC or directly into the heart.[53]

When the portal vein is absent, the hepatic artery is larger than expected relative to the size of the liver and the patient's age.[52] When the portal vein is present, it is small (Fig. 92.14A). The shunt's vascular connection may be demonstrated by ultrasound imaging, particularly with the aid of color Doppler imaging (Fig. 92.14B), but CTA and MRA are more likely to demonstrate its complete course and anatomy (Fig. 92.15). Associated hepatic parenchymal nodules may be demonstrated by all cross-sectional imaging modalities.

***Treatment and Prognosis.*** Treatment, particularly in symptomatic patients, is aimed at surgical or endovascular occlusion of the abnormal connection if evidence exists that intrahepatic flow can be restored; otherwise, extrahepatic portal hypertension will ensue. Liver transplantation may be needed in persons with symptomatic extrahepatic shunts with agenesis of the portal vein and its branches.[51,52,54]

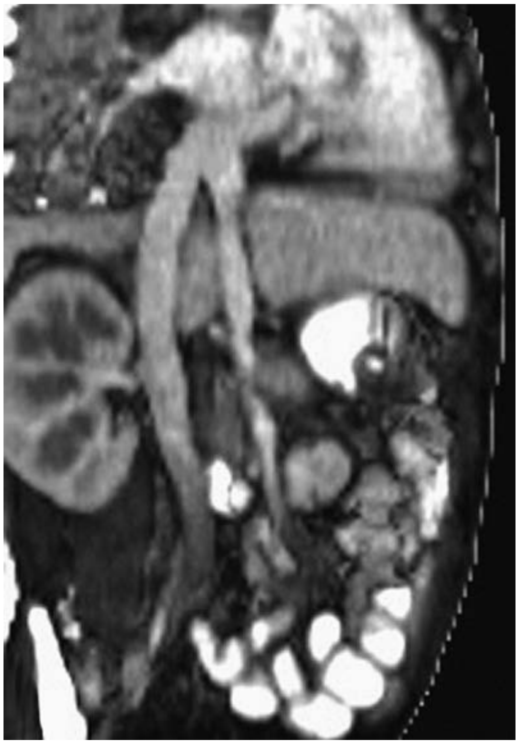

**Figure 92.15. Extrahepatic portosystemic shunt.** Coronal oblique reformatted CTA image shows the superior mesenteric vein connecting to the suprahepatic IVC, bypassing the liver.

## Intrahepatic Congenital Portosystemic Shunts

***Overview.*** Intrahepatic congenital portosystemic shunts are relatively rare anomalies, in which one or more intrahepatic portosystemic venous shunts may be present. They are classified into four types.[55] Type I, the most common, is a single large vein connecting the right portal and hepatic veins. Type II features peripheral single or multiple communications in one segment. Type III consists of an aneurysm connecting a peripheral portal vein and a hepatic vein branch. Type IV represents diffuse communications in multiple lobes.

***Etiology.*** Intrahepatic congenital portosystemic shunts represent persistent communications between the portal and hepatic venous derivatives of the embryologic vitelline veins, or between the vitelline and subcardinal veins (Fig. 92.16).[52,56] A patent ductus venous represents a form of portosystemic shunt from the left portal vein into the IVC.

***Clinical Presentation.*** These shunts may be asymptomatic and diagnosed incidentally. When encountered in neonates, some of

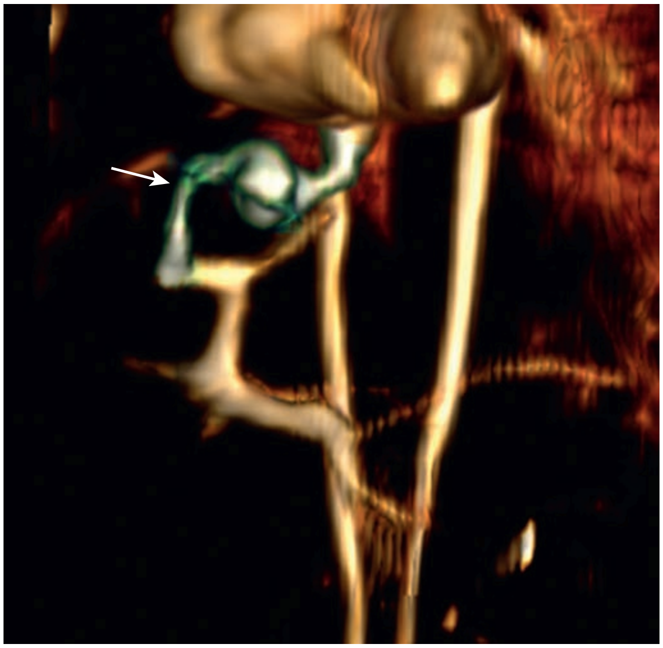

**Figure 92.16. Intrahepatic portosystemic shunt.** 3D reconstructed contrast-enhanced CT image shows a tortuous anomalous connection *(arrow)* between the left portal vein and intrahepatic IVC.

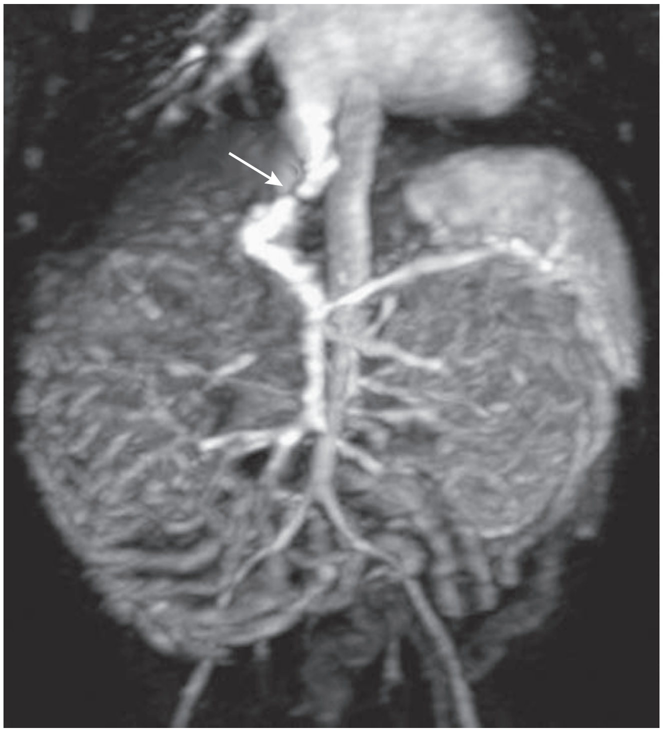

**Figure 92.17. Intrahepatic portosystemic shunt in an infant with hyperammonemia.** MR venographic image shows the anomalous connection *(arrow)* between the intrahepatic portal vein and the IVC. The portal vein was larger than normal on ultrasound.

these shunts may resolve spontaneously within the first 12 to 24 months of life; however, the proportion of patients in whom this occurs is not known.[52]

When these shunts are clinically apparent, presentation can include jaundice, hyperammonemia, hypergalactosemia, encephalopathy, and pulmonary hypertension.[51,52] Type IV shunts may be associated with massive shunting and heart failure. Cutaneous hemangiomas have been described in neonates with intrahepatic portosystemic shunts.

***Imaging.*** Intrahepatic congenital portosystemic shunts often are demonstrated by ultrasound imaging, sometimes when evaluating a child with a cutaneous hemangioma. The nonuniform size of the portal vein and hepatic vein branches may locate additional communications. The flow pattern in the portal veins, and at times also in the splenic vein, may demonstrate a biphasic or triphasic pattern, reflecting bypass of the hepatic parenchyma. Intrahepatic shunts are well demonstrated by CTA and MRA (Fig. 92.17).

***Treatment.*** Asymptomatic children with mild metabolic abnormalities can be treated conservatively by dietary means and Doppler imaging follow-up, because some of these shunts may close spontaneously.[51] Contemporary literature has described endovascular treatment with increasing frequency using a variety of surgical techniques and devices.[54,56]

## Subdiaphragmatic Anomalous Pulmonary Venous Connections

***Overview.*** Although anomalous pulmonary venous connections usually occur above the diaphragms, multiple subdiaphragmatic embryonal connections may persist, with subdiaphragmatic partial or total pulmonary venous drainage.

***Etiology.*** Pulmonary veins develop as a plexus that initially drains into both the cardinal veins and the umbilicovitelline venous system. As lung development proceeds, the common pulmonary vein is formed by the confluence of the four pulmonary veins and fuses with the posterior wall of the left atrium. If this normal fusion and drainage into the left atrium does not occur, embryonic connections to the splanchnic and umbilicovitelline systems persist.[44,57] Total anomalous pulmonary venous return below the diaphragm drains most frequently into the portal vein or ductus venosus.

***Clinical Presentation.*** Patients with infradiaphragmatic venous return are invariably obstructed and present with severe pulmonary edema. The obstruction may be at the level of the diaphragm, through intrinsic stenosis of the anomalous vessel, through closure of the ductus venosus, or through passage across the hepatic vascular bed in cases of drainage into the portal vein.[57,58]

***Imaging.*** On sonography, the anomalous common pulmonary vein is seen as a large vascular channel that enters the diaphragmatic hiatus anterior to the esophagus and inserts into the left portal vein or ductus venosus. CT and MRI show the same findings (Fig. 92.18).

***Treatment and Prognosis.*** Treatment of this anomaly is surgical (see Chapter 71).[59]

## HEPATIC ARTERIOVENOUS MALFORMATION AND FISTULA

***Overview.*** Arteriovenous malformations refer to a tangled collection of nonneoplastic vessels; they are much less common than infantile hemangiomas, although occasionally the two may be difficult to differentiate. Unlike hemangiomas, they do not regress and do not respond to medical therapy.[44,60]

Arterioportal fistulas refer to direct connections between the hepatic arterial and portal venous system, which can be intrahepatic or extrahepatic. They are classified according to their afferent supply[61]: Type 1 is supplied by either the right or left hepatic artery; type 2 is supplied by both right and left hepatic arteries or their braches; and type 3 refers to a complex lesion, with vascular supply including extrahepatic arteries. Fistulas between the arterial and the systemic hepatic venous system are exceedingly rare, and when congenital, they are seen most often in the setting of other anomalies, such as hemorrhagic telangiectasia, hepatic carcinoma, and hemangioma.[11]

***Etiology.*** Congenital arteriovenous fistulas may be single or multiple and may be isolated lesions or part of the spectrum of hereditary hemorrhagic telangiectasia and Ehlers–Danlos syndrome. Most lesions are not congenital but are acquired in patients with biliary cirrhosis or after blunt or penetrating trauma, such as a liver biopsy.[60,62]

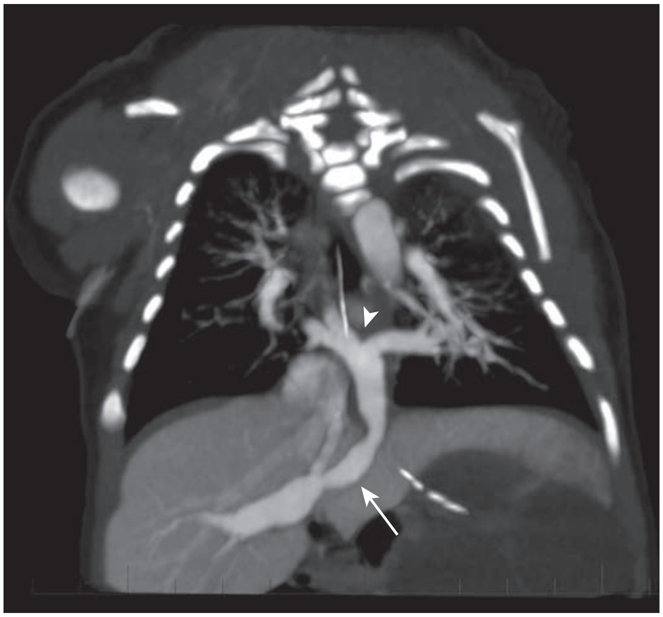

**Figure 92.18. Total anomalous pulmonary venous return.** Angled coronal MIP image from a CTA shows abnormal pulmonary venous return into the left portal vein *(arrow)*. The anomalous vein at the confluence of the inferior pulmonary veins *(arrowhead)* courses caudally through the diaphragm (where it is mildly constricted) to join the left portal vein.

***Clinical Presentation.*** Arteriovenous malformations may present with congestive heart failure, hepatic ischemia, or portal hypertension.[60] Clinical manifestations of arterioportal fistulas are presinusoidal portal hypertension, with consequent ascites, splenomegaly, and gastrointestinal bleeding, as well as malabsorption and failure to thrive.[60,61] A murmur and thrill may be detectable over the right upper quadrant in approximately 50% of cases.[61] High-output heart failure may be seen in infants, mainly when the ductus venosus is patent; acute closure of the ductus venosus can result in fatal gastrointestinal bleeding.[60] Acquired postbiopsy fistulas that are small, peripheral, and produce no symptoms are usually self-limited.

***Imaging.*** Hepatic congenital arteriovenous malformations and arteriovenous fistulas can be diagnosed with ultrasound, CT, and MRI. In congenital arteriovenous malformations, ultrasound demonstrates a tangle of vessels of variable size.[60] The size of the hepatic artery is proportional to the size of the shunt; the draining hepatic veins are distended, and the aorta may taper after the takeoff of the celiac axis (Fig. 92.19). The hepatic artery demonstrates very high systolic Doppler shifts and high diastolic flow, whereas the hepatic veins demonstrate pulsatile or arterialized high-velocity flow.

In patients with arteriovenous fistulas, ultrasound demonstrates enlargement of the hepatic artery as well as dilatation of the portal vein at the site of the fistulous connection.[44] Portal venous flow is reversed on Doppler sonography in the draining vein of an arterioportal fistula and may be reversed in the MPV as well as in the splenic and superior mesenteric veins, depending on shunt size.[1] The reversed portal venous flow usually is arterialized on spectral Doppler evaluation, with high flow velocity. The hepatic artery, or the branch that leads into the fistula, demonstrates high velocity and a decreased resistive index. Ascites and bowel wall thickening may be present. The fistula is intensely visible by color and power Doppler imaging, with vibration artifact in the hepatic vein. CT and CTA demonstrate intense enhancement and rapid washout in malformations and fistulas; rapid appearance of the portal vein occurs during the arterial phase, with enhancement

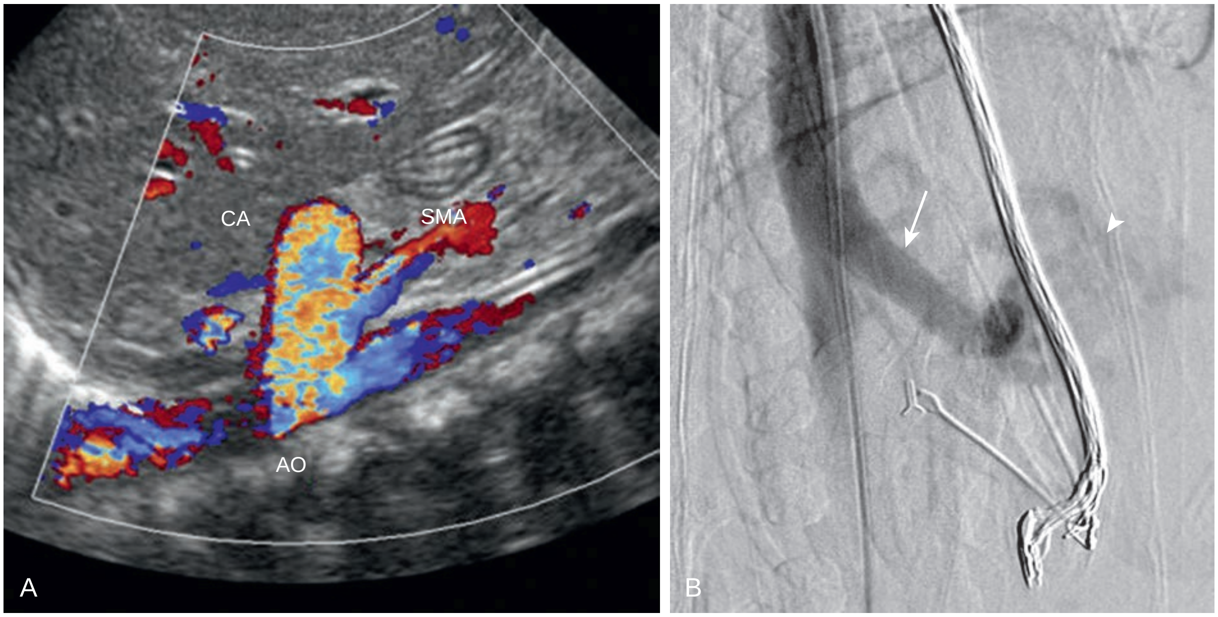

**Figure 92.19. Congenital hepatic arterioportal shunt.** (A) Color Doppler sonogram in a 4-month-girl with heart failure secondary to a congenital arterioportal shunt shows an enlarged celiac artery *(CA)* relative to the adjacent aorta *(AO)* and superior mesenteric artery *(SMA),* with color aliasing indicative of high flow velocity. (B) Lateral aortogram confirms an enlarged celiac trunk *(arrow)* and decreased caliber of the more distal aorta. Early filling of the shunt vessels *(arrowhead)* is seen over the liver.

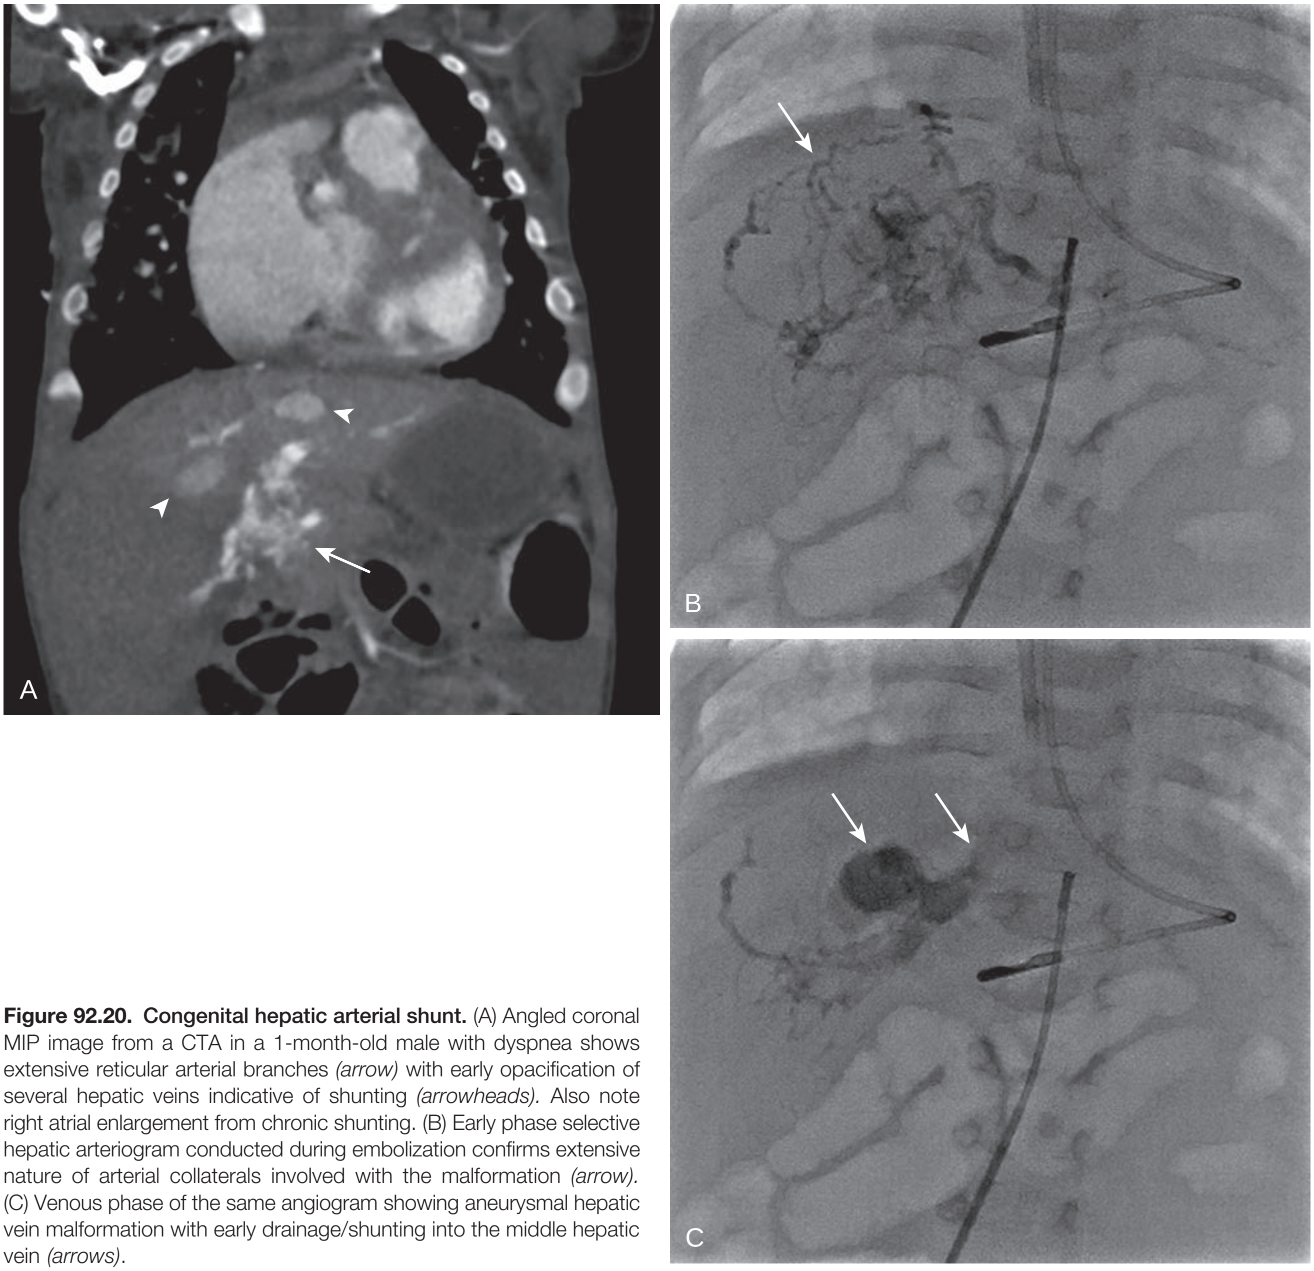

**Figure 92.20. Congenital hepatic arterial shunt.** (A) Angled coronal MIP image from a CTA in a 1-month-old male with dyspnea shows extensive reticular arterial branches *(arrow)* with early opacification of several hepatic veins indicative of shunting *(arrowheads).* Also note right atrial enlargement from chronic shunting. (B) Early phase selective hepatic arteriogram conducted during embolization confirms extensive nature of arterial collaterals involved with the malformation *(arrow).* (C) Venous phase of the same angiogram showing aneurysmal hepatic vein malformation with early drainage/shunting into the middle hepatic vein *(arrows)*.

intensity similar to that of the aorta.[44] The enlarged arterial supply and venous drainage are well demonstrated by CTA, with early appearance of the draining veins.[44] The excellent temporal resolution of fast-sequence MRA allows visualization of the vascular nidus and identification of fast clearance in arteriovenous malformations and fistulas. Angiography shows similar findings (Fig. 92.20) and is reserved for imaging before therapeutic embolization.[60]

***Treatment and Prognosis.*** Congenital hepatic arteriovenous malformations and fistulas do not respond to medical management. Treatment is aimed at obliteration of the abnormal arteriovenous connection and consists of embolization, surgical ligation, hepatic lobectomy, or liver transplantation.[1,44] As noted earlier, infants with biliary atresia and arterioportal shunt present a special problem; they are unlikely to tolerate interruption in hepatic arterial flow, and early liver transplantation may be the treatment of choice.[44,63,64] Prognosis depends on the severity of the underlying disease and the success of various treatments.

## KEY POINTS

- Portal hypertension is defined as a rise in pressure within the splanchnic venous system above 10 mm Hg.
- Cirrhosis is the most common cause of portal hypertension.
- HPS is associated with hepatic vascular abnormalities that alter the normal portosystemic circulation, leading to right to left intrapulmonary shunting.
- Budd–Chiari syndrome may be caused by a caval web, hepatic vein or IVC thrombosis, tumor extension into the IVC, external compression, or be idiopathic.
- Hepatic SOS develops most frequently in patients undergoing myeloablative therapy for hematopoietic stem cell transplantation and is primarily a clinical diagnosis.
- Abnormalities in development of the vitelline and subcardinal veins can result in a variety of vascular anomalies and intrahepatic shunts.

# 93 Liver Transplantation in Children

*Douglas C. Rivard and Geetika Khanna*

## OVERVIEW

The first liver transplantation was performed in 1963, with posttransplant survival reaching 1 year in 1968.[1] Subsequent use of immunosuppressants such as cyclosporine and tacrolimus, coupled with improved surgical techniques, has resulted in 1-year survival rates exceeding 90%.[2,3] The development of surgical techniques that allow surgeons to transplant portions of livers from adult donors has completely changed the fate of liver transplantation in pediatric patients.[4–6] Pediatric liver transplants account for approximately 7.8% of all liver transplants in the United States.[7]

The major indications for liver transplantation in children in North America include biliary atresia (32%), metabolic/genetic conditions (22%), acute liver failure (11%), cirrhosis (9%), liver tumor (9%), immune mediated liver and biliary injury (4%), and other miscellaneous conditions.[7] At least 80% of patients with biliary atresia receive transplants by 20 years of age, with the majority undergoing the procedure at younger than 4 years of age.[8] Technical variant grafts (i.e., split liver, living donor) are often used in smaller children, and the 10-year actuarial graft and patient survival for liver transplantation in biliary atresia is 73% and 86%, respectively.[9]

Other cholestatic causes of cirrhosis include bile duct hypoplasia syndromes (e.g., Alagille), cystic fibrosis, and primary sclerosing cholangitis.[10–12] Children with cholestasis related to total parenteral nutrition may have underlying short-bowel syndrome and may require combined liver and small bowel transplantation.

Diffuse nonbiliary liver diseases necessitating transplantation include metabolic liver disease, autoimmune hepatitis, neonatal hemochromatosis, graft-versus-host disease, and fulminant liver failure.[13–15] Liver transplantation is a well-established therapeutic option in children with metabolic disorders such as glycogen storage disease, tyrosinemia, and Wilson disease.[16–18] Congenital hepatic fibrosis is associated with autosomal recessive polycystic kidney disease; patients with these diseases may require combined liver and kidney transplantation.[19] Liver transplantation for hepatoblastoma and hepatocellular carcinoma has improved survival and is a viable option for children with unresectable or multifocal tumors without extrahepatic disease or vascular involvement. Patients with unresectable hepatoblastoma and pulmonary metastases can be considered for liver transplantation if the pulmonary metastases show complete response to chemotherapy or pulmonary metastatectomy is performed with tumor-free margins.

Liver transplants performed in older children usually involve the use of a whole cadaveric liver (Fig. 93.1), whereas most young children receive reduced transplants. Liver segments are defined according to the segmental and vascular anatomy.[20] Most living donor transplants use the donor's left lateral segments or left hemiliver, although the right lobe also may be used. A cadaveric liver may be split between two recipients with the left lateral segment used for a pediatric recipient and the rest of the liver used for an adult recipient; however, this results in challenging vascular and biliary connections because of limited pedicle lengths.[5]

Left hemiliver and left lateral segment hila and their cut surfaces face to the right; however, they can be differentiated by the presence of the falciform ligament separating lateral segments two and three from medial segment four in the left lobe transplant, which is absent in left lateral segment grafts. The small bowel, duodenum, colon, and right kidney often migrate into the vacated liver bed; a migrated cecum and right colon may imitate malrotation.

The portal vein usually is connected end-to-end to the recipient portal vein, with as much of the native portal vein preserved during hepatectomy as possible.[21] In case of short vascular pedicles, extension grafts may be used, which are also used in patients with unsuitable native portal veins (small caliber or thrombosed).

The donor hepatic artery usually is anastomosed to the recipient's hepatic artery as a fish mouth anastomosis or to the celiac axis. The hepatic artery may be connected to the infrarenal aorta if technically required (Fig. 93.2). In such cases, the native hepatic artery is ligated and should not be confused with arterial occlusion on imaging. Preoperative knowledge of variant hepatic artery anatomy (which can be present in up to 50% of the population) is essential for the donor and the recipient. The bile duct typically is attached to a Roux-en-Y jejunal loop (Fig. 93.3) in young children and children with biliary atresia, though direct duct-to-duct anastomosis can also be performed.

In split liver transplants, the donor hepatic vein is connected to the recipient's inferior vena cava. In full-size liver grafts, the donor liver is removed with the intrahepatic inferior vena cava (IVC), which is then interposed between the infraatrial and distal native IVC. The "piggyback" technique (with preservation of the recipient vena cava and cavocaval anastomosis) has gained wide acceptance and is the preferred technique for orthotopic liver transplantation at many institutions. In patients with polysplenia and biliary atresia, vascular connections may be modified as a result of the frequent absence of the hepatic segment of the IVC, azygous continuation, malrotation, a preduodenal portal vein, and other anomalies.[5,21,22]

Vascular, biliary, infectious, and immunosuppression-related complications may befall liver recipients postoperatively, including posttransplant lymphoproliferative disease (PTLD). The most common complication of liver transplant is infection, but vascular thrombosis and primary graft nonfunction account for most cases of graft loss leading to retransplantation. Death in most pediatric liver recipients is caused by infection, neurologic complications, or multisystem organ failure. Enteric complications include bowel perforation and obstruction, gastrointestinal hemorrhage, and infectious enteritis. Neurologic complications include cerebral hemorrhage and infarction, infection, and drug toxicity.[23–25] Immunosuppressive drug-induced nephrotoxicity is common, but imaging features generally are nonspecific.

Other complications include hepatic parenchymal defects, pleural effusions, and splenic infarcts, which may occur after splenic artery ligation.[26,27] Right adrenal hemorrhage and right phrenic nerve injury are potential complications seen after the standard transplant operation, but they rarely occur after a cava-sparing operation.

## IMAGING

Postoperative imaging is centered on evaluation of vascular, biliary, and enteric complications. Therefore an understanding of specific surgical practice is essential.

Intraoperative sonography may be performed when vascular anastomoses are difficult or revised and their patency is uncertain. Vascular patency is evaluated daily with Doppler ultrasound for the first few posttransplant days because the fate of the transplant

## Abstract:

Pediatric liver transplant is performed for a variety of indications. Knowledge of various surgical techniques and potential complications is relevant to the radiologist as medical imaging plays an integral role in evaluation of children receiving liver transplant.

## Keywords:

Pediatric liver transplant

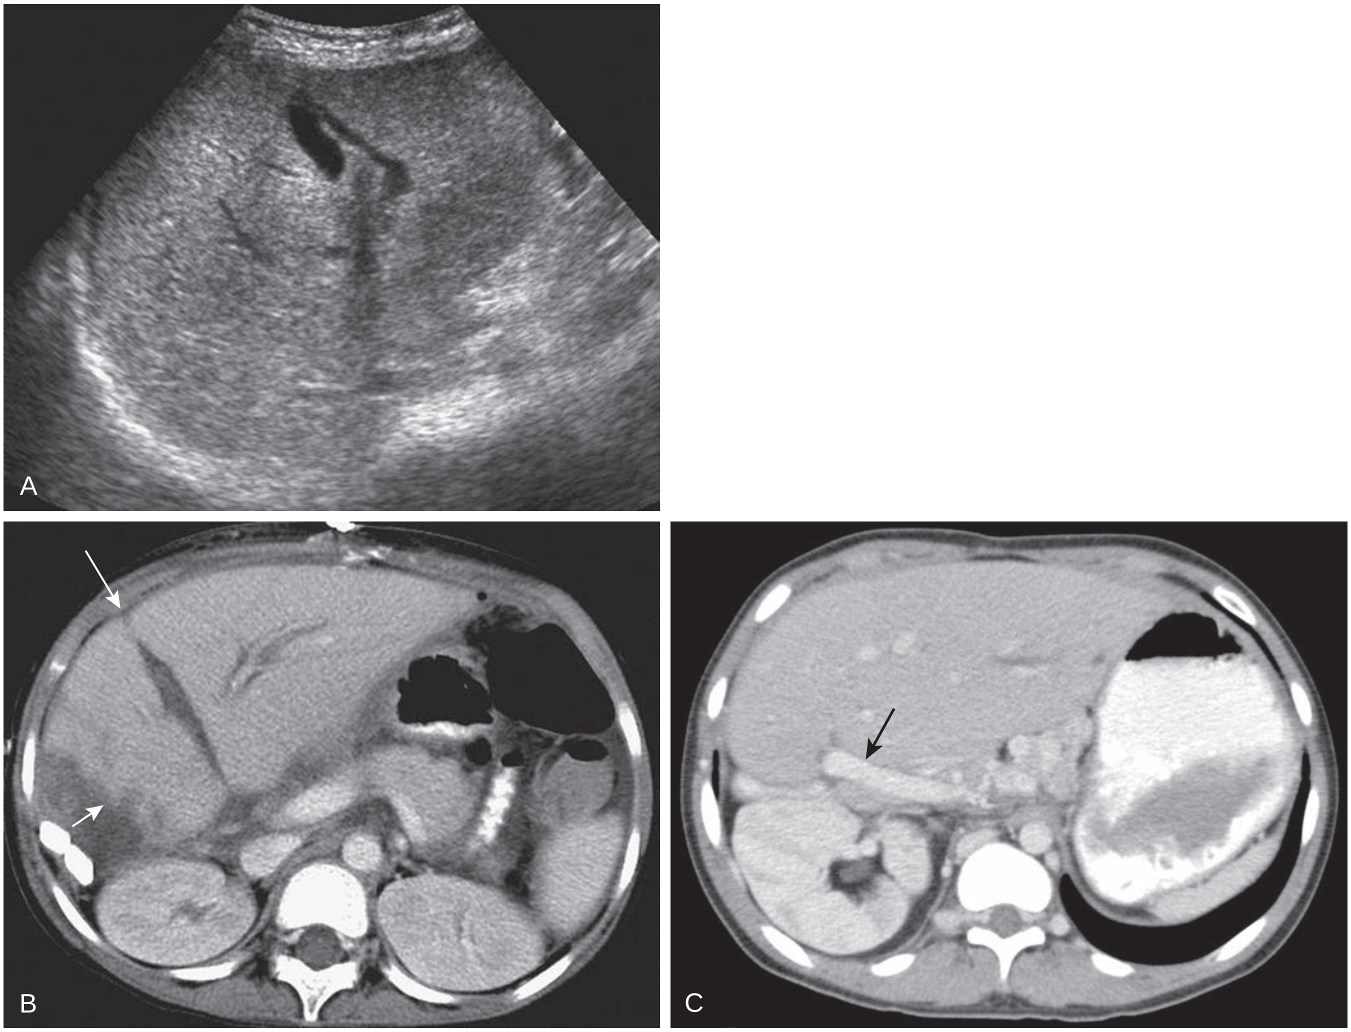

**Figure 93.1. Types of liver transplants.** (A) Transverse sonogram of a whole liver transplant. Fluid along the falciform ligament demarcates the left lateral and medial segments. A right lobe is also present. (B) Axial contrast-enhanced CT image of a left lobe liver graft shows an ill-defined, irregular cut edge with adjacent fluid *(short arrow)*. Fluid along the falciform ligament *(long arrow)* separates the left lateral segment (segments two and three) from the medial segment (segment four). is much improved if vascular occlusions are diagnosed and managed early. The frequency of required ultrasound examinations then decreases, based on individual needs and clinical concerns.[28,29]

Early postoperative ultrasound may be challenging because of poor acoustic windows caused by dressings, open incisions, free intraabdominal air, and body wall edema. The flow patterns in all vessels vary in the early postoperative period because of edema of the anastomosis and surrounding tissues, as well as hemodynamic changes in the graft's vascular bed. Vascular patency, flow direction, pulsatility pattern, and velocity can be evaluated using gray-scale, spectral, and color Doppler ultrasound techniques. The color velocity scale may have to be adjusted for each vessel separately to avoid aliasing in the faster flowing vessels, which can lead to ambiguity of flow direction. Efforts must be made to interrogate at the anastomoses, where stenosis, thrombosis, and occlusion are most likely.[28]

Early findings seen in otherwise normal liver grafts include increased periportal echogenicity (low attenuation on computed tomography [CT] and increased signal on water-sensitive magnetic resonance [MR] sequences) related to transient lymphatic engorgement (Fig. 93.4), which can last up to 1 year posttransplantation. Other postoperative findings include right pleural effusion, subhepatic fluid collections, and biliary air in recipients with choledochojejunostomies.[26,27]

Periodic long-term ultrasound screening of liver recipients is mandatory because vascular complications may be clinically silent. CT, CT angiography (CTA), magnetic resonance cholangiopancreatography (MRCP), and magnetic resonance angiography (MRA) are used to determine the need for biliary and vascular interventions in selected patients. The choice of CT versus magnetic resonance imaging (MRI) depends on the individual center's expertise. CT is preferred in the acutely sick patient and provides better spatial resolution for evaluation small vessels. Biliary complications such as strictures and bilomas can be well evaluated with MRCP with or without the use of hepatocyte-specific contrast agents.

## PRETRANSPLANT IMAGING

Preoperative imaging is tailored to the patient's underlying disease and coexistent conditions. The goals are to document vascular

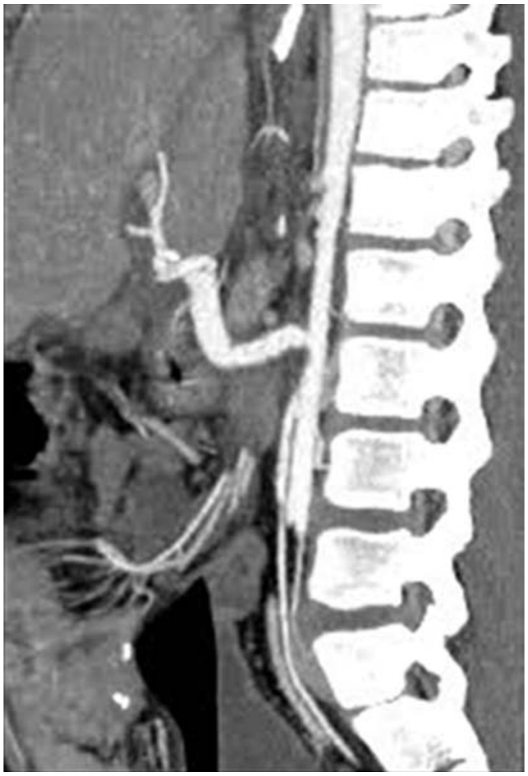

**Figure 93.2. Hepatic artery conduit.** Sagittal oblique reformatted contrast-enhanced CT maximum intensity projection (MIP) image shows an infrarenal conduit, arising just above the level of the inferior mesenteric artery, feeding the transplanted hepatic artery.

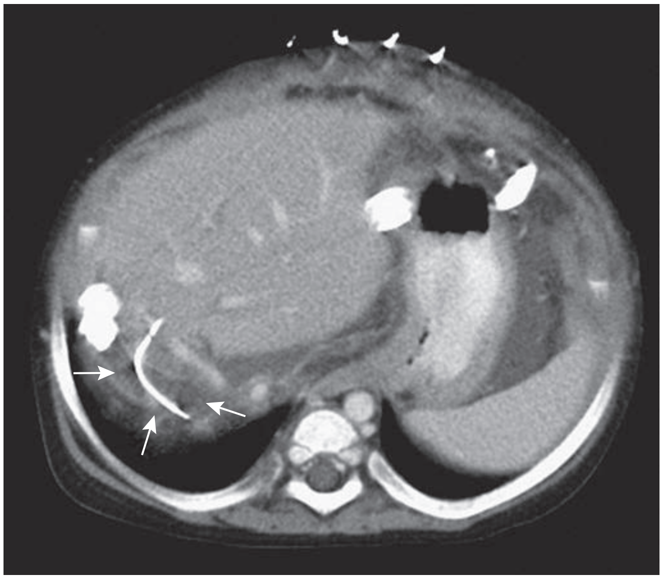

**Figure 93.3. Roux-en-Y biliary anastomosis.** Axial contrast-enhanced CT image early after transplantation show the biliary anastomosis and loop are marked by a small biliary stent *(arrows)*. Being an efferent loop from the liver, it frequently does not fill with intestinal contrast, making it difficult to differentiate from a pathologic fluid collection. Diffuse mesenteric edema and skin staples are noted.

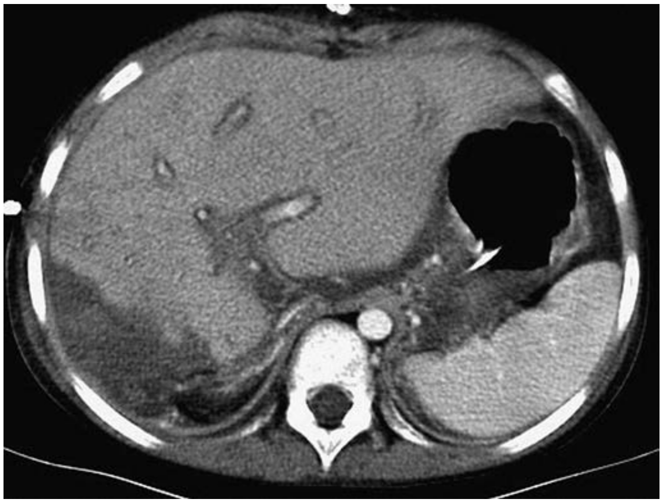

**Figure 93.4. Early CT findings in liver transplantation.** Axial contrast-enhanced CT image shows diffuse periportal hypoattenuation, irregularity of the liver cut surface edge with adjacent fluid. These are expected findings in the immediate post operative period.

patency, define visceral and vascular anatomy, exclude contraindications, evaluate the extent of liver disease and portal hypertension, and assess liver volumes.

Pertinent anatomic features for surgical planning include a small, absent, or occluded portal vein; IVC thrombosis; biliary atresia associated with polysplenia syndrome and absent intrahepatic IVC, with hepatic veins draining into the right atrium; systemic drainage of the splenic veins; congenital portosystemic shunts; and malrotation. Transplantation may be impossible when the portal and superior mesenteric veins are occluded or in cases of nonresponsive metastatic hepatoblastoma. Detection of hepatocellular carcinoma in a patient with cirrhosis changes the transplant urgency and requires tumor staging and decisions about pretransplant therapy, which affect the timing and feasibility of transplantation.[28]

Ultrasound is the first-line imaging modality in the preoperative evaluation of pediatric transplant candidates. Doppler ultrasound assesses vascular patency and hemodynamics. CT or MRI with intravenous contrast is excellent for showing vascular and visceral anatomy. Bone radiographs may detect rickets, osteopenia, and fractures, and chest radiographs may show cardiomegaly and vascular prominence in patients with hepatopulmonary disease (see Chapter 92).[30,31] Angiography is seldom needed but is reserved for patients for whom additional information may be required, such as if the patency of portal tract is questionable.

## VASCULAR COMPLICATIONS

### Hepatic Artery

***Overview.*** Hepatic arterial complications include thrombosis, occlusion, stenosis, peripheral arteriovenous fistula, and aneurysm. Hepatic artery thrombosis is the most common vascular complication as well as a major cause of graft loss and mortality in the early postoperative period. Early hepatic artery thrombosis is associated with a high incidence of transplant loss secondary to liver infarction.[32] If the problem is diagnosed within the first 2 to 3 days and the patient is still asymptomatic, most transplanted livers with hepatic artery thrombosis can be salvaged. However, if elevated liver function tests, bile leak, liver abscess, or sepsis have supervened, graft loss may reach 75%.[33] Late thrombosis typically presents with biliary complications.

***Imaging.*** The hepatic artery is much more difficult to visualize by gray-scale ultrasound than the portal vein because of its small

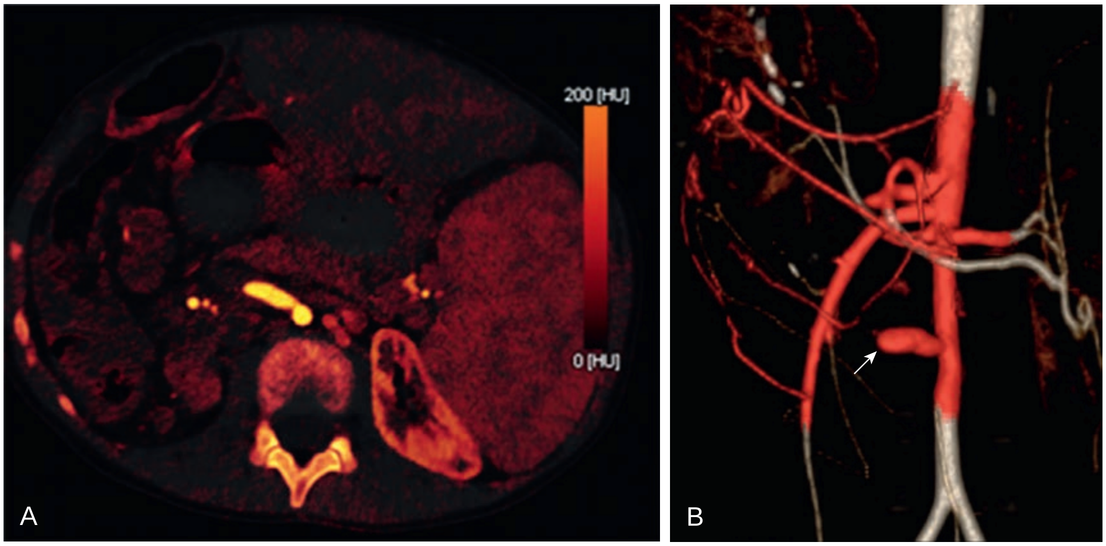

**Figure 93.5. Hepatic artery occlusion.** (A) Dual-energy CT iodine map shows abrupt termination of the infrarenal hepatic artery conduit with a nonperfused parenchyma of the transplanted liver. (B) 3D rendered reconstruction also demonstrates abrupt occlusion of the infrarenal arterial conduit *(arrow)*.

size. It is best evaluated by color and power Doppler ultrasound.[26] It is easier to follow the artery to its anastomosis when it is attached to the native hepatic artery or celiac axis rather than to the infrarenal aorta, where much of its course may be obscured by bowel gas. CTA and MRA are useful in showing hepatic artery anatomy, course, and complications, though CTA maybe preferred in the immediate postoperative period due to short examination time (Fig. 93.5).[27]

The hepatic artery flow pattern may vary considerably in the early postoperative days, demonstrating high and low resistive indices, without consistent prognostic implications.

The diagnosis of hepatic artery thrombosis is made by the inability to detect hepatic artery signal on color and spectral Doppler ultrasound.[26] Acute arterial thrombosis is treated by thrombectomy, revision, and occasionally retransplantation.[34] High-grade narrowing is manifested by turbulence and severely attenuated velocity distally with a parvus-tardus pattern in intrahepatic branches, with narrow systolic peaks and absent diastolic flow beyond the anastomosis.[32]

Later-onset hepatic artery occlusion may manifest with biliary leaks, strictures, and infection, including peribiliary abscess and sepsis because the biliary tree depends on hepatic arterial supply. In longstanding hepatic artery occlusion, hilar or transcapsular collaterals may result in a detectable arterial Doppler signal.[32]

Stenosis of the hepatic artery may be silent or may manifest with biliary complications and infection. High velocity and turbulence may be seen at the stenotic site. The flow pattern is abnormal, with a low-amplitude, parvus-tardus waveform representing a systolic acceleration time longer than 0.08 second and a resistive index lower than 0.5.[32] Very high-grade stenosis manifests with narrow and low-amplitude systolic peaks and absence of diastolic flow. The stenosis itself is usually extrahepatic and difficult to demonstrate directly by Doppler ultrasound (Fig. 93.6).[27,32] The hemodynamic changes of hepatic artery stenosis may be more dramatic than its appearance on CTA or MRA.

Hepatic artery pseudoaneurysm may occur at the anastomosis or within the liver at a biopsy site.[27,32] Liver biopsy also is a cause of intrahepatic arteriovenous fistulas.[34]

## Venous System

***Overview.*** Obstructive lesions of the portal vein, hepatic vein, and IVC may manifest with progressive ascites, deterioration of liver function, gastrointestinal bleeding, decreased platelet count, and increased spleen size. Pulmonary hypertension and intrapulmonary shunting may develop. Doppler signal in the intrahepatic portions of the portal vein do not exclude stenosis or obstruction, which may be present in the extrahepatic segment, with intrahepatic flow reconstituted by collateral vessels.[30] Portal vein, hepatic vein, and IVC stenosis result in flow acceleration at the stenosis and a jet of increased flow at the poststenotic segment, which appears as a contrasting color as a result of aliasing when the scale is adjusted to the velocity below the stenosis. The jet velocity is proportional to the pressure gradient across the stenosis.[26,27]

### Imaging

***Portal Vein.*** Ultrasound of the transplant portal vein requires visualization of its entire course. One must measure the diameter at any site of narrowing and interrogate the portal vein by spectral and color Doppler along its extrahepatic and hilar course, as well as its major intrahepatic branches. The curved course of the portal vein in left lobe and left lateral segment transplants and the size discrepancy between donor and recipient veins frequently cause dilation at the neohilum because of altered flow dynamics (Fig. 93.7) with a "yin-and-yang" swirling pattern on color Doppler. This pattern has not been proved clinically important. Anastomotic and periportal edema causing relative narrowing with jet formation is very common in the early postoperative period; these instances of edema are most often transient but may progress or persist and should be monitored. Complications include early thrombosis, stenosis, and late occlusion (Fig. 93.8).[26,27]

A hypoechoic thrombus may not be recognized by gray-scale ultrasound but shows absence of signal on color Doppler imaging. Reversal of superior mesenteric or splenic vein flow also is seen. Early thrombosis usually is treated by surgical thrombectomy and revision. Early posttransplant reversal of entire portal vein flow may reflect extensive hepatic necrosis and arterioportal shunting—an ominous sign associated with frequent organ loss.[27]

Later onset of portal vein thrombosis or occlusion may be clinically silent, manifesting with increasing plasma levels of hepatic enzymes, an enlarging spleen, and gastrointestinal bleeding. Intrahepatic portal venous flow frequently is reconstructed from collaterals recruited from superior mesenteric vein branches via varices in the Roux-en-Y loop and from transcapsular collaterals.

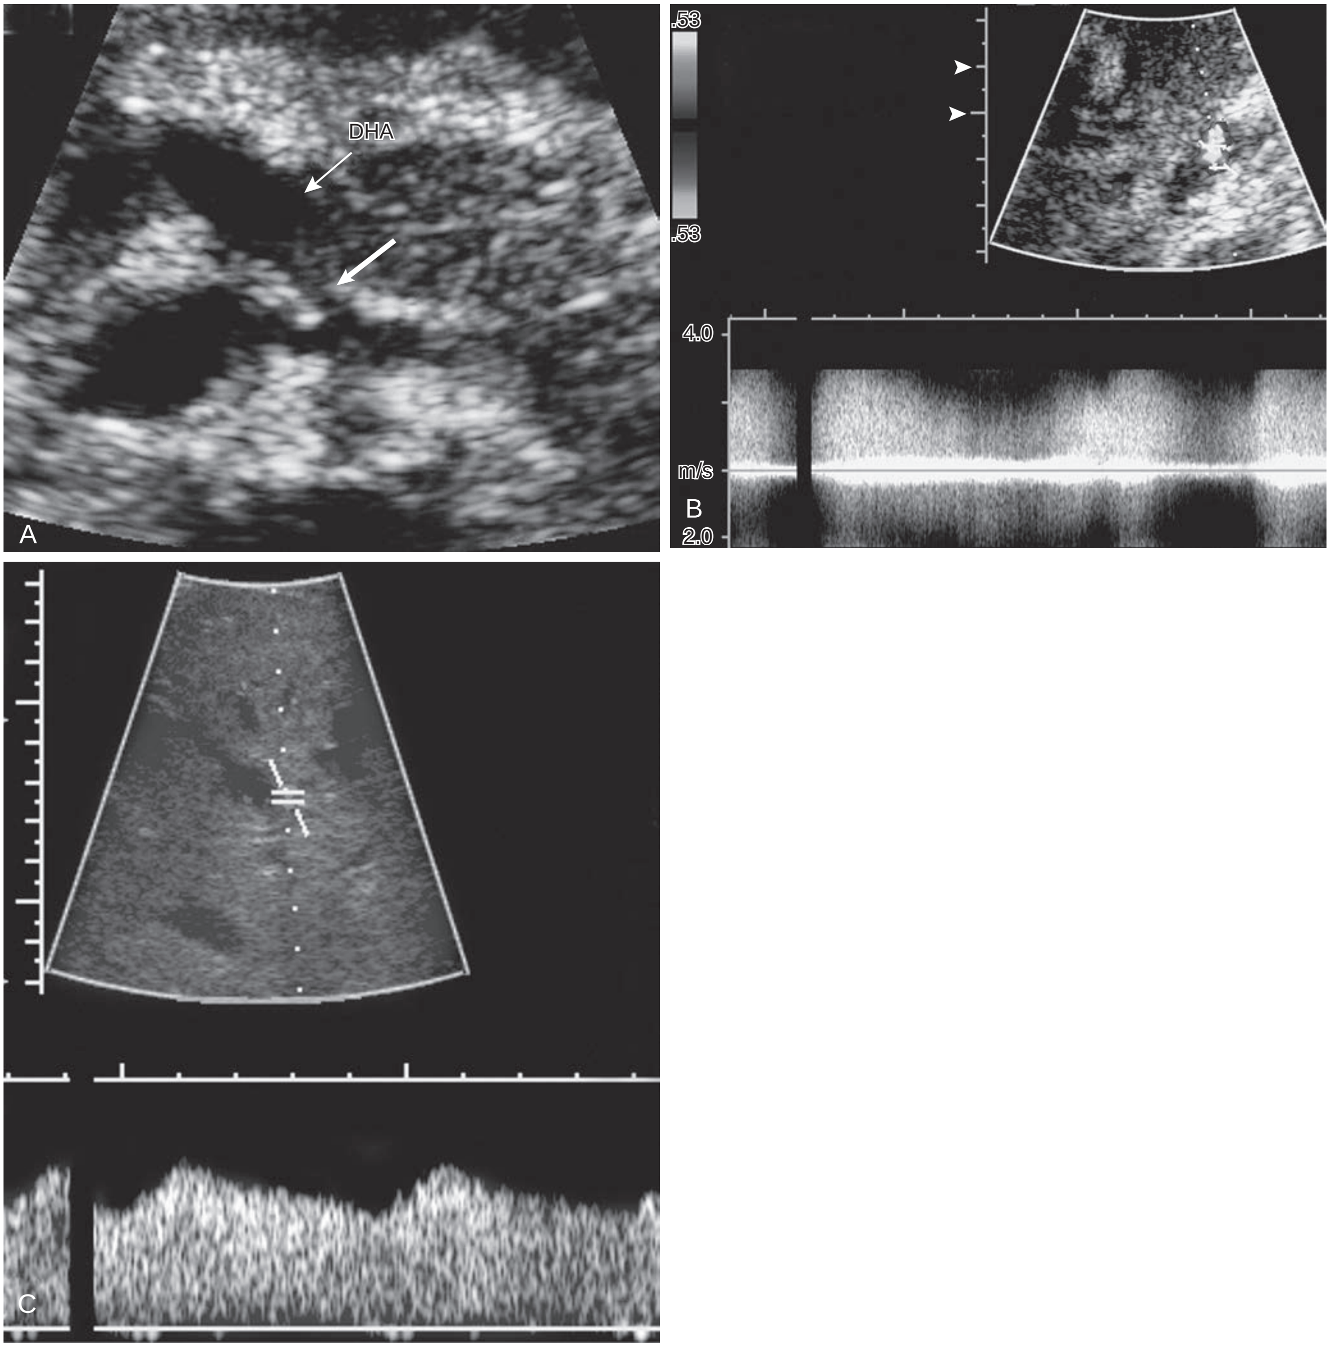

**Figure 93.6. Ultrasound and Doppler characteristics of hepatic artery stenosis.** (A) Transverse sonogram shows stenosis immediately distal to the celiac axis *(thick arrow)*. The donor hepatic artery *(DHA)* distal to the anastomotic stenosis is marked by a *thin arrow*. (B) Spectral and color Doppler at the stenosis show extreme turbulence and high velocity. The normal arterial signal is difficult to recognize because of aliasing. (C) Spectral and color Doppler in an intrahepatic hepatic artery branch show a slow systolic upstroke (parvus-tardus waveform), and relatively high diastolic flow producing an abnormally low resistive index.

In the latter event, flow in the receiving portal vein branches may be reversed with segment-to-segment shunting.

Stenosis usually occurs at anastomoses and in extension grafts (Fig. 93.9).[35] Because of the curved extrahepatic course of the portal vein, it may be difficult to demonstrate stenosis by ultrasound. The jet created at the stenotic site dissipates, such that flow velocity measured at the hilum is frequently normal despite a hemodynamically significant portal vein stenosis more proximally.[27] The jet also may exaggerate the dilation of the portal vein at the hilum. After successful angioplasty, the jet velocity decreases and the diameter at the stenotic site increases (Fig. 93.10). Less operator-dependent CT and MRI are highly useful and more consistent than ultrasound in the evaluation of portal vein occlusion and stenosis.[30,32,36]

***Hepatic Vein.*** Hepatic vein stenosis occurs mainly in reduced-size transplants at the anastomosis to the recipient IVC. In a posttransplant patient with the onset of portal hypertension, special efforts must be made to evaluate the hepatic veins and IVC if a

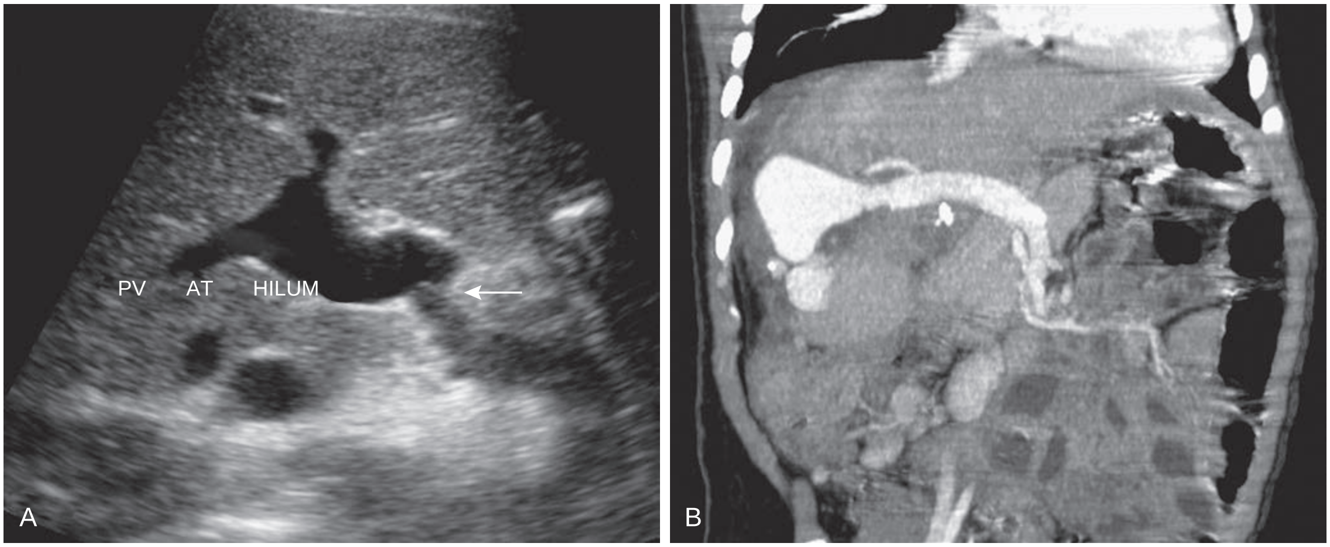

**Figure 93.7. Portal vein in segmental transplantation.** (A) Transverse sonogram shows a size discrepancy *(arrow)* between the native and donor portal veins *(PV AT HILUM)*. (B) Coronal CTA reconstruction demonstrates the extrahepatic portal vein coursing from the left to the right edge of the transplant, near the right abdominal wall. The portal vein is dilated at the neohilum. Note slight narrowing at the anastomosis in this early transplant, which can be a transient finding.

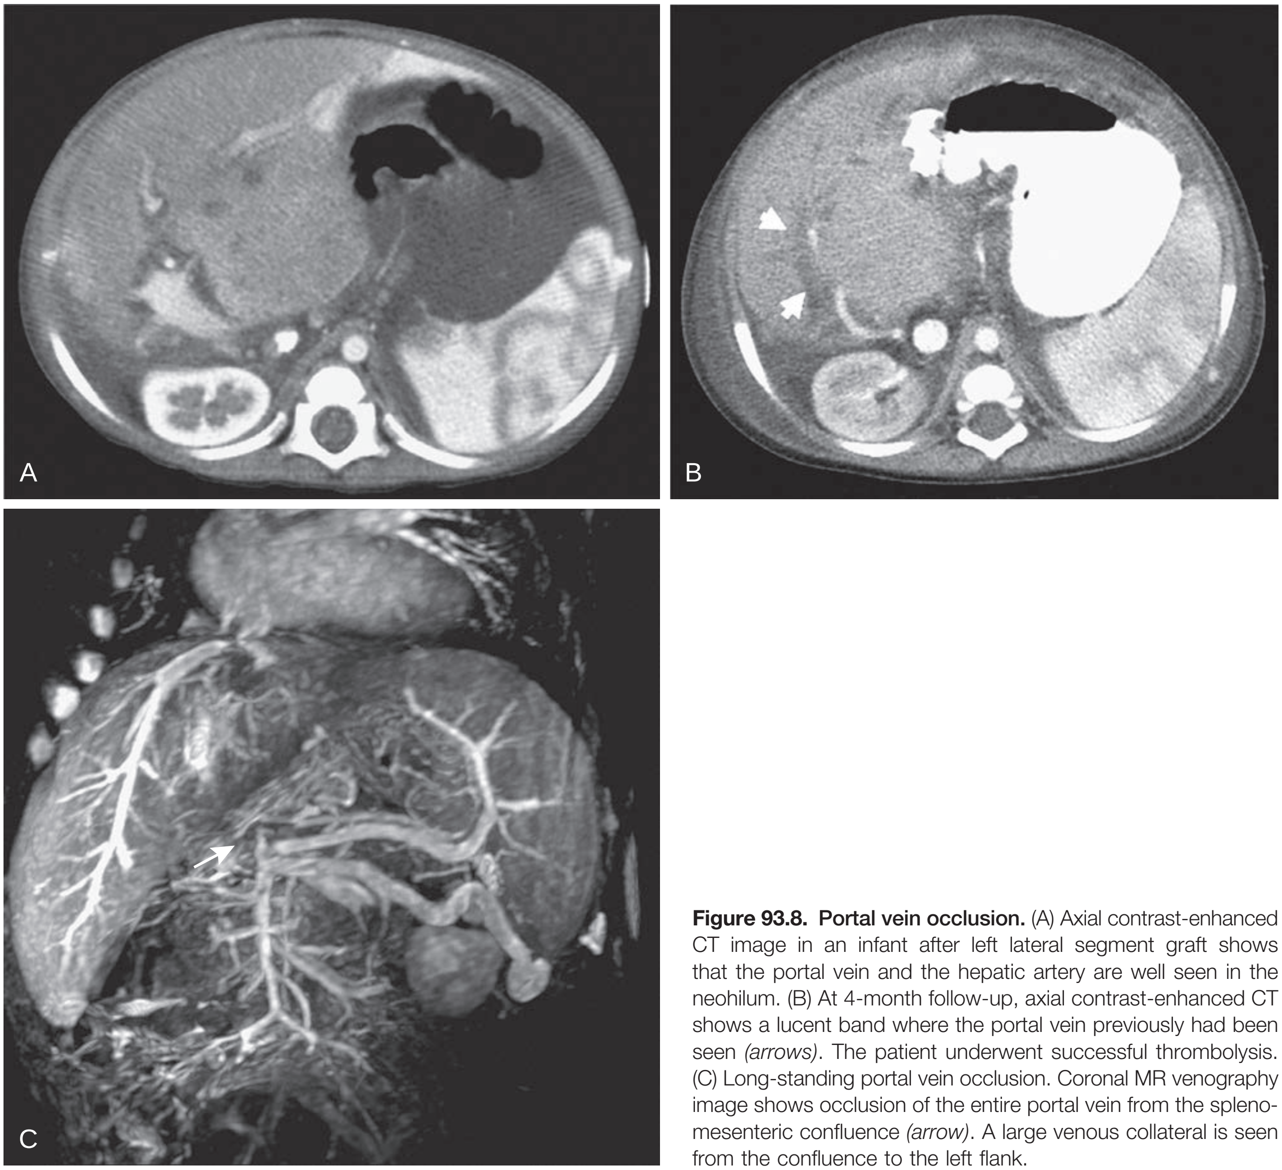

**Figure 93.8. Portal vein occlusion.** (A) Axial contrast-enhanced CT image in an infant after left lateral segment graft shows that the portal vein and the hepatic artery are well seen in the neohilum. (B) At 4-month follow-up, axial contrast-enhanced CT shows a lucent band where the portal vein previously had been seen *(arrows)*. The patient underwent successful thrombolysis. (C) Long-standing portal vein occlusion. Coronal MR venography image shows occlusion of the entire portal vein from the splenomesenteric confluence *(arrow)*. A large venous collateral is seen from the confluence to the left flank.

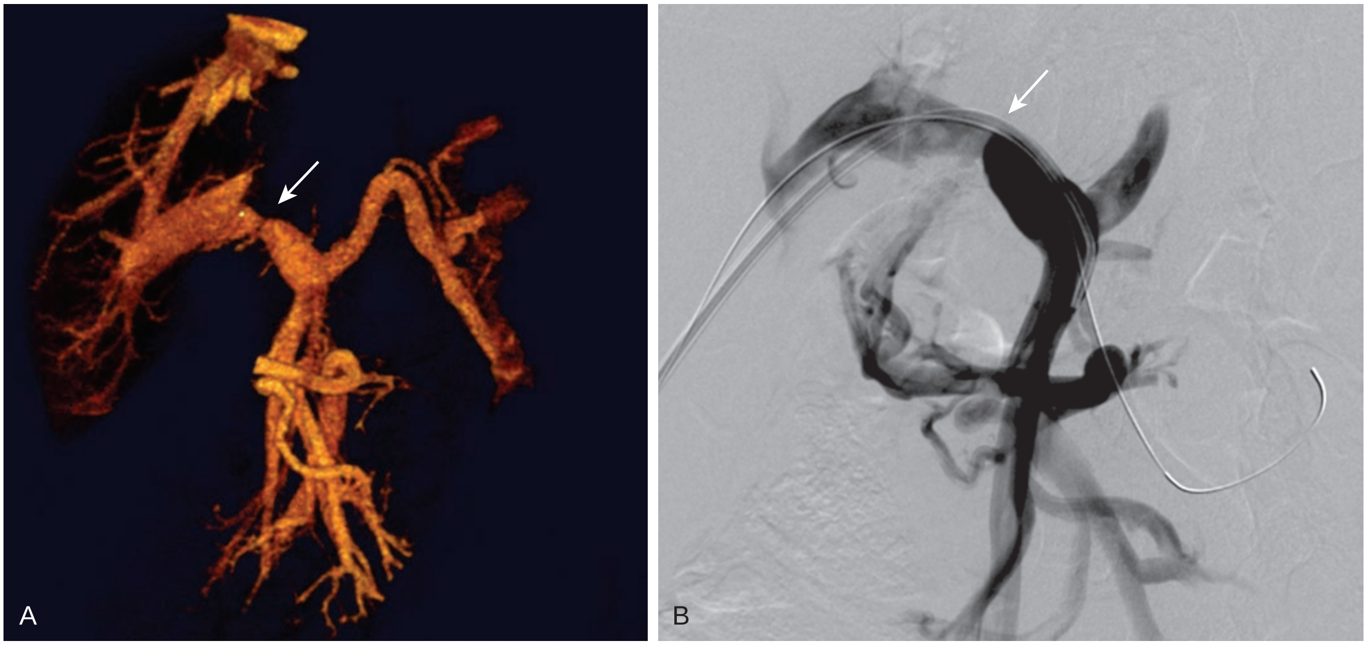

**Figure 93.9. Portal vein stenosis.** (A) Reconstructed images from contrast-enhanced CT shows anastomotic stenosis *(arrow)* in a patient with a whole liver transplant. (B) A portal venogram in the same patient confirms the portal vein stenosis *(arrow)*.

portal vein complication is not seen. Stenosis is near the diaphragm, making it difficult to demonstrate by ultrasound (Fig. 93.11). Doppler ultrasound demonstrates increased flow velocity and a jet with loss of triphasic flow.[32,37] A caveat is that triphasic flow may be absent without obstruction. CTA and MRA are excellent to demonstrate or confirm the diagnosis.[27]

***Inferior Vena Cava.*** IVC stenosis and obstruction may occur at the anastomosis. Anastomotic stenosis and obstruction may be short or long segment and may result from compression or graft torsion (Fig. 93.12). The clinical manifestations of IVC stenosis or obstruction depend on the location. If the problem is at or above the hepatic veins, it manifests with ascites and portal hypertension. If it is at a lower level, it may be clinically silent.[27]

IVC obstruction can be diagnosed by all cross-sectional modalities; however, several pitfalls may be encountered with Doppler ultrasound. Flow in the hepatic veins may be normal and triphasic if the IVC obstruction is distal to their insertion. On the other hand, when the obstruction is proximal to the hepatic vein insertion, hepatic venous blood may enter the IVC and flow retrograde to decompress into systemic collaterals. In patients with a surgical portosystemic shunt, IVC obstruction prevents adequate decompression, sometimes reversing flow in the shunt and increasing preexistent varices.[32,35]

## Biliary Complications

Biliary complications have been reported in up to 14.5% of children undergoing liver transplantation.[38] The small caliber of bile ducts and the presence of multiple ducts in segmental grafts increases the risk of these complications. Bile leaks and strictures occurring early after transplantation are related to technical surgical problems, such as anastomotic leak and narrowing or kinking. Biliary complications with a later onset commonly are associated with arterial ischemia.[32] Biliary strictures are more common in reduced-size liver transplants than in full-sized ones.[39] Inspissated bile and biliary compression by a mucocele or cystic duct remnant have been described.[30] Chronic rejection may be associated with loss of bile ducts and mild chronic dilation. Biliary strictures can be focal (at the site of the anastomosis) secondary to fibrotic proliferation or multifocal/intrahepatic secondary to arterial insufficiency. Hepatic arterial insufficiency can also result in biliary ischemia, bilomas, and biliary necrosis with sloughing of the duct epithelium into the biliary channels (Fig. 93.13).

Ultrasound identifies biliary dilation and is the primary screening modality. When bile duct dilation is found, further imaging is indicated.[26] MRCP increasingly is used to assess biliary obstruction and the need for intervention.[40–42] Direct transhepatic cholangiogram usually is performed as part of the therapeutic approach and patients can require multiple biliary interventions and indwelling draining catheters (Fig. 93.14).

## Fluid Collections

Early postoperative bleeding from leaking anastomoses or inadequate hemostasis leading to visible fluid collections occurs in as many as 15% of recipients. Up to half of these patients undergo operative exploration. Most fluid collections occur at the cut edge, contain serous fluid, blood, or bile, and are transient and clinically insignificant. Other collections may result from an anastomotic bile leak, abscess, or bowel perforation. The imaging appearance of perihepatic fluid collections is nonspecific; most contain some debris.[26] Specific diagnosis may require fluid aspiration or surgery.

When a fluid collection is suspected, it is important to realize that, although the blind end of the Roux-en-Y loop may dilate, the normal loop at the hilum of the transplanted liver may mimic a fluid collection on ultrasound and may not fill with oral contrast during CT scanning.[29,35]

Though the diagnosis for a bile leak can typically be established by the nature of the draining fluid, if clinically indicated, hepatobiliary iminodiacetic acid scan (HIDA) scan or delayed phase imaging with hepatocyte-specific contrast agents can be used to confirm the diagnosis of bile leak and identify the exact source of the leak (Fig. 93.15). Ascites is also common in the days after transplantation and usually is self-limited. If large in amount or prolonged in duration, an evaluation for the cause may be required.

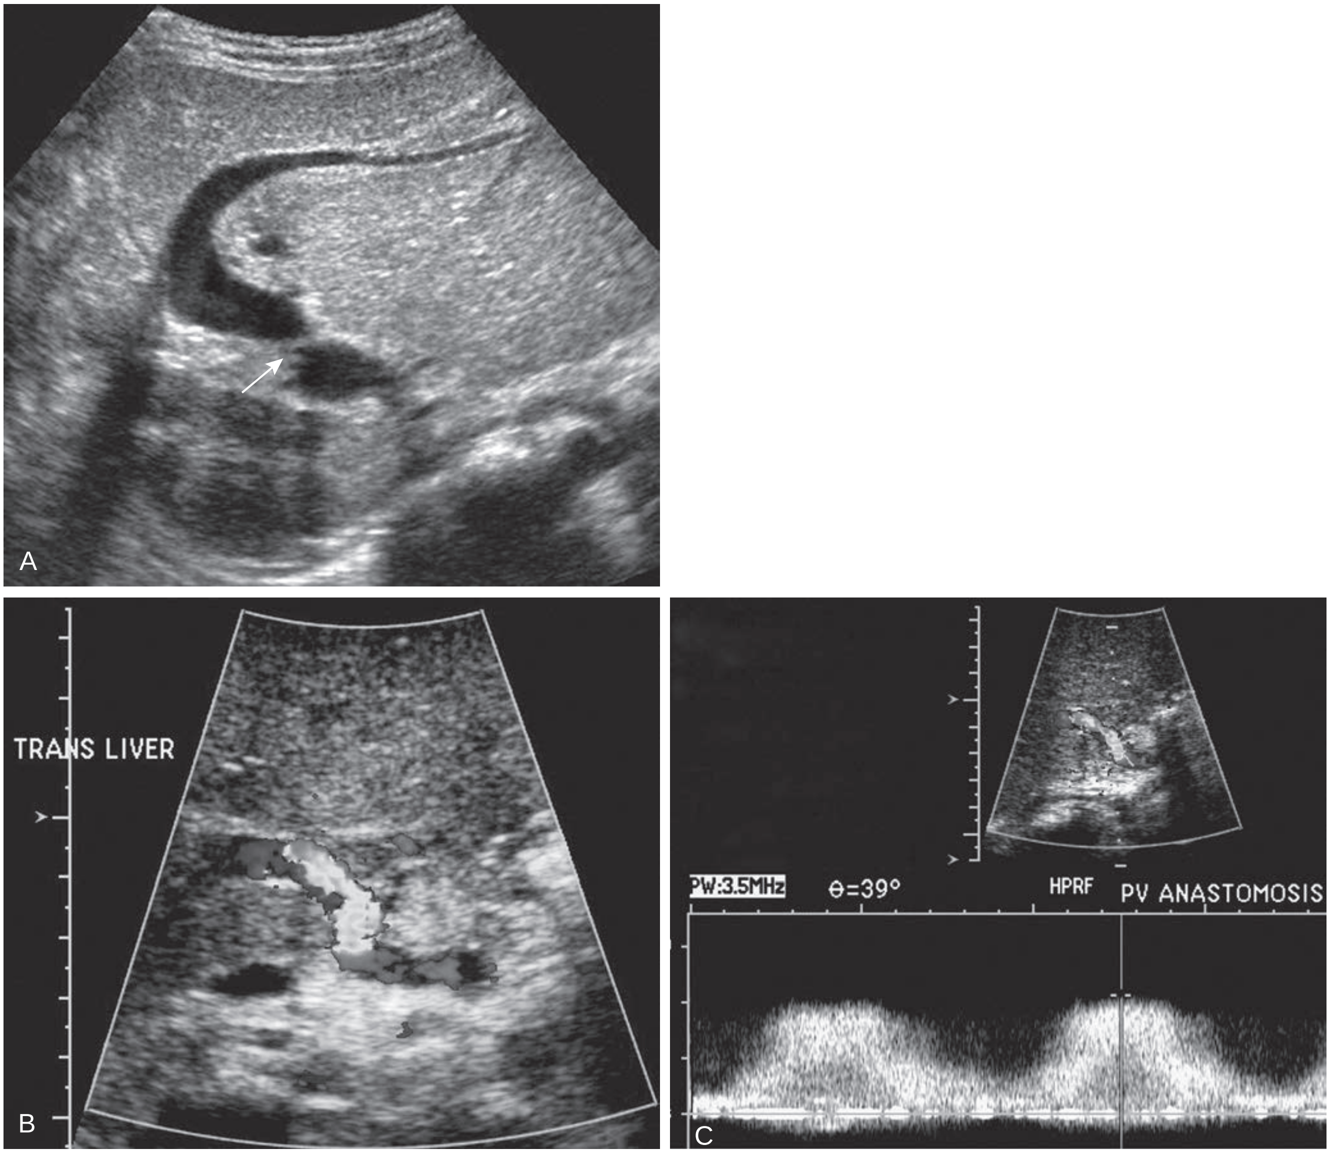

**Figure 93.10. Ultrasound and Doppler characteristics of portal vein stenosis.** (A) Transverse sonogram of a child with a left lateral segment graft shows a stenosis *(arrow)* outside the liver hilum, beyond the portal vein curvature. (B) On color Doppler, the velocity scale is adjusted such that aliasing demonstrates the higher velocity jet outlining the stenotic site. (C) On spectral and color Doppler with sampling at the jet, maximal flow velocity is obtained to assess the hemodynamic impact of the stenosis. The maximal jet velocity exceeds 2 m/sec.

## Infection

Postoperative infection develops in most liver recipients at some time, although consequent mortality is less than 10%. Bacterial and fungal infections are most common during the first postoperative month. Risk factors include hepatic artery occlusion, immunosuppression, central venous catheters, and nosocomial exposure. Viral and opportunistic infections usually occur between 30 and 180 days after transplantation.[43] Ultrasound and CT are the mainstay for assessing intraabdominal infections, particularly abscesses.[44] Cholangitis may prompt evaluation with MRI or percutaneous transhepatic cholangiography.[40]

## Rejection

Imaging plays a relatively minor role in the diagnosis of rejection, which is established mainly by liver biopsy. Rejection may be associated with mild degrees of nonobstructive bile duct dilation and an increase in hepatic arterial resistive indices. However, neither hepatic arterial waveforms nor flow pattern in the hepatic veins have proved to be predictive of rejection.[36]

## Posttransplantation Lymphoproliferative Disease

PTLD represents a spectrum of abnormalities of lymphoid proliferation linked with Epstein-Barr virus (in 98% of pediatric patients) and immune cell proliferation that ranges from polyclonal reversible B cell proliferation to aggressive monoclonal B cell lymphoma.[45] Risk factors for the development of PTLD are seronegativity for Epstein-Barr virus at transplantation, young age, intensity and type of immunosuppression (especially antilymphocyte antibody), cytomegalovirus infection, and type of transplant.[41] PTLD develops in children about three times as often as in adults, reported at 9.7% versus 2.9%, respectively.[46]

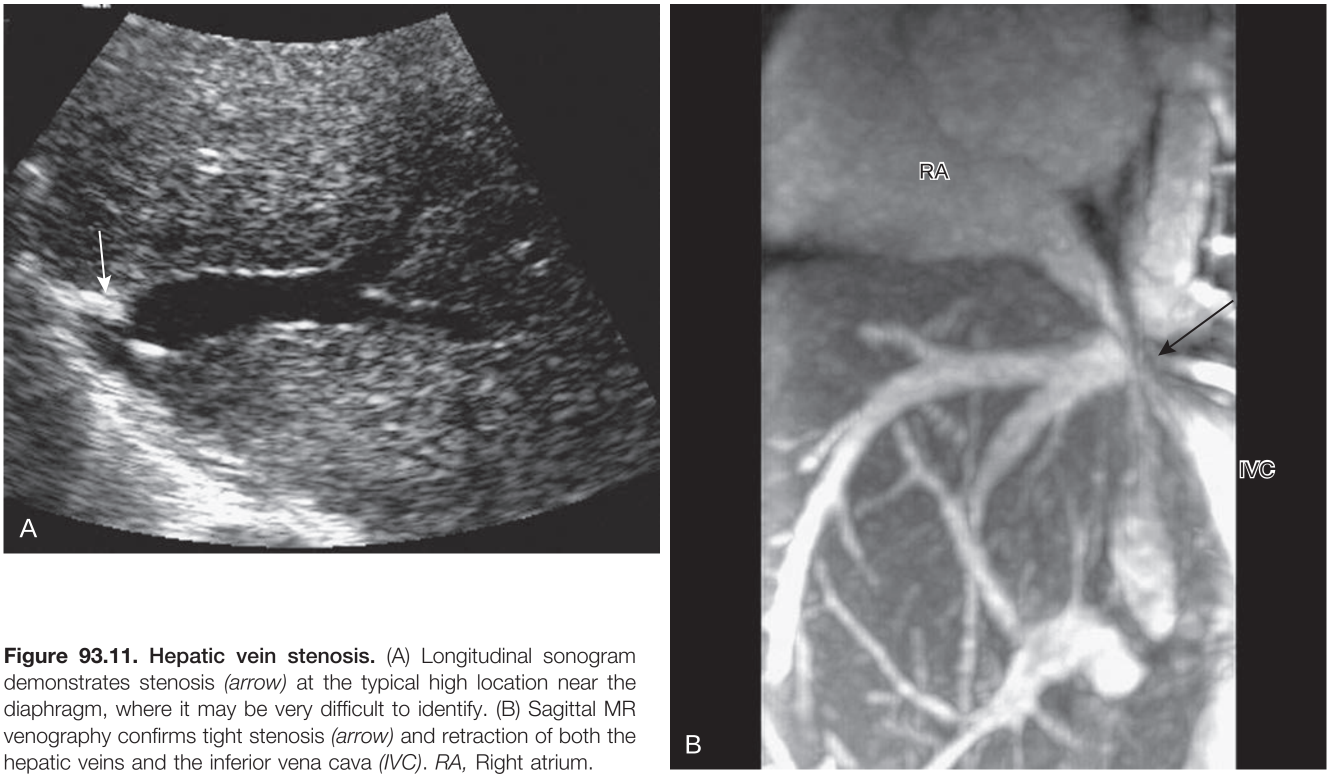

**Figure 93.11. Hepatic vein stenosis.** (A) Longitudinal sonogram demonstrates stenosis *(arrow)* at the typical high location near the diaphragm, where it may be very difficult to identify. (B) Sagittal MR venography confirms tight stenosis *(arrow)* and retraction of both the hepatic veins and the inferior vena cava *(IVC)*. *RA,* Right atrium.

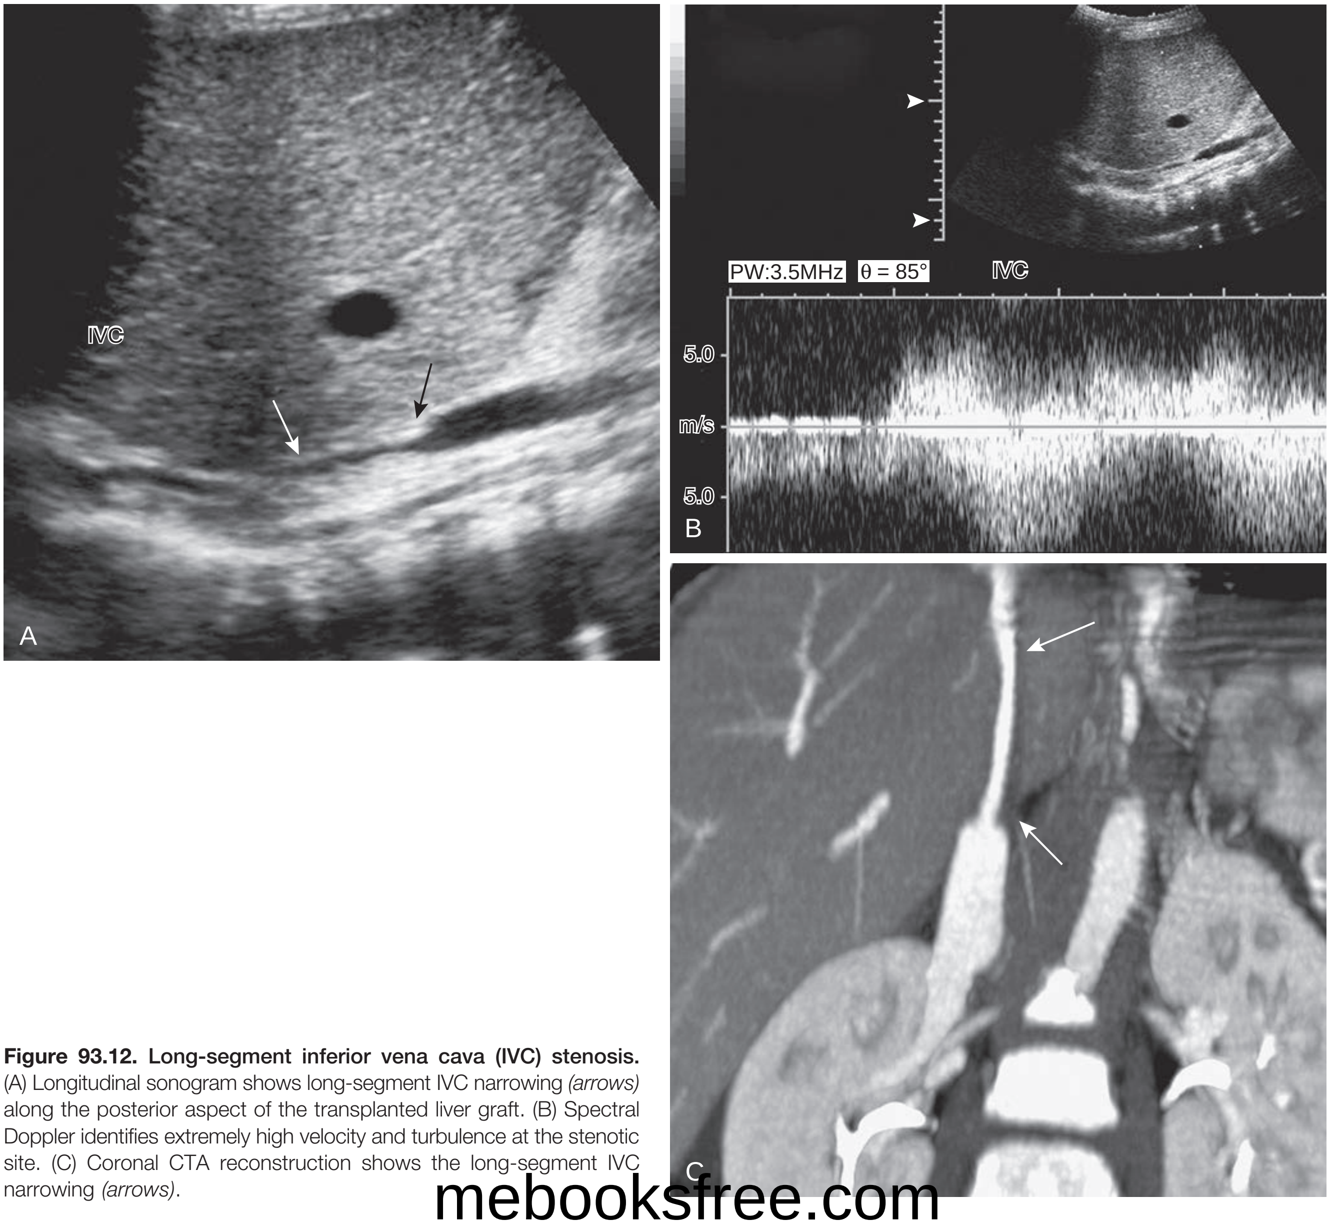

**Figure 93.12. Long-segment inferior vena cava (IVC) stenosis.** (A) Longitudinal sonogram shows long-segment IVC narrowing *(arrows)* along the posterior aspect of the transplanted liver graft. (B) Spectral Doppler identifies extremely high velocity and turbulence at the stenotic site. (C) Coronal CTA reconstruction shows the long-segment IVC narrowing *(arrows)*.

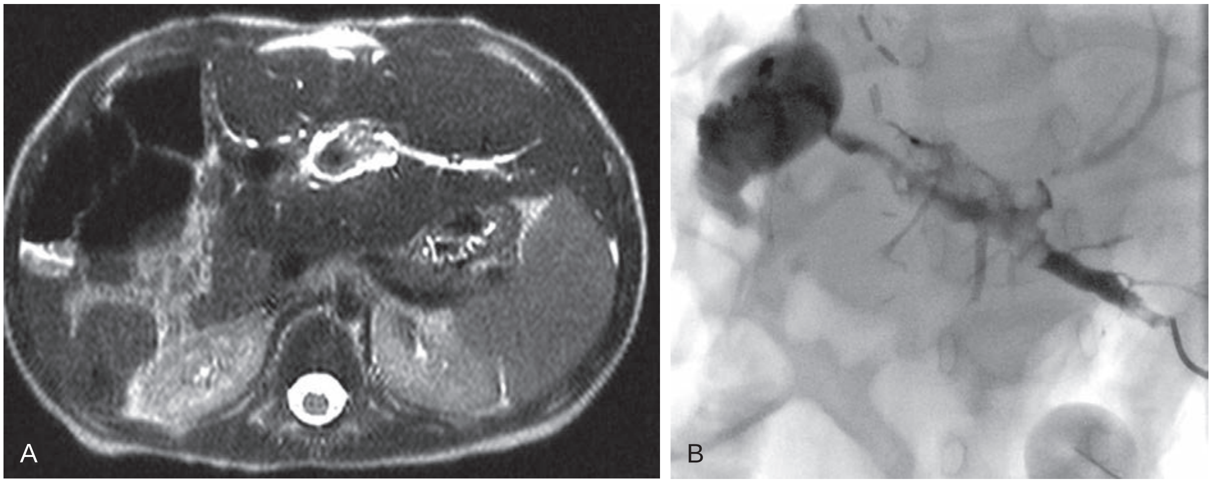

**Figure 93.13. Biliary necrosis secondary to late hepatic artery thrombosis.** (A) Axial T2-weighted MR image shows biliary duct dilation with hypointense filling defects in the bile duct. (B) Percutaneous cholangiogram shows irregular biliary channel with multiple filling defects secondary to sloughed biliary epithelium.

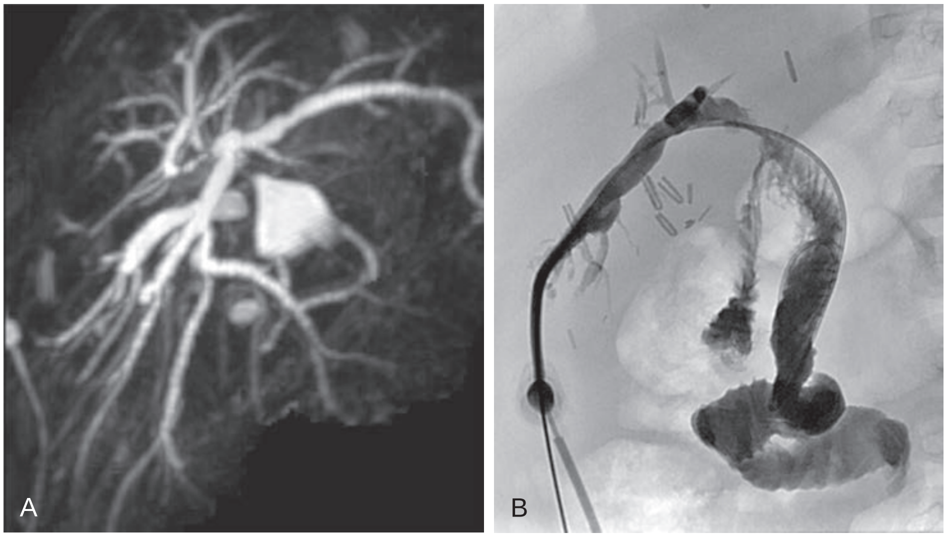

**Figure 93.14.** (A) 3D maximum intensity projection MRCP image shows marked intrahepatic biliary dilation with a tight stricture near the Roux-en-Y loop. (B) Percutaneous cholangiogram confirms the stricture and is used to deploy a biliary drainage catheter after stricturoplasty.

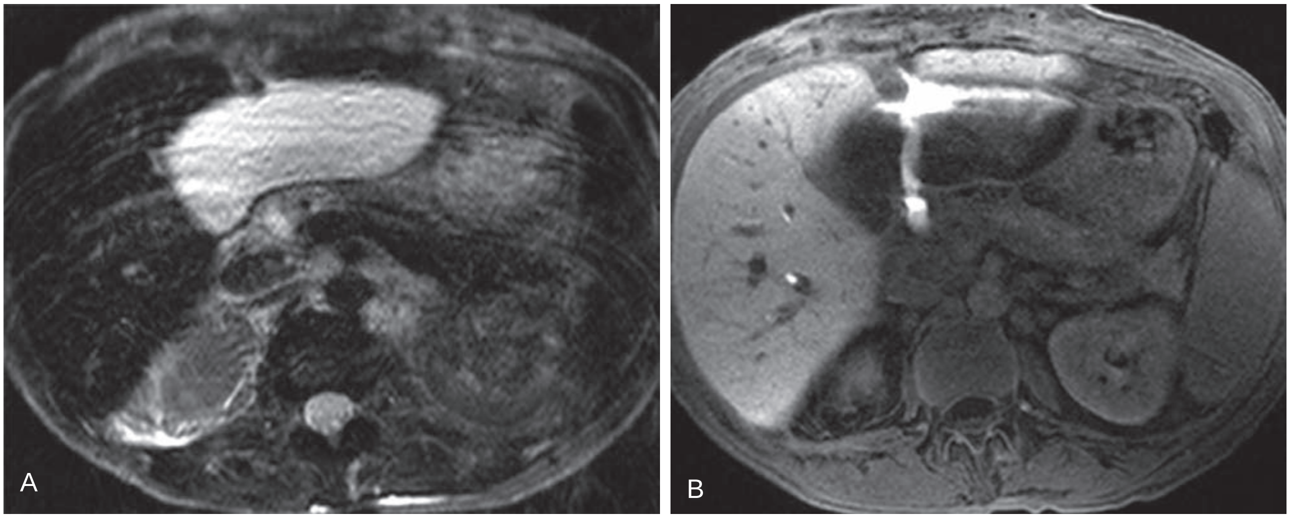

**Figure 93.15. Bile leak.** (A) Axial T2-weighted MR image shows a large fluid collection adjacent to the left lobe of the liver in a patient with a whole liver transplant. (B) 1-hour delayed T1-weighted image obtained after injection of hepatocyte-specific contrast agent confirms the bile leak and helps determine the exact site of the leak at the level of the duct anastomosis.

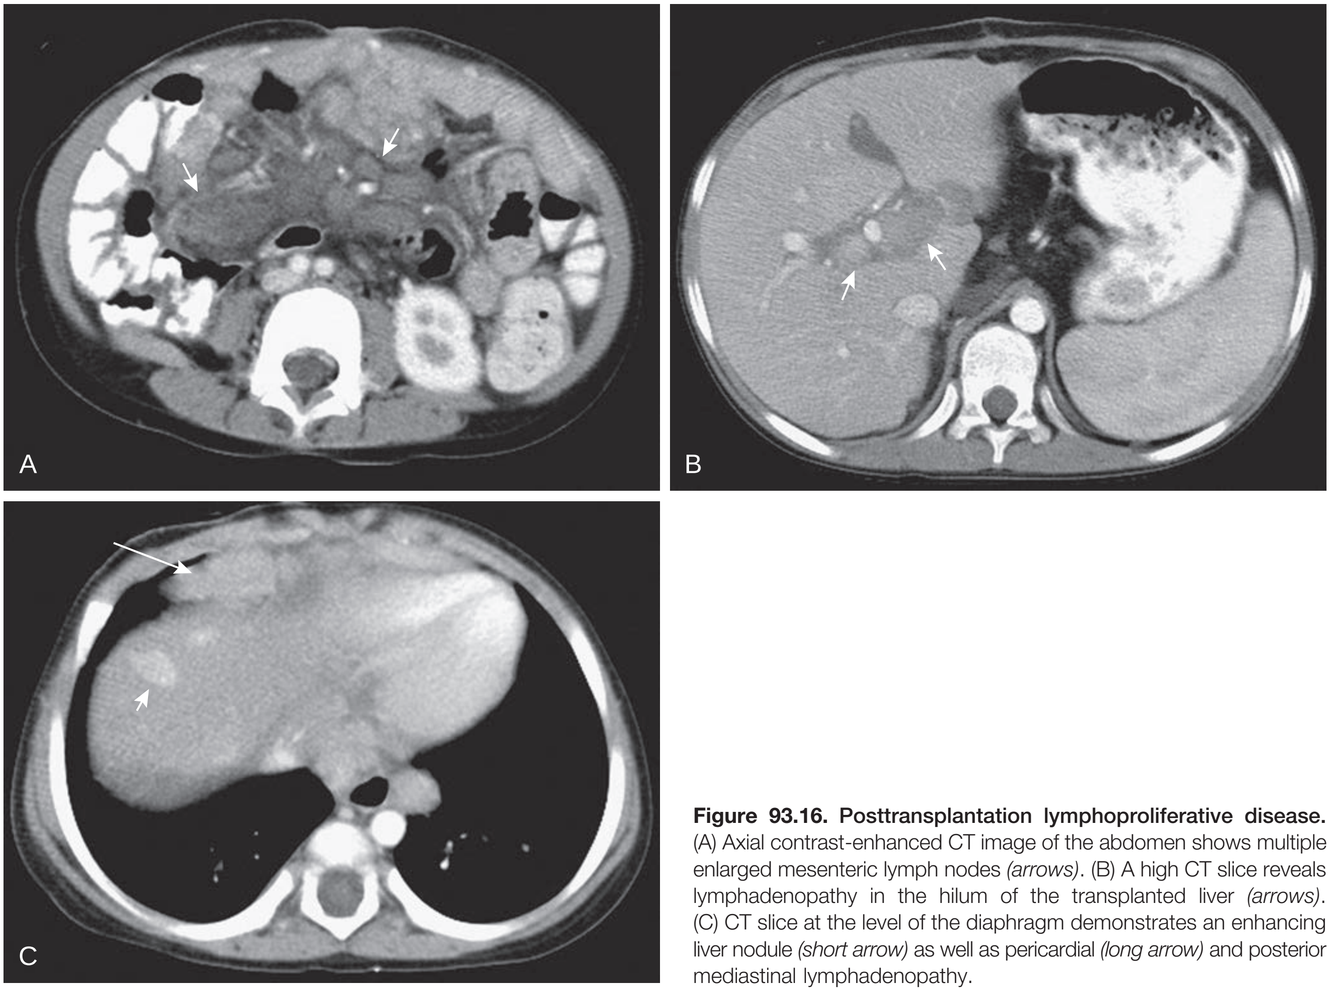

**Figure 93.16. Posttransplantation lymphoproliferative disease.** (A) Axial contrast-enhanced CT image of the abdomen shows multiple enlarged mesenteric lymph nodes *(arrows)*. (B) A high CT slice reveals lymphadenopathy in the hilum of the transplanted liver *(arrows)*. (C) CT slice at the level of the diaphragm demonstrates an enhancing liver nodule *(short arrow)* as well as pericardial *(long arrow)* and posterior mediastinal lymphadenopathy.

The time from transplantation to the development of PTLD averages about 8 months in children, although it may be shorter in patients treated with tacrolimus, occurring as early as within a few weeks.[47] Survival is better in patients with polyclonal PTLD and those with limited disease. In persons with polyclonal disease, PTLD may reverse completely with modifications of immune suppression.[48]

Sites of involvement in children include lymphoid tissue (particularly Waldeyer ring, pericardial, and mesenteric nodes), the gastrointestinal tract, the spleen, and the transplanted liver (Fig. 93.16). Newly enlarged tonsils and adenoids in a child with a transplanted liver should raise suspicion of PTLD. Unusually large mesenteric nodes are common in children with PTLD, although lack of normal standards makes it difficult to set a threshold size for diagnosis. Central nervous system involvement is uncommon.[42] The appearance of PTLD in the transplanted liver consists of multiple nonspecific focal lesions.[49]

## KEY POINTS

- Pretransplant imaging should include information on the patency and size of the portal vein, hepatic vascular variants, absence of hepatic neoplasm, and volumetric assessment of the liver.
- Early posttransplantation flow patterns may suggest vascular stenosis as a result of edema of the anastomosis and surrounding tissues. These findings are usually reversible but should be monitored.
- Doppler signal in the intrahepatic portions of the hepatic artery and portal vein may be present in spite of stenosis or obstruction in the extrahepatic segment as a result of collateral vessels. When transplant vessels are evaluated, screening ultrasound must be performed at the anastomosis, the narrowest portion, and at the site of maximal jet seen by color Doppler ultrasound.
- Reversal of portal venous flow in a lobar or segmental branch is a strong indication of main portal vein occlusion.

# The Spleen

*Josephine M. Ndolo, Stephanie E. Spottswood, and Marta Hernanz-Schulman*

## OVERVIEW

The spleen is an intraperitoneal organ supported by the gastrosplenic ligament and the splenorenal ligament (Fig. 94.1). Other ligaments that help support the spleen are the phrenicosplenic, splenocolic, pancreaticosplenic, phrenocolic, and pancreaticocolic.

The spleen is the largest of the body's lymphatic structures and the second largest organ of the reticuloendothelial system. A combination of red pulp (75%) and white pulp (25%) constitute the splenic parenchyma,[1] which is surrounded by a capsule. The red pulp is composed of the splenic cords and vascular sinuses, containing a large number of erythrocytes, while the white pulp is composed largely of lymphocytes and macrophages. The lymphoid cell organization within the white pulp is similar to that of the cortex of a lymph node.[2] The unique anatomy of the spleen is closely linked to its function and results in normal variants seen on computed tomography (CT) and magnetic resonance imaging (MRI), while the functional aspects can be evaluated scintigraphically. The primary function of the embryonic spleen is erythropoiesis, which decreases beyond the second trimester. The spleen is later responsible for filtering red blood cells that are aged or lack contractility, as well as antigen-coated cells, bacteria, and foreign particles. The spleen also acts as a platelet reservoir, releasing platelets in response to epinephrine release or consuming platelets in case of splenomegaly.[1]

## IMAGING

The spleen is seen in the left upper quadrant on abdominal radiographs (Fig. 94.2A) and may displace the left colon and/or stomach when enlarged.

The spleen has a homogeneous sonographic texture, slightly more echogenic than kidney, and iso- to slightly hyperechoic to the liver. The splenic hilar vessels are usually well seen (Fig. 94.2B), but intrasplenic branches typically require Doppler for identification.

On CT, the normal spleen has a higher attenuation than the liver, approximately 45 Hounsfield units (HU). A diffuse increase in splenic density can be observed in patients with hemosiderosis, sickle-cell disease, and lymphoma.[3] Transient heterogeneous splenic enhancement patterns are commonly encountered during rapid bolus contrast administration (Fig. 94.3). This normal phenomenon is thought to be secondary to variations in blood flow through the red and white pulp of the spleen; it is more pronounced with contrast injection rates of 1 mL/sec or greater and in children older than 1 year. Common patterns observed include archiform bands of alternating density, focal areas of low density, and diffuse mottled inhomogeneity.[4] More uniform enhancement is seen approximately 70 seconds after initiation of the contrast injection.

On MRI, the spleen signal intensity varies with age (Table 94.1 and Fig. 94.4). In the neonate, the spleen is T1 and T2 iso- to hypointense with respect to the liver. The T2 hypointensity is because of immaturity of the white pulp. After age 8 months, the spleen is T2 hyperintense relative to the liver due to white pulp maturation and maintains this appearance through adulthood.[5] The imaging sequences for the evaluation of the spleen can include T2-weighted, gradient-echo in and out of phase, pre- and post-contrast imaging, and the optional addition of T2* sequences to evaluate for the presence of hemosiderin.[6]

Scintigraphic splenic imaging with technetium-99m–labeled sulfur colloid, which is removed from the blood by the reticuloendothelial system, is useful for the identification of splenic ectopia, as well as several entities discussed later. It is not useful in cases of heterotaxy because splenic and hepatic tissue cannot be distinguished when neither location nor shape is an identifying criterion. Similarly, selective spleen scans can be misleading when the spleen is absent (e-Fig. 94.5).[7]

## ACCESSORY SPLEENS

***Overview.*** Accessory spleens are present in 20% to 35% of the normal population[8] and are usually found incidentally at autopsy or on imaging studies, most commonly located in the splenic hilum, in the gastrosplenic or splenorenal ligaments.[6] They can be found, however, virtually anywhere in the abdomen. They rarely exceed 2 cm in diameter and can be confused with splenic hilar or parapancreatic lymph nodes.

***Etiology.*** Accessory spleens are small splenic masses that fail to coalesce with the main mass of splenic tissue.

***Imaging.*** Accessory spleens can be identified on ultrasound (US), CT, or MRI; if questioned, definitive imaging study can be done with scintigraphy using technetium-99m sulfur colloid or denatured red blood cells.

***Treatment.*** Accessory spleens are considered a normal variant of development and, as such, require no treatment.

## SPLENOSIS

***Overview.*** These are acquired ectopic implants, which typically are seen in the peritoneum, but rarely can occur outside, such as in the pleural spaces.[6]

***Etiology.*** They are a result of seeding and implantation of splenic cells following trauma or splenectomy. The implants are usually multiple and of varying size.[6]

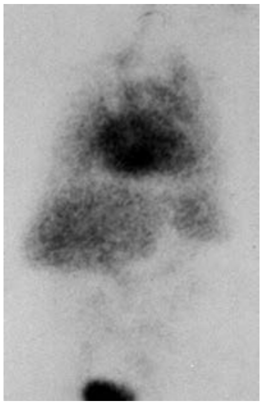
***Imaging.*** The ectopic splenic tissue demonstrates the same imaging characteristics as a normal spleen. It is important to differentiate these from adenopathy. Scintigraphy with Tc-99m sulfur colloid or denatured red cells is the most specific study for this purpose.[9]

***Treatment.*** No treatment is necessary.

## WANDERING SPLEEN

***Overview.*** This congenital anomaly results from maldevelopment of the splenic suspensory ligaments. Acquired cases may be a consequence of splenomegaly, traumatic injury, or ligamentous laxity.

***Etiology.*** Normally, during embryonic life, the residuum of the dorsal mesogastrium fuses with the posterior peritoneum, helping to support the spleen in its normal position. When this



**e-Figure 94.5. Asplenia.** Damaged red blood cell (RBC) scan in an infant with asplenia shows midline liver, with extension into the left upper quadrant, which could be erroneously construed to represent the spleen.

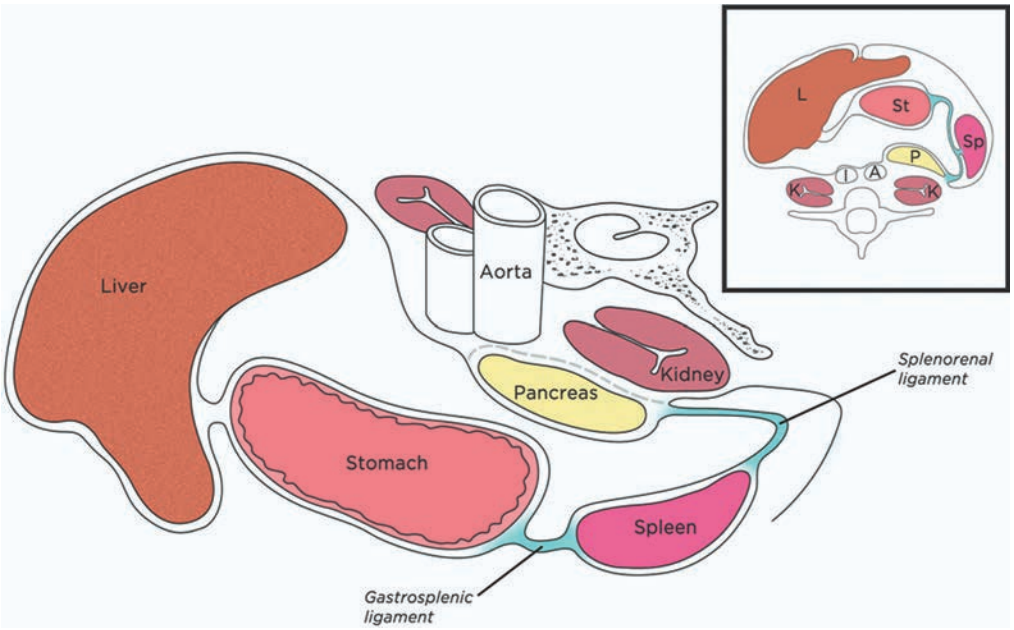


**Figure 94.1. Splenic attachments.** Oblique axial two-dimensional rendering of the fetal abdomen reveals the position of the gastrosplenic and splenorenal ligaments, which arise from the dorsal mesogastrium.

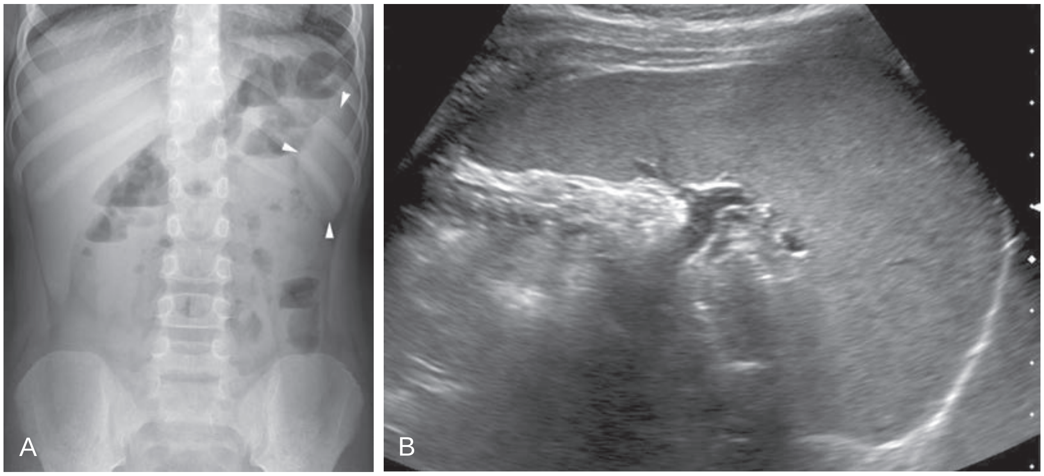

**Figure 94.2. Normal spleen.** (A) Frontal upright abdominal radiograph of a 6-year-old boy shows the normal spleen as circumscribed soft tissue fullness *(arrowheads)* in the left upper quadrant. (B) Transverse sonogram in a 15-year-old girl shows normal homogeneous parenchymal echotexture and hilar vessels.

**TABLE 94.1** MR Signal Intensity of Spleen Relative to Liver—By Age

| AGE | T1 | T2 |
|---|---|---|
| Neonate | Iso/Hypointense | Iso/Hypointense |
| Infant | Hypointense | Minimally hyperintense |
| >8 months | Hypointense | Hyperintense |

fusion does not take place, the dorsal mesogastrium may persist as a long mesentery, allowing the spleen to migrate, yielding the so-called *wandering spleen*. The most common location is the left lower quadrant.

***Clinical Presentation.*** The clinical presentation is variable; patients may be asymptomatic or present with a mobile mass on physical exam. More typically, the presentation is an acute abdomen, due to torsion of the vascular pedicle, with subsequent ischemia, impaired venous return, acute enlargement, and painful capsular tension.[10] Torsion is described in 64% of children[11] and may be a cause of recurrent abdominal pain due to intermittent torsion and detorsion.[12]

***Imaging.*** The abnormal position and orientation of the spleen can be identified by US, CT, MR, or radionuclide imaging, but this can be overlooked if close attention is not focused on these findings. If an ectopic spleen is found on ultrasound, scanning with the child in various positions can demonstrate splenic mobility.[13] When the spleen undergoes torsion, a "whorled" appearance of the splenic artery in the splenic pedicle has been described as a characteristic CT sign of torsion[14] (Fig. 94.6A). When ischemic secondary to torsion, the spleen has little or no uptake on radionuclide scintigraphy[15] and no contrast enhancement on CT (Fig. 94.6B). Color Doppler sonography similarly shows lack of flow in the splenic hilar vessels (Fig. 94.6C) and may also demonstrate the whorled appearance at the splenic hilum.

***Treatment.*** Treatment is operative, consisting of splenopexy if the spleen is viable or splenectomy if it is nonviable.[16] Because of the defective ligamentous support, gastric volvulus has been associated with wandering spleen[11] (Fig. 94.6D).

## SPLENOGONADAL SYNDROME

***Overview.*** The splenogonadal syndrome is a rare anomaly in which a portion of the spleen is conjoined with left gonadal tissue. Although this is an uncommon congenital anomaly, its identification is important because 30% to 50% of cases result in unnecessary orchiectomy for concern of extratesticular neoplasm.[17,18]

***Etiology.*** Splenogonadal fusion results when a portion of the splenic anlage fuses with primitive left gonadal tissue between the fifth and eighth weeks of gestation. Despite the fused splenic tissue, a normal spleen is present in the left upper quadrant. The splenogonadal fusion shows a splenic cord continuous with the ectopic, fused splenic tissue in approximately 55% of cases; it is discontinuous in approximately 45% of cases.[17] Splenogonadal fusion has been reported in association with transverse testicular ectopia.[19]

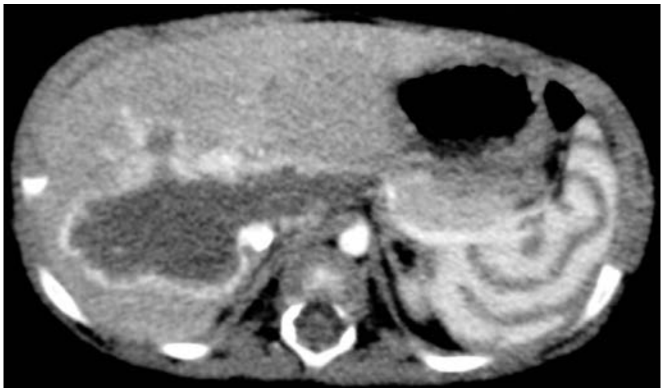

**Figure 94.3. Contrast bolus artifact on early arterial phase CT.** An arcuate or "archiform" contrast enhancement pattern is seen in the spleen, with ringlike or zebra-stripe bands of alternating density. CT with rapid bolus technique was performed to evaluate the hepatic hemangioma.

***Clinical Presentation.*** Splenogonadal fusion is much more common in males, with a male-female ratio of 16:1. The condition may be asymptomatic and discovered incidentally or at autopsy. It may be associated with left cryptorchidism, inguinal hernia, or testicular torsion, particularly when continuous. Multiple other anomalies may be present, particularly in the continuous type. In females, there is fusion of splenic tissue with the left ovary or mesovarium; this connection does not result in ovarian ectopia.

***Imaging.*** Sonography can reliably demonstrate the extratesticular location of a palpable scrotal mass in these cases, although at times it may resemble an intratesticular lesion.[20] The mass is typically oval or round and of similar echotexture to the adjacent normal testis but often is a slightly different size or configuration (e-Fig. 94.7A). Using a high frequency linear transducer, the ectopic splenic tissue has a nodular pattern caused by the lymphoid system and follicles of the white pulp in children between the age of 1 year to 5 years.[21] Color Doppler sonography shows abundant vascularity in the splenic tissue (e-Fig. 94.7B). Radionuclide imaging with technetium-99m sulfur colloid adds specificity to the diagnosis by revealing radiopharmaceutical uptake in the ectopic splenic tissue either in the left hemiscrotum or in the left inguinal canal when associated with cryptorchidism. A linear pattern extending from the left upper quadrant of the abdomen to the pelvis or scrotum may be detected in the continuous type (e-Fig. 94.7C).

MR or contrast-enhanced CT may reveal a rounded, enhancing, well-circumscribed soft tissue mass in the left hemiscrotum or left hemipelvis that may or may not continue cephalad toward the spleen.[22]

***Treatment.*** When the diagnosis is confirmed by means of imaging and the child is asymptomatic, no treatment is necessary. However, if surgical exploration is performed, the splenic tissue can be dissected safely off the tunica albuginea and the testis can be preserved.[17]

## SPLENORENAL FUSION

***Overview.*** Splenorenal fusion is a rare but well-recognized developmental anomaly in which there is congenital fusion of splenic and renal tissue. Fusion usually involves the left kidney and rarely the right.[23] Unlike posttraumatic splenosis, patients with congenital splenorenal fusion demonstrate an intact spleen with a separate blood supply. The importance of recognizing this anomaly is to prevent unnecessary nephrectomy for presumed malignancy.

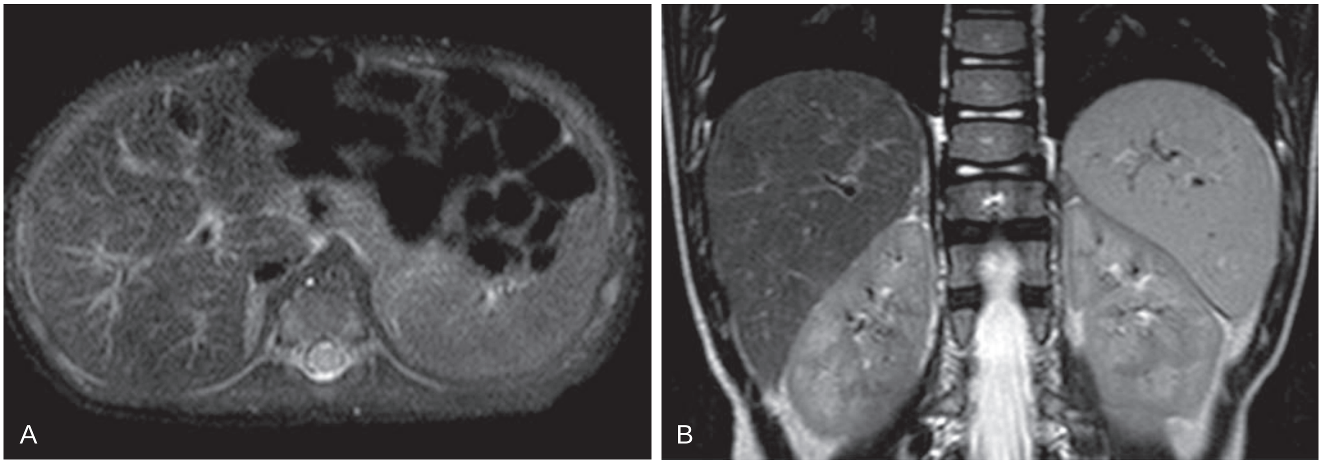

**Figure 94.4. Change in spleen T2 MR signal with age.** (A) Axial T2-weighted fat-suppressed MR image of the upper abdomen in a 2-month-old child shows that the spleen is nearly isointense to the liver. (B) Coronal T2-weighted fat-suppressed MR image of the upper abdomen in a 4-year-old child shows hyperintensity of the spleen compared with the liver.

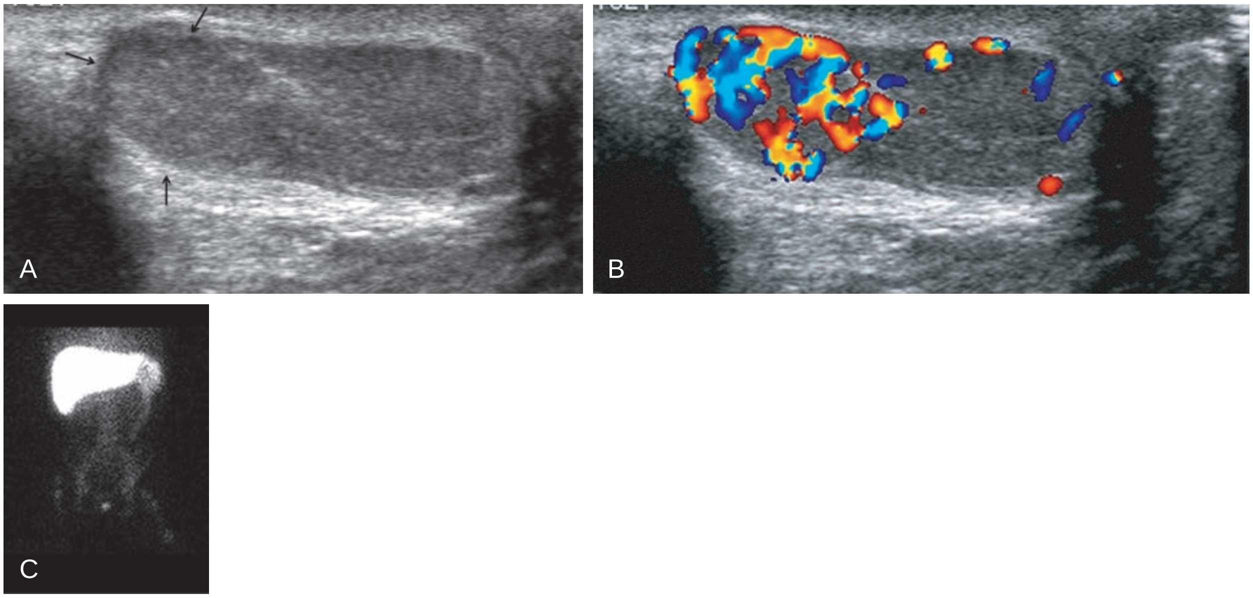

**e-Figure 94.7.** Splenogonadal fusion in a boy with a painless left scrotal mass. (A) Longitudinal sonogram of the left hemiscrotum reveals round-shaped splenic tissue cephalad to the testicle *(arrows)*, similar in echotexture and fused to the more oval-shaped testis below. (B) Color Doppler image shows increased vascularity of the splenic tissue compared with that of the testicle. (C) Technetium-99m sulfur colloid liver-spleen scan shows radiopharmaceutical uptake in the spleen in the left upper quadrant as well as in the left hemiscrotum; note continuous radiopharmaceutical uptake within the persistent cord of tissue connecting the spleen with the left testis. *(Courtesy of A. Schlesinger, MD, Houston, TX.)*

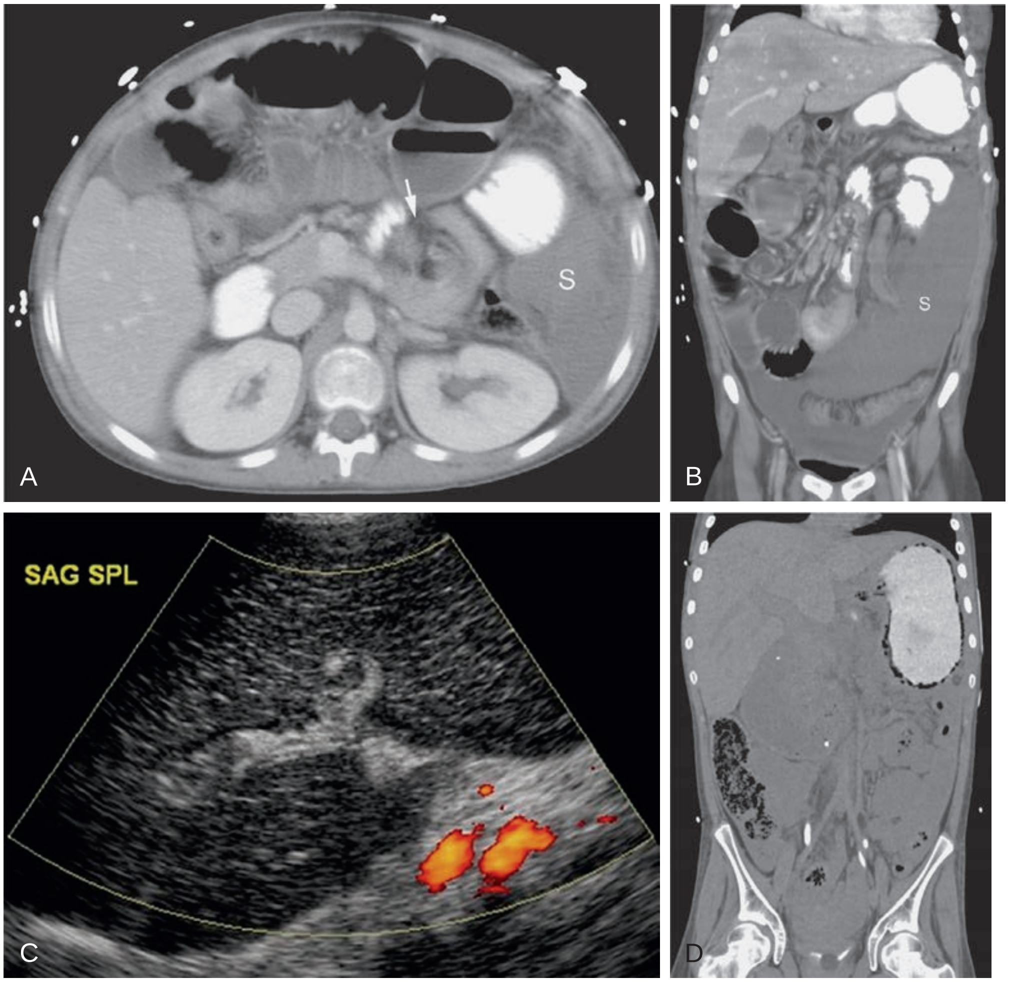

**Figure 94.6. Wandering spleen.** A 14-year-old girl with Niemann-Pick disease and acute abdominal pain. (A) Contrast-enhanced CT image of the abdomen show a “whorled” appearance of the splenic vessels and pancreatic tail *(arrow)* at the expected location of the splenic hilum. The spleen *(S)* shows low attenuation without contrast enhancement secondary to absent perfusion. (B) Coronal reformat underscores the displacement and abnormal orientation of the spleen *(S)* and again shows lack of contrast enhancement. (C) Color Doppler US image shows no vascular flow in the splenic hilum. Also note the abnormal echotexture of the spleen. (D) One year after splenectomy, the child presented with hypotension and abdominal distension. Coronal reconstruction of abdominal CT performed with oral contrast reveals reversal of the usual relationship of the gastric fundus and gastric outlet, consistent with gastric volvulus. Note the gastric pneumatosis. *(Courtesy of Jeanne G. Hill, MD, MUSC.)*

***Etiology.*** One theory to explain the origin of this anomaly is that fusion of the mesogastrium and left posterior peritoneum brings the splenic anlage and the left mesonephric ridge in close proximity during the eighth week of gestation, allowing the two organs to fuse.[24] Alternatively, it is postulated that splenic cells could migrate caudally to reach the metanephros and retroperitoneum, where there is no barrier to crossing the midline; this theory would explain reported right-sided fusion anomalies.[24,25] Splenorenal fusion may also be acquired from posttraumatic or postsplenectomy splenosis, where splenic tissue implants on the kidney and regrowth occurs.[24]

***Clinical Presentation.*** The condition may present incidentally on imaging or may cause symptoms due to mass effect or hypersplenism, manifesting as anemia and thrombocytopenia.

***Imaging.*** Conventional imaging with US, CT, or MR typically will not reliably distinguish this entity from a renal or retroperitoneal malignancy. When suspected, the diagnosis can be reliably made with technetium-99m sulfur colloid imaging, or, in the case of hypersplenism, with technetium-99m labeled, heat-damaged red blood cell imaging.

***Treatment.*** When the diagnosis is confirmed by means of imaging and the child is asymptomatic, no treatment is necessary.

## ABNORMAL VISCEROATRIAL SITUS

***Overview.*** Abnormal visceroatrial situs is an intriguing spectrum of abnormalities in which there is derangement of the normal viscerovascular asymmetry, with ambiguity of many asymmetric structures which may partially resemble their right- or left-sided counterparts, and typically involve abnormalities of the spleen. This is a relatively rare condition, cited to occur in approximately 1:10,000 patients,[26] although it is fairly common in pediatric centers that care for children with congenital heart disease. The normal visceroatrial anatomy is known as situs solitus, which translates from the Latin as “usual position.” Situs inversus refers to mirror-image visceroatrial anatomy *in toto*. Patients with situs inversus are frequently asymptomatic, although there is a slightly higher incidence of congenital heart disease than in patients with situs solitus. Situs ambiguous, or visceroatrial heterotaxia, refers to deranged visceroatrial asymmetry, which is neither situs solitus nor situs inversus. Patients with this abnormality are divided into two major groups: those with a tendency toward right-sided symmetry and those with a tendency toward left-sided symmetry; therefore each patient, within broad categories, has a unique constellation of anatomic findings that must be evaluated and described within the individual context.[7,27]

***Etiology.*** Although the exact mechanism by which normal viscerovascular asymmetry is established is not yet clear, it is clear that this occurs very early in the embryo. One theory relates to cellular chirality such as derived from cytoskeleton as early as the blastomere stage in some animal embryos.[28] A theory supported by considerable evidence in mammalian embryos suggests involvement of ciliated structures related to the midline embryo node, a pitlike transient structure in the anterior tip of the primitive streak.[29] Rotating cilia in cells in nodal cells generate a right-to-left flow leading to asymmetric expression of signaling molecules,[30] leading to asymmetric structures.[31] The exact mechanism by which this cascade is generated remains unclear.[32,33]

In humans, there is significant genetic heterogeneity in the heterotaxy population, with autosomal dominant, recessive, and X-linked inheritance patterns in some family units, but only a minority of patients demonstrate mutations in likely genetic pathways. Genetic copy number variants and genes with cilia-related functions have been implicated.[26,28]

***Clinical Presentation.*** Congenital heart disease occurs in approximately 96% of patients with heterotaxy,[26] although this is likely an overestimate, as those children who are asymptomatic are underdiagnosed. However, for any given congenital heart disease, patients with heterotaxy have greater comorbidities, complications, and poorer outcomes.[26]

Patients with right-sided atrial isomerism typically lack the spleen, a condition known as asplenia, which is associated with immune deficiency and overwhelming sepsis, particularly due to *S. pneumoniae*.[34] The ambiguous atrium resembles the right atrium, and severe congenital cardiac lesions are typically present, usually with cyanosis and diminished pulmonary blood flow. Patients will thus present with cyanosis and/or pulmonary edema.[7,27] Despite modern palliative procedures, mortality remains high.[35,36] Intestinal malrotation is typically present.

Patients with left-sided atrial isomerism characteristically have multiple splenules or polysplenia. Congenital heart disease is often present, although some patients with polysplenia are asymptomatic, and the diagnosis of heterotaxy may be made incidentally. Approximately 14% of patients in a large series of left atrial isomerism had a normal heart and presented with extracardiac abnormalities. This condition is associated with biliary atresia in as many as 10% of patients.[37] As in patients with asplenia, intestinal malrotation is the rule.

***Imaging.*** In patients with situs ambiguous plain radiographs may denote abnormal situs, with discordance of heart, stomach, and liver position. Patients with right-sided atrial isomerism may demonstrate bilateral right lungs with bilateral minor fissure and eparterial bronchi. Patients with left-sided isomerism on the other hand may demonstrate bilateral left-sided hila with hyparterial bronchi. However, in pediatric patients, hilar anatomy is often not clear due to overlying thymus, and plain films are at times normal.[7,38]

Ultrasound, CT, and MRI are very helpful in determining the viscerovascular anatomy. In patients with left-sided atrial isomerism, splenules will be invariably identified dorsal to the stomach, along its greater curvature, whether the stomach lies predominantly in the right or left upper quadrants,[7] because splenic tissue develops in the dorsal mesogastrium.[39] The appearance of the splenules is variable and ranges from a conglomerate of multiple splenules to a sometimes septated, largely single splenic mass (Fig. 94.8 and e-Fig. 94.9A). Interruption of the intrahepatic inferior vena cava (IVC) is seen in at least 50% of patients, with either right- or left-sided azygous continuation (e-Fig. 94.9B).[7] When the IVC is present, it may lie to the right or left of the aorta. A preduodenal portal vein may be seen (see Chapter 102). In patients presenting with biliary atresia, it is important to evaluate the continuity of the IVC and the course of the portal vein, because these vascular derangements are important in patients later referred for liver transplantation.[40–42]

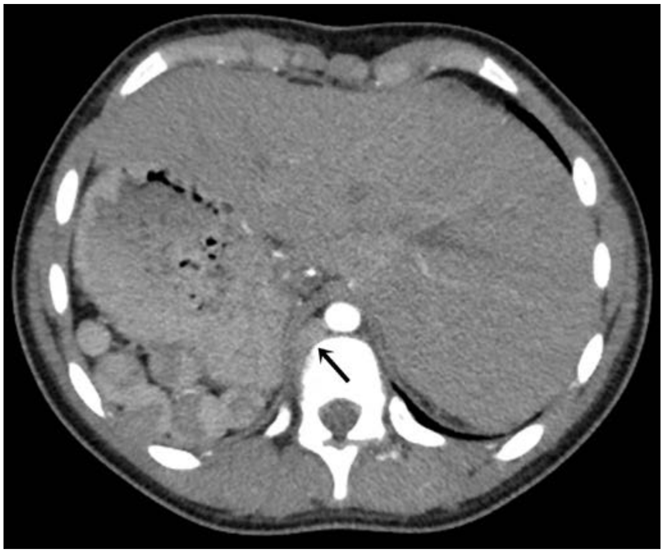

**Figure 94.8. Polysplenia.** Axial upper abdominal image from chest CTA on a 12-year-old girl with polysplenia and complex heart disease. There are multiple small splenules along the greater curvature of the right-sided stomach. An enlarged, not yet opacified retrocrural azygous vein *(arrow)* denotes azygous continuation of the suprarenal IVC.

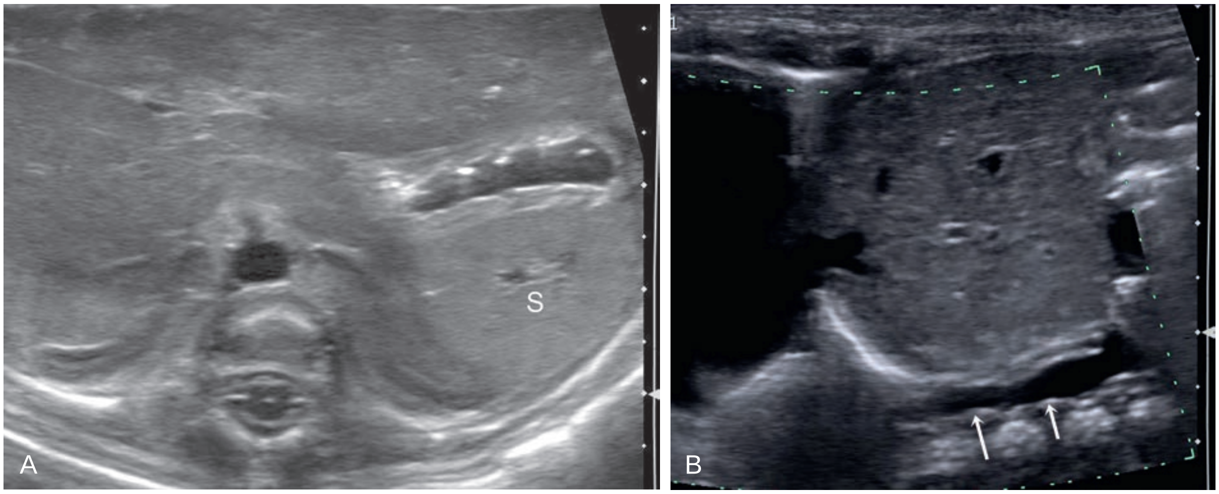
In patients with right-sided atrial isomerism, imaging confirms absence of the spleen (e-Fig. 94.10A) and may identify other anomalies such as horseshoe adrenals fused in the midline (e-Fig. 94.10B).[43,44] Subdiaphragmatic total anomalous venous connections are easily identified, as the anomalous vessel courses anterior to the esophagus into the abdomen (e-Fig. 94.10C and D).[7] The IVC is nearly invariably present and may lie to the right or left of the aorta, crossing the midline anterior to the aorta to enter the atrium, if necessary.[7,38] A preduodenal portal vein may be present. On UGI, microgastria may be seen; malrotation is the norm. Scintigraphy can be misleading as hepatic activity can erroneously suggest the presence of splenic tissue (e-Fig. 94.5).[7]

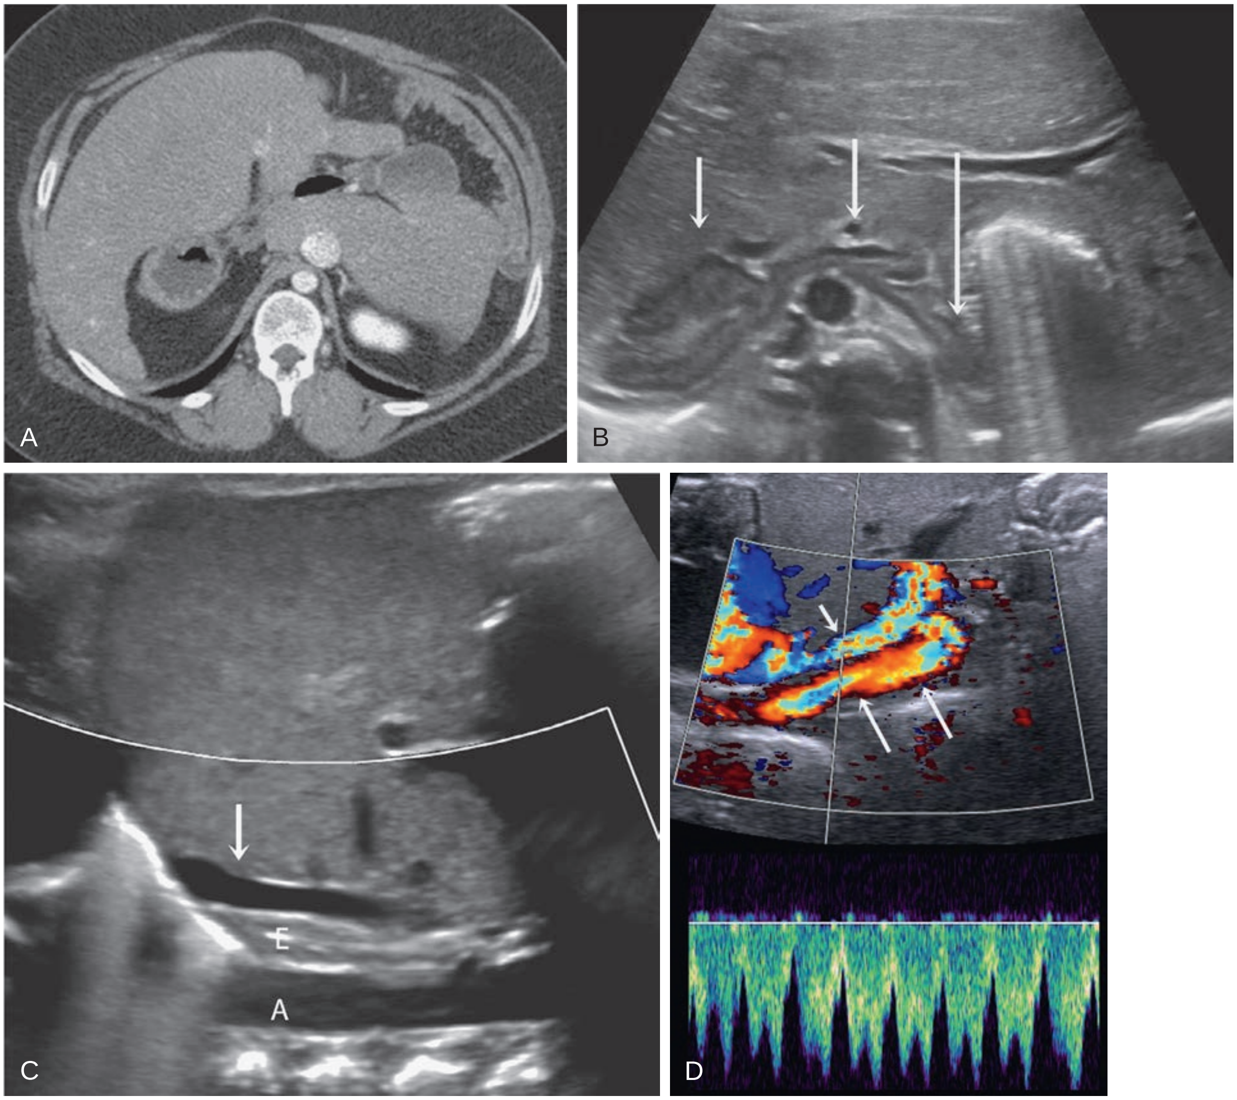
***Treatment.*** Treatment is individualized based on the associated anomalies. Patients with asplenia are at risk for sepsis and need to be treated for immunodeficiency. Those with congenital heart disease or gastrointestinal anomalies, such as biliary atresia, typically require surgical intervention. Although some have advocated prophylactic Ladd procedure for malrotation, more recently others have shown that, in these patients with significant comorbidities, complications resulting from a prophylactic Ladd procedure are greater than those resulting from observation alone.[45–49]

## SPLENOMEGALY

***Overview.*** Splenomegaly refers to enlargement of the spleen, usually as a result of excessive destruction of abnormal blood cells, excessive antigenic stimulation, storage or infiltrative disorders, or portal venous congestion. Hypersplenism refers to the syndrome of sequestration of blood cell lines, particularly platelets by the enlarged spleen.



**e-Figure 94.9. Polysplenia.** (A) Axial sonogram on 1-day-old infant with polysplenia and complex congenital heart disease shows splenic tissue in a conformation that seems to be a single spleen *(S)* in the left upper quadrant, posterior to the greater curvature of the stomach. Prominent central vessel is due to an unusually oriented hilum. (B) Sagittal image on same patient shown in (A) shows azygous continuation, with the enlarged, retrocrural azygous vein *(arrows)* coursing immediately anterior to the spine. There was no intrahepatic IVC.



**e-Figure 94.10. Asplenia.** (A) Axial contrast-enhanced CT on a 12-year-old girl with complex congenital heart disease and asplenia. A portion of the liver extends behind the right-sided stomach, but there is no spleen. The IVC is seen anterior to the crus and anterior to the aorta. She also had a preduodenal portal vein *(not shown)*. (B) Horseshoe adrenal gland in a 1-day-old with asplenia. The adrenal gland *(arrows)* crosses the midline in continuity, anterior to the aorta. As in the patient in (A), a portion of the liver extends behind the stomach, but there is no spleen. (C) Total anomalous venous connection to left portal vein in a 1-day-old with asplenia. The anomalous vein *(white arrow)* extends into the abdomen anterior to the esophagus *(E)* and the aorta *(A)*. (D) Doppler image in same child as shown in (C) but in a different plane shows the anomalous vein *(long white arrows)* draining into the portal vein, with the flow returning to the right atrium via the ductus venosus *(short white arrow)*.

## BOX 94.1 Causes of Splenomegaly in Children

**INFECTION**

Bacterial, viral (e.g., Epstein-Barr), fungal, protozoan

**CONGESTIVE STATES RELATED TO PORTAL HYPERTENSION**

Cirrhosis
Portal or splenic vein thrombosis
Right heart failure

**LYMPHOHEMATOGENOUS DISORDERS**

Hodgkin lymphoma
Non-Hodgkin lymphoma
Lymphoproliferative disease
Hemolytic anemias (e.g., acute splenic sequestration in sickle cell anemia)
Thalassemia
Extramedullary hematopoiesis

**STORAGE DISEASES**

Gaucher, Niemann-Pick, Mucopolysaccharidoses

**IMMUNOLOGIC–INFLAMMATORY**

Idiopathic thrombocytopenic Purpura
Systemic lupus erythematosus
Juvenile Idiopathic arthritis

**CYSTS**

Congenital
Acquired

**BENIGN NEOPLASMS/MASSES**

Hemangioma
Lymphangioma
Hamartoma

**MISCELLANEOUS**

Sarcoidosis
Langerhans cell histiocytosis
Collagen vascular diseases

***Etiology.*** The spleen may become enlarged in several inherited conditions (Box 94.1). The hemolytic anemias frequently lead to splenomegaly, with hereditary spherocytosis, hereditary elliptocytosis, and thalassemia among the most common causes. Sickle cell anemia initially leads to splenomegaly; the pathophysiology is sequestration of impaired red blood cells by the spleen, leading to splenomegaly, anemia, and thrombocytopenia. This is followed by splenic atrophy in older children, secondary to multiple infarcts.

Patients with portal hypertension from a number of causes may have congestive splenomegaly.

Splenomegaly has been reported in a group of neonates who have undergone extracorporeal membrane oxygenation (ECMO) cannulation; the mechanism proposed was sequestration of cells damaged in the ECMO circuit.[50]

Splenomegaly can also occur in a variety of acquired disorders, including infection and neoplasm.

***Clinical Presentation.*** Patients with splenomegaly present with the signs and symptoms of the underlying condition. Acute splenic sequestration crisis is manifested clinically by sudden enlargement of the spleen and a rapid fall in hematocrit. This condition typically occurs in young children, with 76% of episodes occurring before 2 years of age. The episode can manifest emergently, with hypovolemic shock potentially progressing to death within a few hours.[51] The condition is rare beyond age 8, due to developing splenic fibrosis. Once a child has a sequestration crisis, there is a higher risk of recurrence.

**TABLE 94.2** Spleen Length in Children and Adolescents*

| Group | No. | 10th Centile | Median | 90th Centile | Upper Limit |
|---|---|---|---|---|---|
| 0–3 mo | 28 | 3.3 | 4.5 | 5.8 | 6.0 |
| 3–6 mo | 13 | 4.9 | 5.3 | 6.4 | 6.5 |
| 6–12 mo | 17 | 5.2 | 6.2 | 6.8 | 7.0 |
| 1–2 yr | 12 | 5.4 | 6.9 | 7.5 | 8.0 |
| 2–4 yr | 24 | 6.4 | 7.4 | 8.6 | 9.0 |
| 4–6 yr | 39 | 6.9 | 7.8 | 8.8 | 9.5 |
| 6–8 yr | 21 | 7.0 | 8.2 | 9.6 | 10.0 |
| 8–10 yr | 16 | 7.9 | 9.2 | 10.5 | 11.0 |
| 10–12 yr | 17 | 8.6 | 9.9 | 10.9 | 11.5 |
| 12–15 yr | 26 | 8.7 | 10.1 | 11.4 | 12.0 |
| 15–20 yr (male) | 5 | 9.0 | 10.0 | 11.7 | 12.0 |
| 15–20 yr (female) | 12 | 10.1 | 11.2 | 12.6 | 13.0 |

*All measurements are in centimeters. Upper limits are the next highest whole integer over the 90th percentile.

**TABLE 94.3** Length of Spleen in Children Versus Body Height and Age*

| Body Height (cm) | No. | Age Range (mo) | Mean ± SD | Range | Normal Limits |
|---|---|---|---|---|---|
| 48–64 | 52 | 1–3 | 53 ± 7.8 | 33–71 | 30–70 |
| 54–73 | 39 | 4–6 | 59 ± 6.3 | 45–71 | 40–75 |
| 65–78 | 18 | 7–8 | 63 ± 7.6 | 50–77 | 45–80 |
| 71–92 | 18 | 12–30 | 70 ± 9.6 | 54–86 | 54–85 |
| 85–109 | 27 | 36–59 | 75 ± 8.4 | 60–91 | 55–95 |
| 100–130 | 30 | 60–83 | 84 ± 9.0 | 61–100 | 60–105 |
| 110–131 | 36 | 84–107 | 85 ± 10.5 | 65–102 | 65–105 |
| 125–149 | 29 | 108–131 | 86 ± 10.7 | 64–114 | 65–110 |
| 137–153 | 17 | 132–155 | 97 ± 9.7 | 72–100 | 75–115 |
| 143–168 | 21 | 156–179 | 101 ± 11.7 | 84–120 | 80–120 |
| 152–175 | 12 | 180–200 | 101 ± 10.3 | 88–120 | 85–120 |

*All measurements are in centimeters.
*From Rosenberg HK, Markowitz RI, Kolberg H, et al: Normal splenic size in infants and children. sonographic measurements.* AJR Am J Roentgenol *1991;157:119–121.*

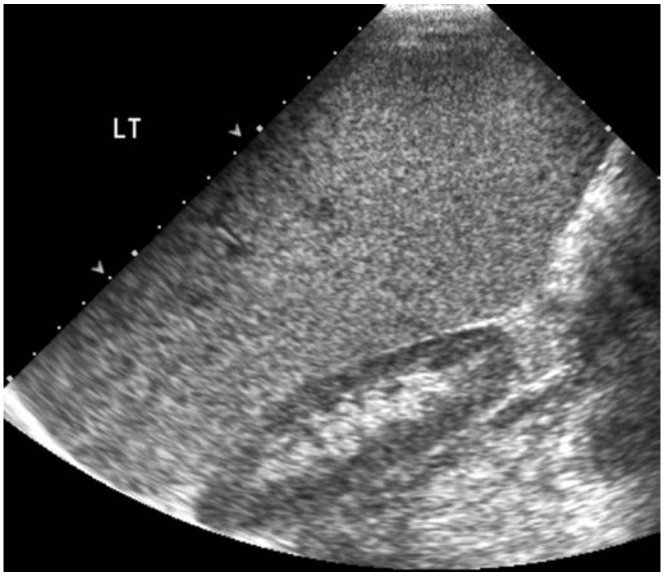
***Imaging.*** Plain radiographs of the abdomen may reveal an enlarged spleen in the left upper quadrant, displacing the stomach medially and the colon inferiorly.

Ultrasound readily detects splenomegaly, using the coronal imaging plane with the splenic hilum in view. Splenic length has been correlated with patient age[52] (Table 94.2) and with body height/length[53–56] (Table 94.3). When correlated against body mass index, the strongest correlate was with body weight according to the formula:

$$69.875 + \text{body weight [kg]} \times 0.371.$$ [57]

Reference ranges based on gestational age exist.[58] As a general rule, the tip of the spleen should not extend below the inferior pole of the left kidney (e-Fig. 94.11), and the spleen should not exceed 1.25 times renal length.[56]

CT and MRI also readily reveal an enlarged spleen and may allow for more standardized and reproducible measurement. Spleen volume can be readily measured with CT or MRI. Normal pediatric spleen volume, as measured on CT, correlates with body weight in a linear relationship.[59,60]



**e-Figure 94.11. Splenomegaly.** Splenomegaly in a 14-year-old boy with anemia. Coronal ultrasound image shows that the spleen extends below (caudad to) the lower pole of the left kidney.

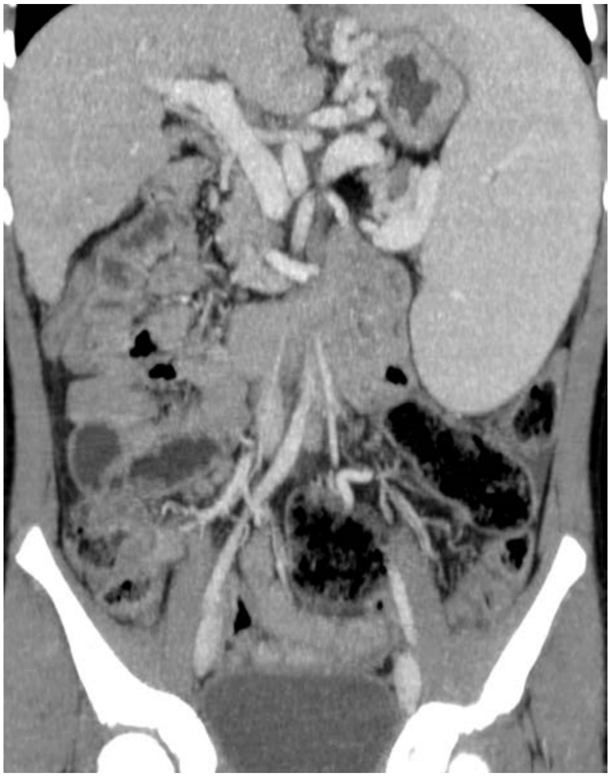


**Figure 94.12. Splenomegaly.** Splenomegaly secondary to portal hypertension in an 11-year-old girl with liver disease. Coronal reconstruction of contrast-enhanced CT of the abdomen shows splenic extension to the left mid abdomen. Multiple variceal collaterals are clearly depicted.

The imaging findings in splenomegaly are nonspecific as to cause, unless there is evidence of extramedullary hematopoiesis or infarcts, or ancillary findings are identified, such as varices in patients with congestive splenomegaly (Fig. 94.12). Extramedullary hematopoiesis may demonstrate focal areas of increased echogenicity on sonography, whereas infarcts may appear as hypoechoic areas. The storage diseases generally cause nonspecific splenomegaly,[61] but Gaucher disease may lead to focal hyper/hypoechoic or mixed echogenic foci, reflecting collections of Gaucher cells, or extramedullary hematopoiesis.[62] The focal collections may occasionally be hyperechoic secondary to fibrosis. They are isointense on T1-weighted MR imaging and hyperintense on T2-weighted imaging,[62,63] with low signal intensity on gradient recalled echo imaging due to the iron contained in Gaucher cells.[64]

In patients with sickle cell anemia experiencing acute sequestration crisis, the spleen appears larger than expected, and hypoechoic splenic lesions can be seen peripherally on US (Fig. 94.13) due to hemorrhage or infarction. Low attenuation peripheral lesions are demonstrated on contrast-enhanced CT[65] with patency of the splenic artery and vein.[66]

***Treatment.*** Treatment of splenomegaly is directed at the underlying cause. Splenectomy is used sparingly in children. Treatment of children with sickle cell disease is complex and includes supportive care, infection prophylaxis, and transfusion therapy in selected cases.[67]

The long-term management of sequestration syndrome consists of increased awareness of symptoms (primarily worsening anemia), signs (enlarging spleen), and, in some cases, short-term chronic transfusion.[51] In most sickle cell patients, splenic function is diminished because of splenic infarcts, and autosplenectomy is nearly 94% by age 5 to 6 years.[65] Although transfusion has been shown to reverse functional hyposplenism and preserve splenic function,[68–70] hyposplenism is not considered an indication for hypertransfusion.[67] Hematopoietic stem cell transplantation not only prevents further damage to the spleen but has demonstrated recovery of splenic function in children with sickle cell disease.[71]

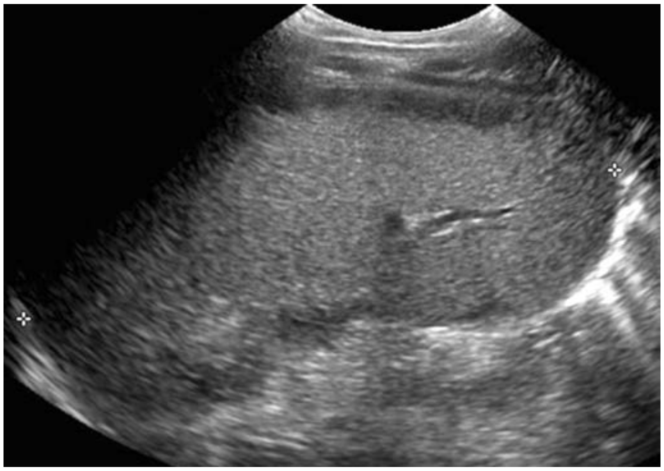

**Figure 94.13. Splenic sequestration crisis.** Longitudinal sonogram of the spleen of a young child with acute splenic sequestration crisis demonstrates numerous peripheral hypoechoic lesions. *(Courtesy of Sarah Fitch, MD, Richmond, VA.)*

## SPLENIC INFARCTION

***Overview.*** Splenic infarction is caused by a lack of perfusion to regions of the spleen or to the entire organ. The causes are numerous including embolic, hematologic, vascular disease, torsion, trauma, malignancy, and pancreatic disease.[72] The most common cause is partial or total occlusion of the splenic artery or its branches. Microinfarctions can be seen in patients with sickle cell anemia, lymphoma, or leukemia.[3]

***Clinical Presentation.*** Most patients will present with left upper quadrant pain, with or without fever and chills. Referred pain to the left shoulder is also a reported feature.[3,5]

***Imaging.*** At US, an acute, focal splenic infarct will typically appear as wedge-shaped, hypoechoic (Fig. 94.14A) and well demarcated lesion pointing toward the splenic hilum, with absent flow on Doppler interrogation.[5] On contrast-enhanced CT, typical splenic infarcts present as wedge-shaped, hypodense areas with the base facing the splenic capsule. Enhancement of the affected region may be observed in delayed phase images. When the entire spleen is infarcted, it results in diffuse splenic hypodensity with a rim of enhancing capsule. This is the so-called "rim sign" that results from persistent arterial supply to small capsular vessels. Splenic infarction as seen in sickle cell can also result in a small, calcified spleen (Fig. 94.14B). Complications include splenic rupture, hemorrhage, or abscess formation.[3]

Gamna-Gandy bodies are small hemorrhages in the spleen caused by hemolytic anemias (sickle cell disease, spherocytosis), portal hypertension, hemochromatosis, lymphoma, leukemia, portal hypertension, or splenic/portal venous thrombosis. They contain hemosiderin and a variable amount of fibrous tissue and calcium.[73] They are best imaged using MR and appear as multiple small foci of low signal intensity on all pulse sequences, due to iron deposition. On gradient-echo sequences or susceptibility weighted imaging, a blooming artifact is seen due to the paramagnetic effect of hemosiderin.[74,75]

***Treatment.*** Treatment consists of management of complications and infection prophylaxis as appropriate.

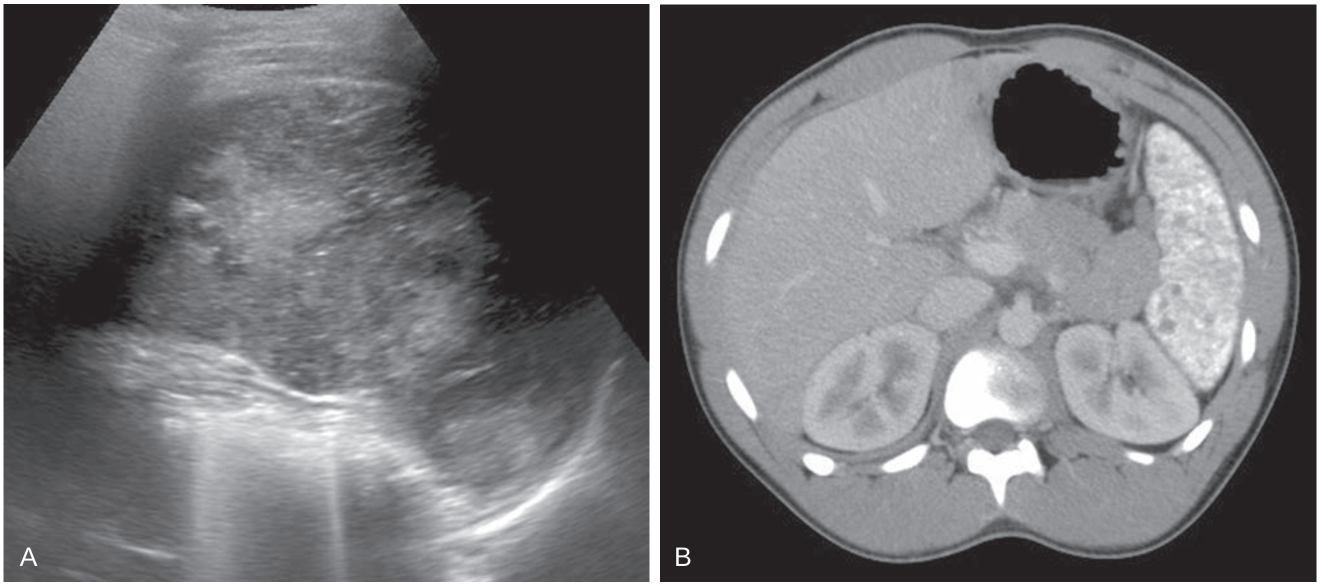

**Figure 94.14. Sickle cell disease complications.** (A) Transverse sonogram of the spleen in a15-year-old boy with sickle cell disease presenting with severe periumbilical pain reveals multiple hypoechoic areas, some peripheral and wedge-shaped, consistent with acute splenic infarcts. (B) Axial contrast-enhanced CT in an 18-year-old boy with sickle cell disease reveals a calcified spleen secondary to chronic infarction.

## INFECTIOUS DISEASES

***Overview.*** Involvement of the spleen in systemic infectious disease is most common in immunocompromised patients, with increasing incidence due to the increasing use of steroids and chemotherapeutic agents.[64] Bacterial, fungal, and granulomatous agents are frequently involved. Splenic involvement can also occur in immune-competent hosts with cat scratch fever, granulomatous diseases such as histoplasmosis, and viral infections. Viral infections, including infectious mononucleosis, are more likely to cause nonspecific splenomegaly due to reactive hyperplasia of the spleen's reticuloendothelial tissue. Splenic abscesses are uncommon lesions and are rare in the pediatric population.[76] Hydatid cysts may rarely involve the spleen.[77]

***Etiology.*** Bacterial splenic abscesses can develop via hematogenous spread, such as from bacterial endocarditis; spread from a contiguous infection, such as pancreatitis or perinephric abscess; and seeding in a spleen compromised by infarction or trauma. In cat scratch fever, the agent, *Bartonella henselae*, is transmitted from asymptomatic cats through biting and clawing. Hydatid disease is caused by echinococcal infection and may involve the spleen in up to 8% of cases (following liver and lung in frequency), typically arising through systemic dissemination or via intraperitoneal spread secondary to intraperitoneal rupture of hepatic disease.[78]

***Clinical Presentation.*** Symptoms of splenic involvement in an infectious process can be nonspecific and may be related to the systemic illness or to the secondary development of splenomegaly. Patients may present with fever, lethargy, and weight loss. Abdominal distension, tenderness, and leukocytosis are commonly found.[76] Cat scratch disease is a relatively common infection in children that typically presents with fever and tender lymphadenopathy.

***Imaging.*** Imaging has an important role in diagnosis, as signs and symptoms can be nonspecific. Early diagnosis and prompt treatment are critical to decrease mortality and morbidity. Splenic abscesses can be solitary, multiple, or multilocular, depending on the source of infection.

Large pyogenic abscesses appear as complex fluid collections with surrounding hyperemia on Doppler interrogation. On contrast-enhanced CT, pyogenic abscesses demonstrate rim-enhancement.[3]

Microabscesses are most commonly seen with fungal infection such as candidiasis. On US, these lesions exhibit a "bull's-eye" appearance due to a central hyperechoic inflammatory core surrounded by hypoechoic fibrous tissue.[79] High resolution imaging, including high frequency and linear transducers, may be necessary for detection of microabscesses. They appear as low-attenuation lesions on contrast-enhanced CT or MRI. It is important to note that small fungal abscesses lack contrast enhancement and may be difficult to detect or may be easily overlooked on CT images.[3] However, CT is generally superior to abdominal sonography in the detection of hepatosplenic fungal lesions.[80] *Candida* species are a frequent causative pathogen of microabscesses, although larger, solitary abscesses may also occur with candidiasis. They may be seen as hypoechoic areas on US, as low-attenuation areas on CT, and as T2-hyperintense lesions without peripheral enhancement.[81] In late stages, calcification may be seen on CT.[79]

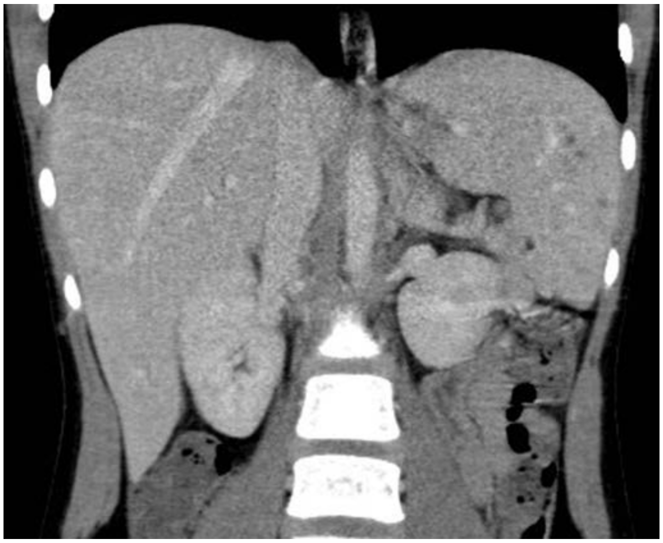
MRI can be utilized for the evaluation of microabscesses, which appear as high signal intensity foci on water-sensitive, fat-suppressed sequences.[81]

In cat scratch disease, US may show hypoechoic lesions ranging from well-defined and homogeneous to indistinct and heterogeneous, while contrast-enhanced CT may show hypoattenuating lesions, isoattenuating lesions, or lesions with marginal enhancement (e-Fig. 94.15). On MRI, lesions demonstrate low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted sequences.[3,82]

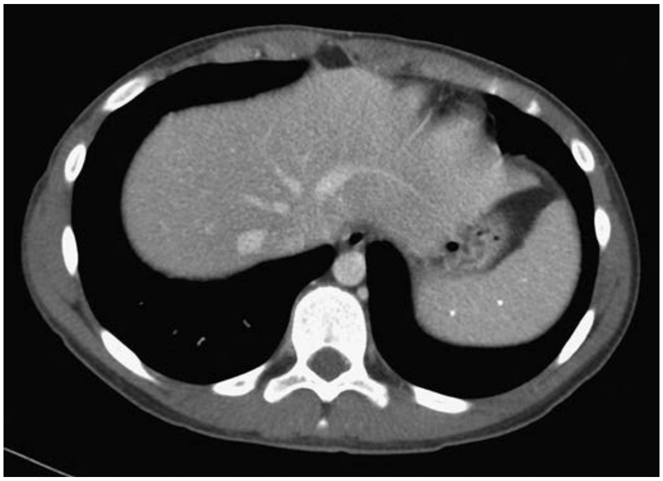
Hydatid cysts may demonstrate calcifications, which can be visible on plain films. The cysts are generally anechoic, although the presence of daughter cysts and membranes may produce septations and internal echoes. CT shows a focal lesion of lower attenuation than the surrounding splenic tissue, and it is the best modality to show rim calcification, when present.[78,83]

Tuberculosis, histoplasmosis, and coccidioidomycosis may produce multiple splenic granulomas, almost always associated with diffuse organ involvement secondary to hematogenous spread (e-Fig. 94.16). Splenic granulomas may be also be detected in patients with chronic granulomatous disease of childhood.

***Treatment.*** Treatment is geared to the underlying diagnosis. Cat scratch disease is usually self-limited and typically does not



**e-Figure 94.15. Cat scratch disease.** Coronal reformatted contrast-enhanced CT image in a 10-year-old girl reveals a normal sized spleen with small round, hypodense lesions of slightly varying size.



**e-Figure 94.16. Histoplasmosis.** Splenic granulomas in a 13-year-old girl with histoplasmosis. Two small foci of calcification representing calcified granulomas are seen within the spleen.

require antibiotic therapy. Hydatid cysts are first medically treated with antihelminthic drugs.[84] Splenectomy, with partial resection whenever possible, is considered a mainstay of treatment; a meticulous surgical approach is important in the treatment of splenic hydatidosis because of the risk of recurrence, spillage, and anaphylaxis.[77,85]

## BENIGN CYSTS AND NEOPLASMS

***Overview.*** Cysts are the most common benign lesions of the spleen. Splenic cysts can be primary or true cysts, which are defined by the presence of an epithelial lining and can be congenital. In most classification systems, secondary cysts or pseudocysts are typically related to antecedent trauma, infection, or infarction.[86,87] A more recent classification proposes that most nonparasitic splenic cysts are congenital in origin and have lost their epithelial lining over time.[88,89] Neoplasms of the spleen include benign lesions, such as hamartomas, and malignant lesions, which are most commonly part of a systemic ailment, such as splenic involvement with lymphoma, and rare primary splenic lesions, such as angiosarcoma.

### Epithelial Cysts

***Overview.*** Epithelial cysts are congenital representing approximately 10% of pediatric splenic lesions worldwide and are thus the most common nonparasitic cysts in the pediatric spleen.[90]

***Etiology.*** Epithelial cysts are believed to be derived from inclusions of the mesothelial lining of the spleen or from adjacent epithelial cells within the embryonic splenic anlage.[90] A few cases of familial occurrence have been reported, which lends support to the congenital origin of these lesions.[91]

***Clinical Presentation.*** Splenic cysts are frequently discovered incidentally on physical examination or imaging performed for other reasons. However, sufficiently large cysts can present as splenomegaly, renal compression with hypertension or varicocele, or radiating lumbar or left shoulder pain. They can also present with cyst rupture and peritonitis, particularly after trauma, which could be relatively minor.[88,92]

***Imaging.*** Primary epithelial/epidermoid cysts are usually solitary but can be multiple, with occasional calcification.[93] Epidermoid/epithelial cysts are frequently large enough to visibly enlarge the spleen on plain radiographs as a left upper quadrant mass displacing the stomach and colon (Fig. 94.17A and B). A rim of calcification may be seen. On US, the cysts are characteristically anechoic and sharply demarcated from the surrounding normal splenic tissue. However, hemorrhage, inflammatory debris, or internal fat droplets may cause the cyst to contain internal echoes, at times resembling a hypoechoic solid mass; movement of the internal echoes may be detectable and can be documented on video clips. Doppler interrogation reveals no internal flow. Liver-spleen scintigraphy demonstrates a focal photopenic defect. CT may be best at identifying calcifications. On CT and MRI, an uncomplicated epidermoid cyst appears as a rounded, sharply demarcated, nonenhancing mass with cystic imaging characteristics (Fig. 94.17C). If it is complicated by hemorrhage, the internal signal intensity of the lesion on MRI reflects the chemical state of the hemoglobin. Posttraumatic cysts may be difficult or impossible to distinguish radiologically from other cysts, but may have irregular walls and internal echoes from debris.

***Treatment.*** Cyst size is not the major impetus for intervention, and splenic cysts should be managed according to the patient's symptoms.[94] Surgical options for symptomatic cysts include: total splenectomy, hemisplenectomy,[95] or total cystectomy.[92]

### Hemangiomas

***Overview.*** Splenic hemangiomas are vascular proliferations made up of channels filled with slow-flowing blood. Hemangiomas are classified as capillary or cavernous, depending on the size of these vascular channels. They are the most common primary neoplasm of the spleen.

***Etiology.*** Splenic hemangiomas are likely congenital in origin, arising from the sinusoidal epithelium. Histologically, they contain a proliferation of vascular channels lined with a single layer of epithelium. They may be single, multiple, or may occur as part of a generalized angiomatosis, such as in Klippel-Trenaunay-Weber, Beckwith-Wiedemann, and Turner syndromes.[96]

***Clinical Presentation.*** Most patients are asymptomatic; when symptoms occur, they may not be manifest until adulthood. Symptoms are typically left upper quadrant fullness and pain. Symptomatic masses are usually a consequence of complications of such as hypersplenism, anemia, thrombocytopenia, and coagulopathy (Kasabach-Merritt syndrome).[90]

***Imaging.*** On US, the solid lesions are typically well-marginated and hyperechoic but may be hypoechoic; they demonstrate internal vascular flow, and calcifications may be seen.[2] On noncontrast CT, hemangiomas are well-defined, hypoattenuating, or isoattenuating masses. Capillary hemangiomas homogeneously enhance with contrast (Fig. 94.18), while cavernous hemangiomas may demonstrate a centripetal or a mottled attenuation on delayed contrast enhancement, due to the presence of fibrosis and microinfarctions.[3] On MRI, splenic hemangiomas are hypo- to isointense on T1-weighted images and hyperintense on T2-weighted images. As on CT, cavernous hemangiomas show peripheral enhancement extending toward the center, while capillary hemangiomas have a more homogenous enhancement.[6] Technetium-99m-labeled red blood cell scans may be helpful in characterizing atypical lesions by demonstrating increased activity on delayed images.[97]

***Treatment.*** Small or asymptomatic lesions are observed; larger lesions may require resection and may necessitate splenectomy.[90]

### Hamartomas

***Overview.*** Hamartomas, also known as splenomas or nodular hyperplasia of the spleen, are rare, nonneoplastic malformations composed of an anomalous mixture of normal splenic red pulp and lymphoid white pulp.[2]

***Etiology.*** It is proposed that splenic hamartomas result from splenic injury and reparative response.[98] Histologically, splenic hamartomas are composed of splenic sinusoidal tissue with no lymphoid follicles (red pulp) and variable chronic inflammation with macrophages, lymphocytes, plasma cells, extramedullary hematopoietic cells, fibrosis, hemosiderosis, and calcification.[98]

***Clinical Presentation.*** Most patients are asymptomatic, and the lesion is found incidentally; if it is large, there is the potential for rupture and hemoperitoneum. In some instances, they can be associated with tuberous sclerosis, Wiskott-Aldrich syndrome, or other hematologic conditions.[3,98]

***Imaging.*** Because hamartomas are composed of normal splenic tissue, they may not be detected with US or CT unless they alter the contour of the spleen, producing a focal bulge. Those that are identified by US are most commonly well-circumscribed, solid, and homogeneous, but some may be partly cystic and heterogeneous. They are variably described as hyperechoic,[2,99] hypoechoic,[100–102] or of mixed echogenicity. The variety of described morphologic patterns is likely derived from the preponderant growth of one or another of several histologic components. Hamartomas typically reveal increased blood flow on Doppler interrogation.[2] On contrast-enhanced CT, they demonstrate prolonged contrast enhancement due to stagnant blood flow within the sinuses of the red pulp. This assists in differentiating hamartomas from malignant tumors. Calcification, central areas of necrosis, and fat can be seen on CT.[3] The fibrous hamartomas are iso- or hyperintense on T1-weighted and hypointense on T2-weighted MRI. The nonfibrous hamartomas, which are more common, are isointense on T1-weighted and hyperintense on T2-weighted MRI.[103] They both demonstrate

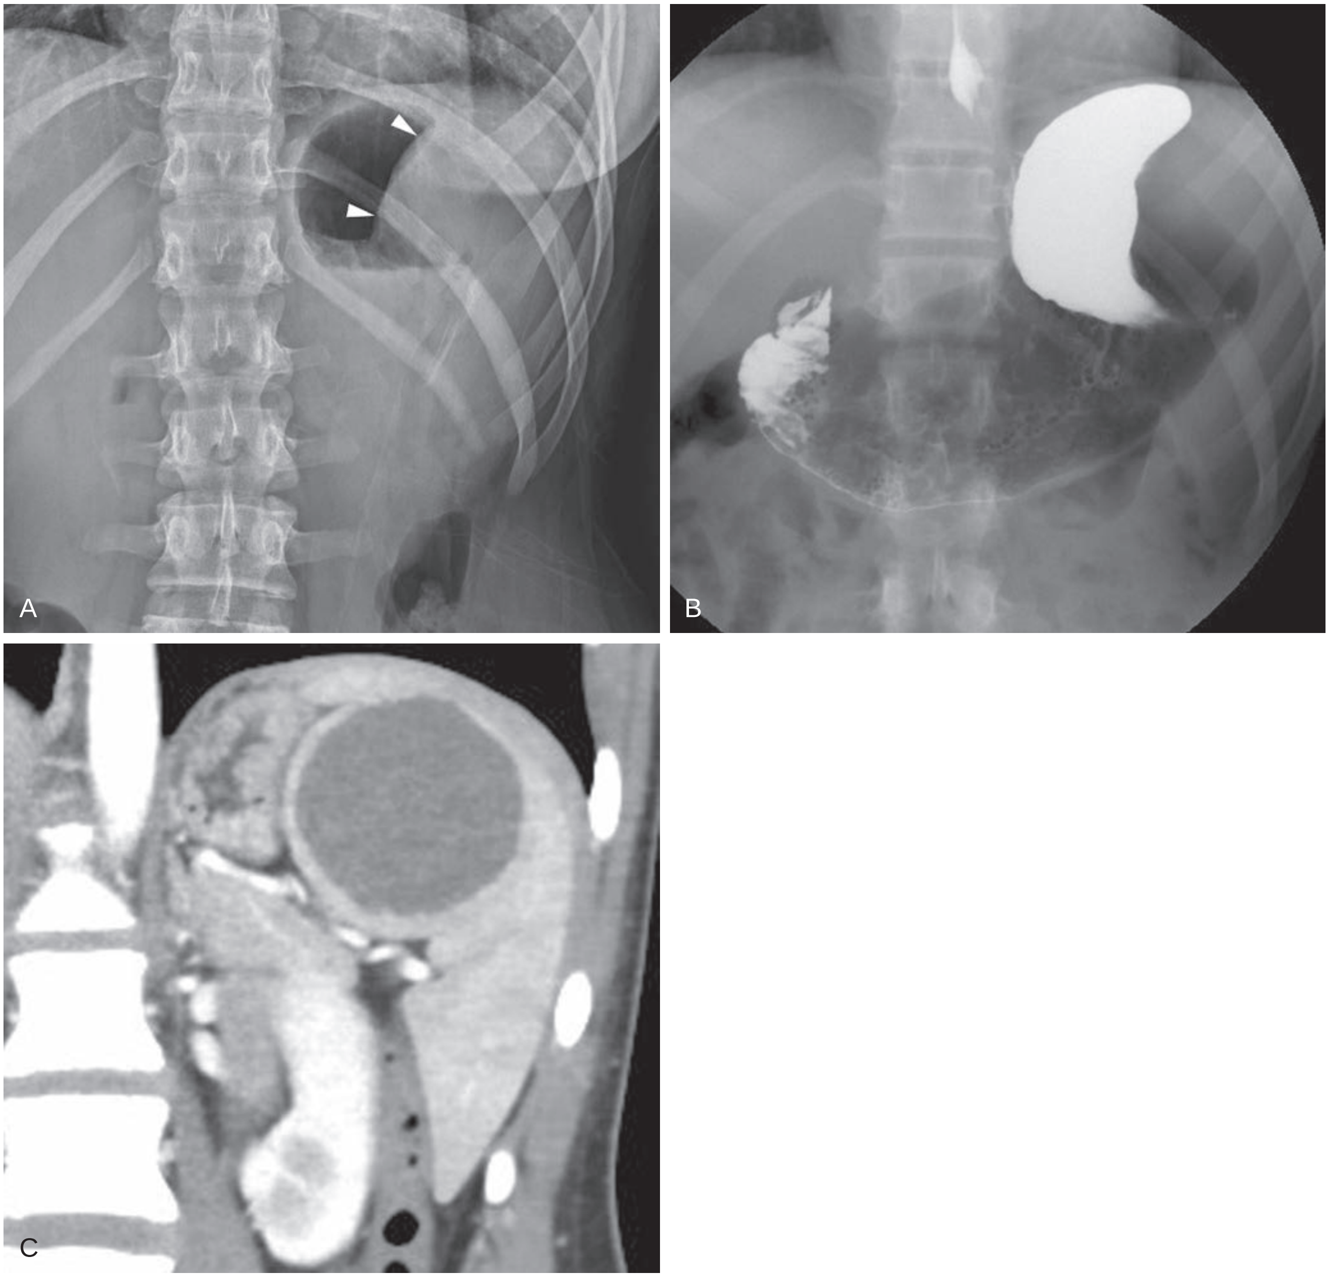


**Figure 94.17. Epithelial cyst.** (A) Frontal upright abdominal radiograph in a 14-year-old girl reveals a well-circumscribed curvilinear mass effect *(arrowheads)* on the lateral gastric air bubble. (B) Supine fluoroscopic image of the upper abdomen obtained during an upper GI examination confirms the mass effect on the fundus, arising from the spleen. (C) Coronal reformatted contrast-enhanced CT reveals a well-circumscribed, round, hypodense lesion in the upper portion of the spleen with mass effect on the decompressed stomach. The lesion measured 40 HU, consistent with a cyst.

diffuse heterogeneous contrast enhancement, with more uniform enhancement on delayed images.[64,96] On technetium-99m sulfur colloid scintigraphy, they may have radiopharmaceutical uptake greater than that in the surrounding normal spleen.[99]

***Treatment.*** If hypersplenism is associated, splenectomy can resolve the hematologic abnormalities.[98]

## Lymphatic Malformation

***Overview.*** Lymphatic malformations are rare, benign tumors, which may be single or multiple and may cause splenic enlargement. Splenic lymphangiomatosis is usually associated with lymphangiomas found elsewhere.

***Etiology.*** As in other sites, splenic lymphangioma is due to an abnormal congenital development of lymphatic channels.

***Clinical Presentation.*** Clinical manifestations range from an asymptomatic incidental finding to a large, symptomatic mass, which may cause symptoms from compression of adjacent structures.[2,104] The presence of splenic lymphangiomas should prompt a search for these lesions in other organs; multiorgan involvement describes lymphangiomatosis syndrome, where the liver, pericardium, mediastinum, lung, and bone may be involved.[2,104]

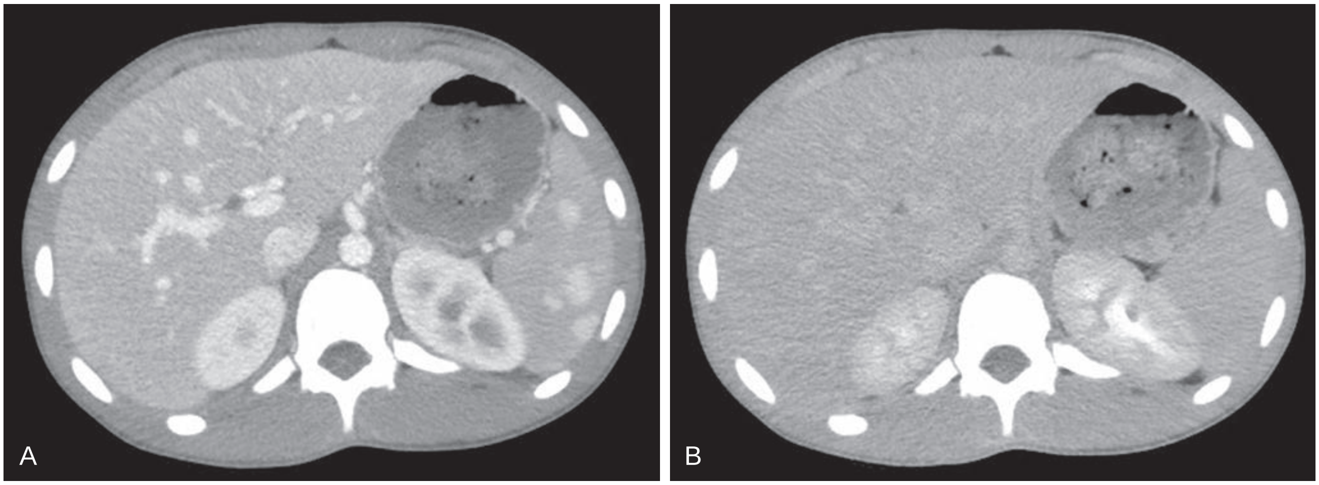

**Figure 94.18. Hemangioma.** (A) Axial contrast-enhanced CT in a 14-year-old boy shows multiple well-circumscribed oblong hyper-enhancing lesions. (B) Delayed image shows equilibration with the diffusely enhancing spleen.

***Imaging.*** On US, CT, and MRI, lymphatic malformations are most commonly sharply marginated, nonenhancing unilocular or multilocular cystic lesions, typically located close to the splenic capsule.[3] Though typically anechoic on US, they may contain internal floating echoes. On CT, they appear as single or multiple thin-walled, low-density, nonenhancing masses with sharp margins and occasional mural calcifications. The cysts generally have low signal intensity on T1-weighted and high signal intensity on T2-weighted MR images (e-Fig. 94.19); however, they may have high signal intensity on T1-weighted images secondary to internal hemorrhage or proteinaceous fluid.

***Treatment.*** Typically, with solitary small or asymptomatic lesions, no surgical intervention is required. Symptomatic lesions may be treated with partial or complete splenectomy, or sclerotherapy.[104]

## Peliosis

***Overview.*** Peliosis is an uncommon entity, consisting of blood-filled cavities, which lend the spleen a dark or purplish hue on gross examination. It is often seen in the setting of peliosis hepatis.

***Etiology.*** The etiology of the sinusoidal dilation leading to formation of multiple cystlike, blood-filled cavities within the splenic parenchyma is not certain.[105] It is associated with the use of anabolic steroids, blood dyscrasias such as aplastic anemia, infectious entities such as tuberculosis, and neoplasia.[90]

***Clinical Presentation.*** Many cases are asymptomatic and discovered incidentally; however, if it occurs along the periphery of the spleen, there is a potential for life-threatening rupture and hemoperitoneum.[106–108]

***Imaging.*** On US, splenic peliosis may reveal an echogenic mass with poorly defined foci of varying echogenicity.[2] The condition may also demonstrate multiple, well-defined, hypoechoic lesions of varying size, and occasionally fluid-fluid levels within the nodules. On CT, it appears as many small lesions of low attenuation without calcification.[109] Due to hemorrhage, peliosis can present as hyperdense lesions.[3] Centripetal enhancement, similar to hemangiomas, has been reported.[110] On MRI, fluid-fluid levels of varying intensity may be present due to blood in the cystic spaces.

***Treatment.*** Surgery is usually required for definitive diagnosis and treatment.[2]

## MALIGNANT NEOPLASMS

Malignant neoplasms of the spleen are usually related to multifocal neoplastic disorders, such as leukemia and lymphoma, and rarely metastases. Angiomatous tumors include littoral cell angioma, hemangiopericytoma, and angiosarcoma.

### Acute Leukemia

***Overview.*** Splenic involvement is often present in children with leukemia. Chronic myelogenous leukemia is rare in children but is frequently accompanied by massive splenomegaly.

***Etiology.*** Diffuse infiltration of the spleen by the leukemic cells leads to splenomegaly.

***Clinical Presentation.*** Splenomegaly is characteristic. Rarely, leukemic infiltration of the spleen can present with splenic infarction, characterized by severe abdominal pain.[111]

***Imaging.*** Imaging studies of the spleen are rarely performed in children with leukemia because the diagnosis is made by other means, and the results of splenic imaging have no impact on staging or prognosis. The spleen is often involved during the hematologically active stages of acute leukemia, and it frequently serves as a sanctuary site during hematologic remission. Cross-sectional imaging may reveal splenomegaly. Low attenuation splenic nodules can be difficult to differentiate from fungal microabscesses based on imaging alone; infarctions may also occur.[112]

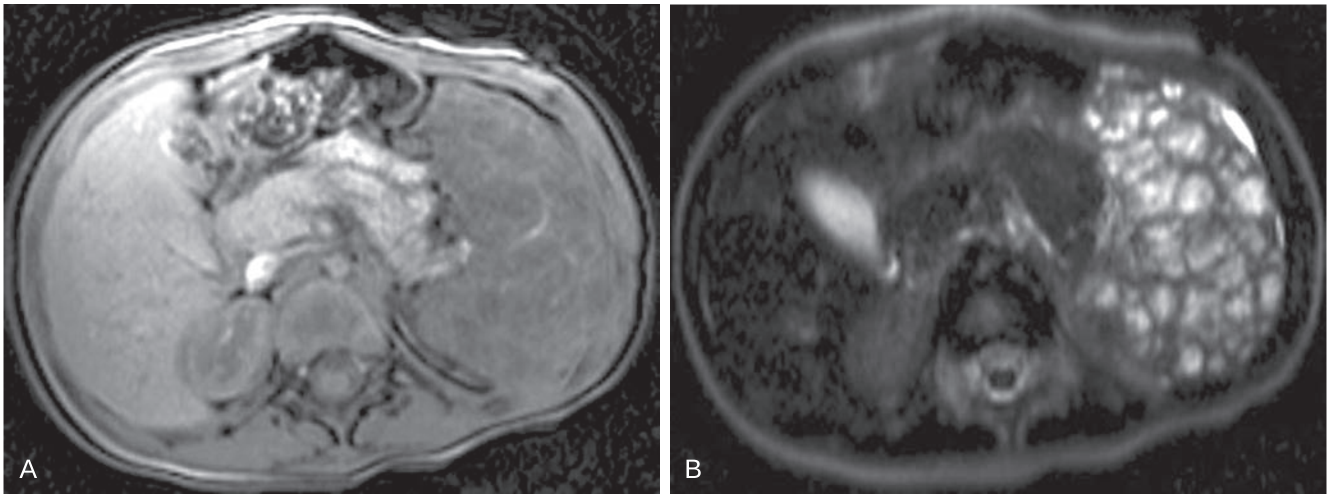
***Treatment.*** Treatment is geared to the underlying malignancy and its complications.

### Lymphoma

***Overview.*** Lymphoma is the most common malignant tumor of the spleen, although primary splenic lymphoma accounts for less than 2% of all lymphomas.[113] The spleen is usually involved secondarily, and accurate imaging of splenic lesions is important because it can alter staging, treatment protocols, and overall prognosis. Nonmalignant conditions may mimic tumor involvement and lead to an erroneous diagnosis.

***Etiology.*** Pediatric lymphoma is a heterogeneous group of malignancies derived from the immune system, characterized by enlargement and proliferation of lymph nodes and secondary lymphoid tissues. Risk factors include immune system disorders, genetic factors, infections such as HIV, and iatrogenic conditions such as after transplantation.[112]

***Clinical Presentation.*** In non-Hodgkin lymphoma, the spleen is affected in 20% of patients, while in Hodgkin disease, the spleen is involved in 30% to 40% of cases at presentation.[114] Organ size alone should not be used to assess splenic



**e-Figure 94.19. Splenic lymphangiomas.** (A) T1-weighted MR image shows numerous lesions of low signal intensity diffusely involving the splenic parenchyma in an 18-month-old girl. (B) On a T2-weighted MR image, the lesions have high signal intensity. *(Courtesy of Jeanne G. Hill, MD, MUSC.)*

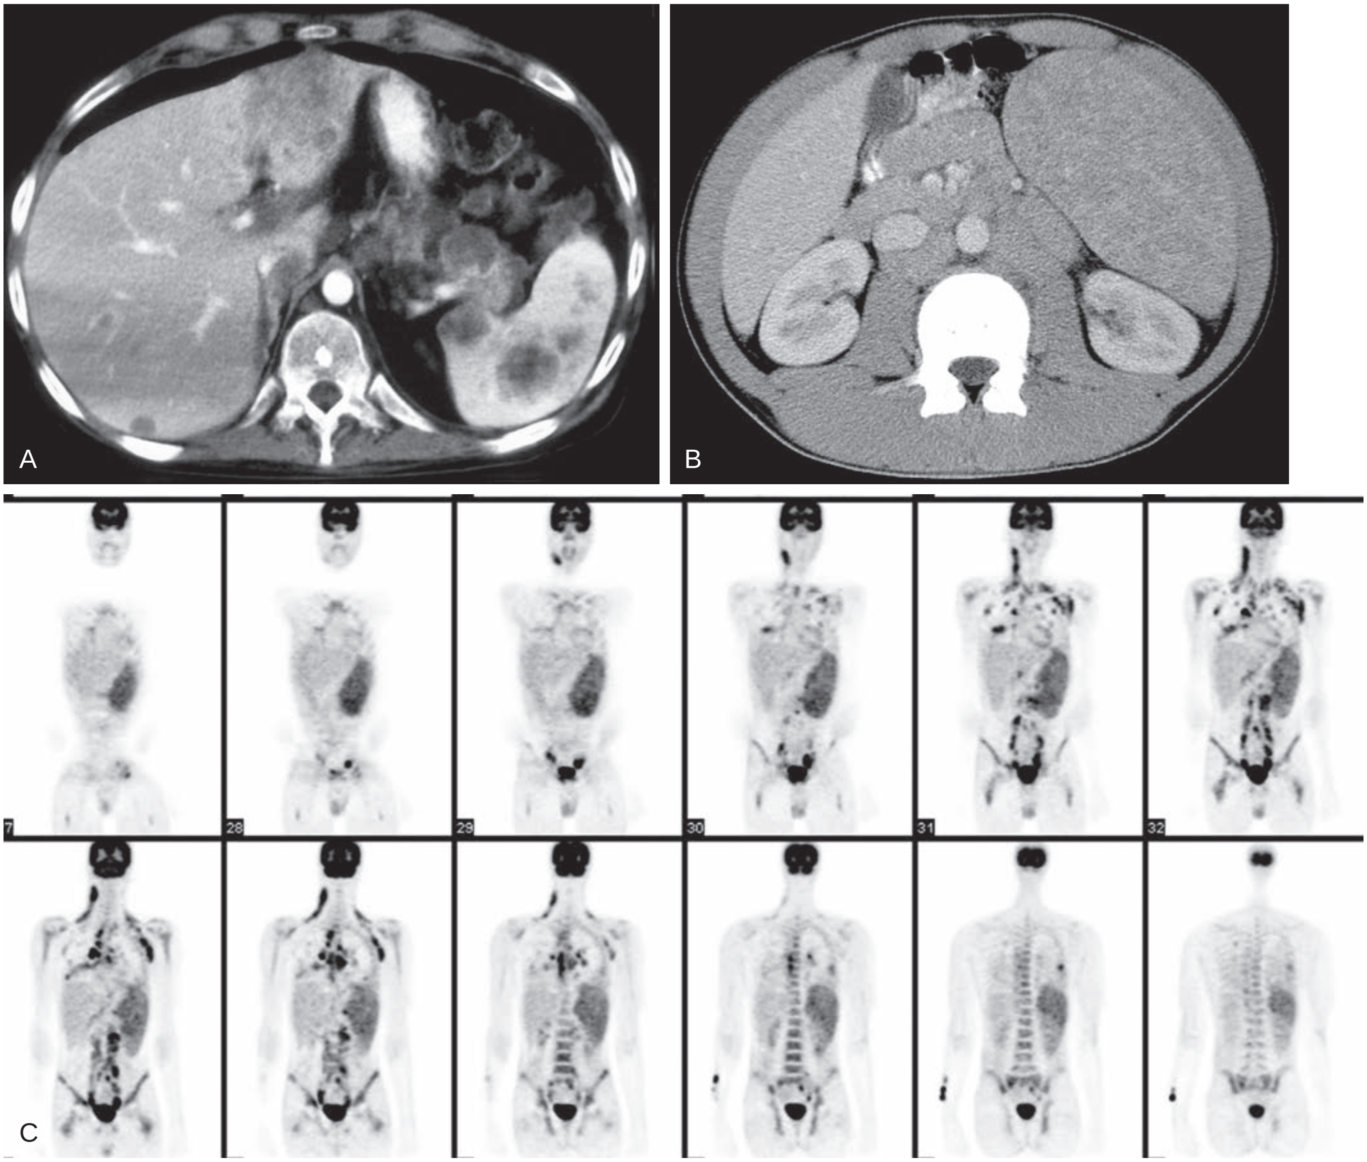


**Figure 94.20. Hodgkin lymphoma.** (A) Axial contrast-enhanced CT image in a 19-year-old with multiple episodes of relapsing disease and new left upper quadrant pain reveals multiple large, round, hypodense, nonenhancing masses in the spleen. Note additional foci of disease in the liver. (B) Axial contrast-enhanced CT image in a 14-year-old boy shows splenomegaly with numerous low-attenuation lesions throughout the spleen. (C) Coronal $^{18}$F FDG-PET images in a 15-year old reveal marked enlargement of the spleen with moderate-to-markedly increased FDG uptake. Note also nodal disease in the neck, supraclavicular regions, mediastinum, lungs, porta hepatis, retroperitoneum, iliac and inguinal regions, as well as the bone marrow.

involvement, because the spleen can be normal in size with tumor infiltration, and it may be enlarged without neoplastic involvement.

***Imaging.*** Non-Hodgkin lymphoma often may appear as splenic enlargement but may also have focal lesions large enough to be seen on US as ill-defined hypoechoic areas, especially in patients with high-grade malignancy. On CT, the low-attenuation lesions may not show appreciable enhancement compared with adjacent parenchyma after intravenous contrast administration. Lymphoma nodules can be challenging to differentiate from sarcoidosis or fungal abscesses, but the presence of splenic hilar lymphadenopathy is suggestive of lymphoma.[115] Hodgkin disease can also cause diffuse splenic infiltration that may or may not be detectable as focal splenic masses on CT (Fig. 94.20). If splenic involvement is the only subdiaphragmatic site, its detection is important for purposes of staging and prognosis. However, false-negative US, CT, and MRI examinations are common because these modalities depend on morphologic changes of enlargement or discrete nodules to diagnose lymphomatous involvement. Unfortunately, the imaging tissue characteristics of Hodgkin disease lesions are similar to those of normal spleen when the organ is diffusely infiltrated with disease that is only microscopically detectable.[112]

Metabolic imaging with 18F fluorodeoxyglucose (FDG) positron emission tomography (PET) is superior to US, CT, and MRI in identifying splenic involvement with lymphoma. F18-FDG PET/CT detects lymphomatous involvement of the spleen by identifying elevated glucose metabolism in tumor cells, regardless of whether there are gross morphologic changes. A meta-analysis reported sensitivity and specificity of F18-FDG

PET for the initial staging and restaging of non-Hodgkin lymphoma and Hodgkin disease as 90.3% and 91.1%, respectively.[116] In a small series, FDG PET correctly identified all patients with and without splenic disease with an accuracy of 100%; the accuracy of CT alone was only 57%.[117] In another study, F18-FDG PET/CT showed a comparable sensitivity of 96.2%, a specificity of 91.7%, and accuracy of 94% in the staging of primary splenic lymphoma.[118] F18-FDG PET/CT is superior to separate CT and F18-FDG PET in the staging and restaging of lymphoma and is the study of choice for staging and follow-up of Hodgkin disease and aggressive Non-Hodgkin lymphoma.[119,120] Treated splenic lymphomatous lesions may appear as necrotic and can eventually become calcific.[121]

***Treatment.*** Treatment options include chemotherapy, radiotherapy, radioimmunotherapy, and splenectomy.

## Littoral Cell Angioma

***Overview.*** Littoral cell angioma is an uncommon tumor that can occur at any age and may have some malignant potential with transformation to angiosarcoma.[122]

***Etiology.*** The lesion originates from the littoral cells of the red pulp with a network of connecting vascular channels.

***Clinical Presentation.*** Patients may be asymptomatic or present with splenomegaly, thrombocytopenia, and anemia. This entity presents as multiple lesions within an enlarged, heterogeneous spleen. The diagnosis should be considered in cases of multiple splenic lesions and hypersplenism. Associations with malignancies including colorectal carcinoma, hepatocellular carcinoma, lymphoma, and pancreatic adenocarcinoma have been reported.[123] It has been postulated that systemic immunosuppression related to the malignant state may be a factor in the development of littoral cell angioma.[124]

***Imaging.*** These lesions are heterogeneously hypoechoic on US and are initially of low attenuation on CT but typically become progressively isodense on delayed images after contrast enhancement[2,125] due to their histologic structure of multiple vascular channels.[126] On MRI, the lesions are well circumscribed and are predominantly T1 hypointense. On T2-weighted images, they may appear hyperintense or they may remain hypointense against the normal bright spleen parenchyma, presumably due to hemosiderin within the lesions.[2] The lesions show progressive contrast enhancement following gadolinium administration.

***Treatment.*** Treatment includes supportive therapy for the coagulopathy and endovascular embolization of the spleen to increase platelet count; when these fail, splenectomy may be indicated.[125]

## Hemangiopericytoma

***Overview.*** Hemangiopericytoma is a rare vascular tumor that most commonly occurs in the soft tissues of the extremities. It rarely originates as a primary tumor in the spleen.

***Etiology.*** Previously thought to originate from capillary pericytes, this tumor is now believed to represent a sarcoma of fibroblastic origin.[112] The tumor has variable biologic behavior and high potential for malignancy.[2,112]

***Clinical Presentation.*** When it occurs in the spleen, patients may be asymptomatic or they may present with splenomegaly, abdominal discomfort or left upper quadrant abdominal pain, hemorrhage, or infection.[112,127]

***Imaging.*** In the spleen, hemangiopericytomas may appear as a single large mass with smaller lesions within the parenchyma. Multiple hypoechoic lesions may be seen on ultrasound. Central Doppler flow has also been described.[128] Calcifications may be seen in the lesions on CT, as well as contrast enhancement of the solid portions and septations. The lesions demonstrate hypointensity on T1-weighted MR sequences and hyperintensity on T2-weighted sequences.

***Treatment.*** The treatment for splenic hemangiopericytoma is wide surgical excision[129] or splenectomy.[127] Careful long-term follow-up is required due to its aggressive behavior and a recurrence rate of 50%.[2]

## Angiosarcoma

***Overview.*** Angiosarcoma is a rare, highly malignant neoplasm that can occur at any age and is less common in children than in adults. It has no gender predilection, and it is considered the most common nonhematolymphoid malignant tumor of the spleen.[2,112]

***Etiology.*** Although the etiology of this lesion is unknown, it originates from endothelial cells in the splenic sinuses.[112] In older patients, angiosarcomas of the spleen are associated with previous chemotherapy for lymphoma and radiation therapy for breast cancer.[2]

***Clinical Presentation.*** The presentation may include left upper quadrant pain, fever, fatigue, weight loss, anemia, and thrombocytopenia. Splenomegaly is common[130] and can lead to splenic rupture at presentation in up to 30% of patients. Prognosis is poor, and metastases are common, typically to liver, lungs, and bone.[112,121]

***Imaging.*** US most commonly reveals a complex, heterogeneous mass, with hypoechoic cystic areas, likely reflecting foci of hemorrhage and necrosis. Solid hyperechoic regions display increased flow on color Doppler imaging. On CT, the lesions are ill-defined, with lower attenuation than the surrounding spleen, and demonstrate heterogeneous contrast enhancement and areas of necrosis.[2] MRI also reflects the heterogeneity of the mass with mixed signal on T1-weighted and T2-weighted images, and heterogeneous enhancement in the solid parts of the tumor. Intra- or perisplenic hemorrhage or hemoperitoneum can be seen on CT or MRI.[131]

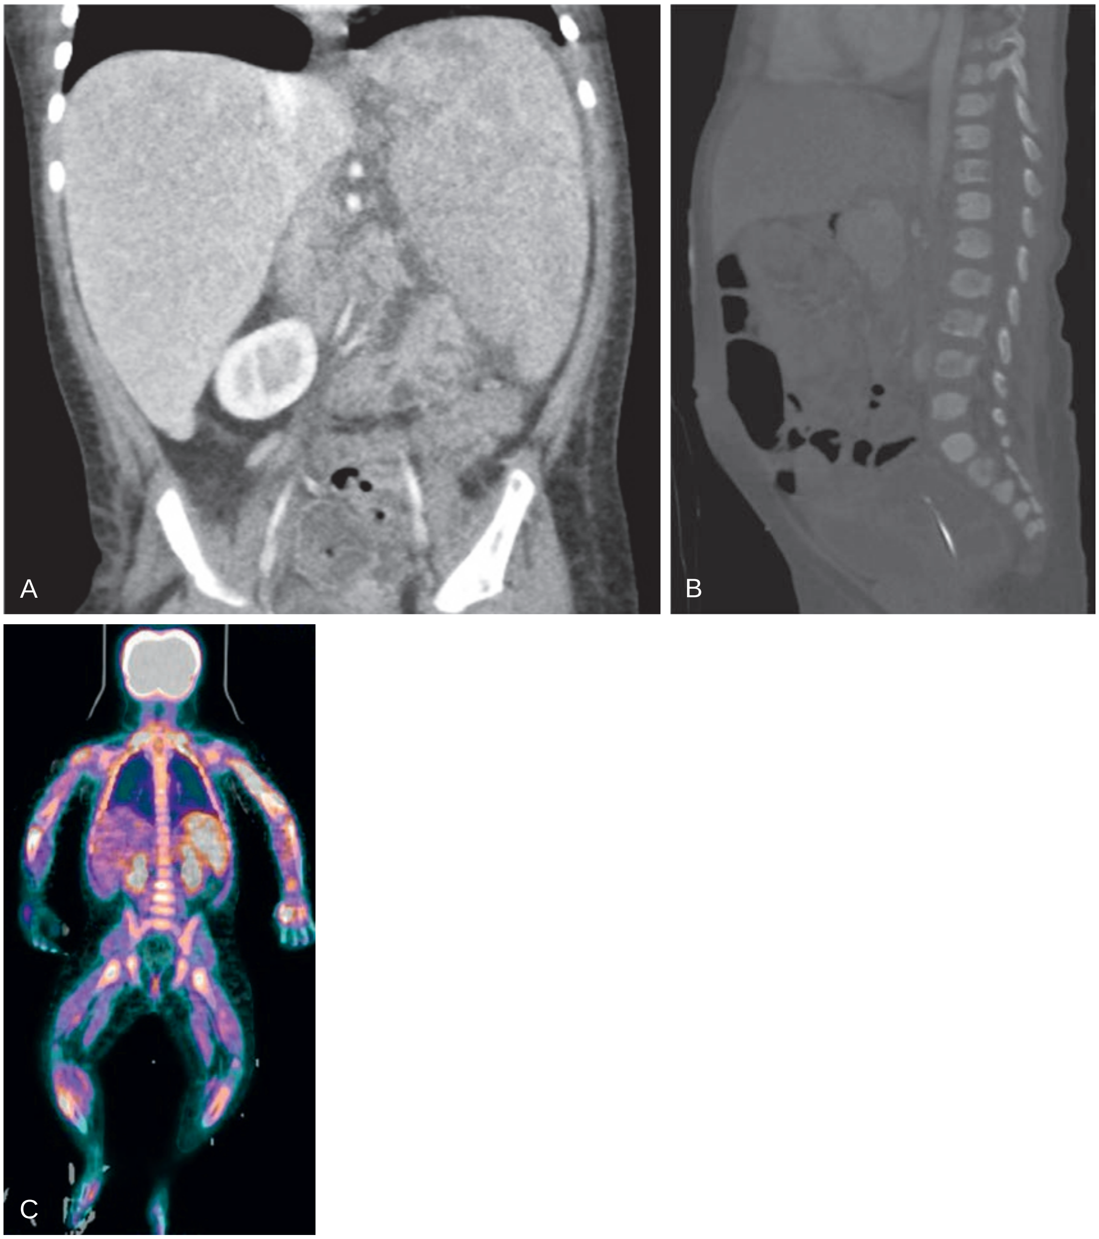
***Treatment.*** If suspected, special care should be taken when performing a biopsy due to the high risk of hemorrhage.[121] Splenectomy is typically performed, followed by chemotherapy, but prognosis remains very poor.[112]

## Histiocytic Sarcoma

Histiocytic sarcoma is a rare hematopoietic neoplasm with malignant proliferation of cells presenting morphologic and immunophenotypic characteristics of mature tissue histiocytes.[132] It often localizes to the skin, lymph nodes, intestinal tract, or soft tissues, and primary splenic involvement is exceedingly rare. The patients present with general symptoms including fever, wasting, lymphadenopathy, hepatosplenomegaly, and progressive pancytopenia.[132] Imaging findings are variable and include splenomegaly, multiple, partially confluent, hypoattenuating masses (e-Fig. 94.21A) and possible hepatic infiltration. Splenectomy or splenic biopsy is useful for definitive diagnosis.[133] Splenic histiocytic sarcoma has a poor prognosis due to aggressive behavior with liver or bone marrow infiltration (e-Fig. 94.21B and C) and a poor response to therapy, though a splenectomy might induce temporary remission.[133]

## Splenic Metastases

Splenic metastases are uncommon and are thought to be due to lack of secondary afferent lymphatics.[134] Metastases from pediatric solid primary tumors are less common than with adult tumors. In general, tumors that most commonly metastasize to the spleen include melanoma and tumors of the lung, breast, and testicular germ cell tumors, particularly choriocarcinoma. Metastases may be single or multiple and frequently do not cause splenomegaly. Splenic metastases portend a poor prognosis.



**e-Figure 94.21. Histiocytic sarcoma.** (A) Coronal reformatted contrast-enhanced CT image in an 8-month-old girl shows a markedly enlarged spleen with patchy areas of heterogeneity. (B) Sagittal reformatted image in bone window shows multilevel lytic lesions of the spine. (C) F18-FDG PET/CT whole body image demonstrates hypermetabolic uptake in the spleen and multiple bones.

## KEY POINTS

- Sonography is the primary imaging modality for evaluating splenic size, shape, location, and multiplicity.
- Radionuclide imaging with $^{99m}$Tc sulfur colloid helps in the assessment of ectopic splenic tissue, such as splenosis or splenogonadal fusion.
- In heterotaxy syndromes, splenic tissue, if present, will be located along the greater curvature of the stomach.
- Transient heterogeneous splenic enhancement patterns are commonly encountered during rapid bolus techniques on contrast-enhanced CT.
- Splenomegaly is usually a manifestation of an underlying systemic condition.
- Hypersplenism is a syndrome of sequestration of blood elements within an enlarged spleen.
- Hamartoma and hemangioma are the most common primary tumors of the spleen.
- Lymphoma is the most common malignancy of the spleen.

# The Pancreas

Anuradha S. Shenoy-Bhangle, Sudha A. Anupindi, and Michael S. Gee*

## EMBRYOLOGY, ANATOMY, AND PHYSIOLOGY

The pancreas (from the Greek words *pan*, meaning "all," and *kreas*, meaning "flesh") arises from two anlagen that develop from the endodermal lining of the duodenum. Before 28 days of gestation, the dorsal pancreatic bud develops as a diverticulum from the dorsal aspect of the duodenum caudal to the hepatic diverticulum. It grows upward and invaginates into the dorsal mesogastrium to form part of the head and the entire neck, body, and tail. The ventral pancreatic bud develops between 30 and 35 days of gestation as a diverticulum from the primitive bile duct that forms part of the head and uncinate process. The ventral pancreas rotates counterclockwise posterior to the duodenum at day 37 of gestation, and the two pancreatic buds fuse at about the sixth week of embryonic life. The ductal systems also fuse, and the duct from the dorsal bud becomes the accessory pancreatic duct (of Santorini) that drains into the minor duodenal papilla; the duct from the ventral bud enlarges to become the main pancreatic duct (of Wirsung) after fusion, with the distal two-thirds of the dorsal duct, which drains into the major duodenal papilla.

Developmental variants of the pancreatic ducts include: bifid pancreas, formed by the ducts of Wirsung and Santorini (60% of cases); a rudimentary duct of Santorini (30%); a dominant duct of Santorini (1%); and *ansa pancreatica*, in which the duct of Santorini curves as it courses to the duct of Wirsung. Ductal narrowing can be seen at the site of fusion of the dorsal and ventral ducts. The absence of proximal dilation allows differentiation of this normal variant from a true stricture. Duodenal obstruction, pancreatobiliary maljunction pancreatitis, and biliary cysts occur secondary to developmental variants. Pancreatobiliary maljunction is associated with congenital common bile duct webs.[1]

The pancreas grows substantially in the first year of life, and growth slows from years 1 through 18. The gland is relatively larger in children than in adults, and the overall ratio of gland size to patient body size decreases with age (Table 95.1). The pancreatic head is more prominent in children compared with the body and tail. The diameter of the pancreatic duct also varies with age (Table 95.2). Enlarged ducts (>1.5 mm at 1–6 years, >1.9 mm at 7–9 years, and >2.2 mm at 13–18 years) are associated with pancreatitis.[2]

The pancreas is a transversely oriented retroperitoneal organ that is divided into the head, neck, uncinate process, body, and tail (Fig. 95.1). The head is to the right of the midline, situated within the "C-loop" of the duodenum. At the junction of the inferior and left margins of the pancreatic head is an extension of the gland called the *uncinate process*. The anterior surface of the pancreatic head is in contact with the transverse colon, gastroduodenal artery, and loops of small intestine. The anterior surface of the uncinate process is in contact with the superior mesenteric artery and vein. The posterior surface of the head is adjacent to the inferior vena cava, common bile duct, renal veins, and the abdominal aorta.

The pancreatic body is in contact with the stomach anteriorly and superiorly. Its posterior portion abuts the abdominal aorta, splenic vein, left kidney, adrenal gland, and origin of the superior mesenteric artery. Loops of jejunum and ileum lie inferiorly. The tail may be more bulbous in children than the head or body and is narrower in adults. The pancreatic tail lies in the phrenicolienal ligament in contact with the gastric surface of the spleen and the splenic flexure of the colon.

The pancreas has both exocrine and endocrine functions. Exocrine function is directed toward digestion, with pancreatic enzymes secreted through the pancreatic duct into the small bowel to aid in breakdown of ingested fats (lipase), proteins (protease), and carbohydrates (amylase). The islets of Langerhans represent endocrine tissue that contains several types of hormone-producing cells (e.g., insulin, glucagon, somatostatin) that help regulate blood glucose levels and digestive function. The B cells produce insulin; A cells, glucagon; G cells, gastrin; D cells, somatostatin; and $D_1$ cells, vasoactive intestinal peptide (VIP) and secretin.

## IMAGING THE PANCREAS IN CHILDREN

The pancreas is not seen on plain radiographs, although calcifications in patients with chronic pancreatitis or cystic fibrosis (CF) may be identified (Fig. 95.2). In acute pancreatitis, dilated loops of bowel and fluid levels within the upper midabdomen indicate localized ileus. A pancreatic mass may be sufficiently large to lead to a paucity of bowel gas in the upper abdomen from displaced bowel loops.[3]

Ultrasonography (US) is the primary modality to evaluate the pediatric pancreas.[4] The pancreas is most easily seen if the stomach and duodenum are not distended with gas. Ingestion of water may improve pancreatic visualization by displacing air within the adjacent duodenum and stomach. The distal body and tail may also be imaged in the prone position using the left kidney or spleen as an acoustic window. Age-matched normal dimensions of the pancreas are given in Table 95.1.[4] Pancreatic size is best measured at its body, but individual variation is sufficient to warrant caution when determining pancreatic size. Enlargement of the pancreas should be mentioned when the anteroposterior dimension of the pancreatic body is greater than 1.5 cm.[5] The normal duct may be seen as a single- or double-track echogenic line anterior to the junction of the splenic and mesenteric veins (see Fig. 95.1). The pancreas has a spectrum of echogenicity relative to that of the liver, but in most children, the pancreas is hypoechoic or nearly isoechoic with the liver. In neonates, particularly premature infants, the pancreatic gland is more echogenic.[6]

Computed tomography (CT) of the pancreas is sparingly performed to avoid radiation. The pancreas is best visualized during bolus injection of intravenous (IV) contrast material during the mesenteric phase, which uniformly enhances the pancreatic parenchyma as well as the adjacent vasculature. The pancreas is hypodense compared with the liver, both on noncontrast and contrast-enhanced CT. The contour of the pancreas may be smooth or mildly lobulated due to the acinar lobar architecture. Contrast-enhanced CT is useful for evaluating pancreatic trauma, pancreatitis and its complications, and for further evaluation of abnormalities detected on US. Thin-collimation volumetric CT coupled with curved planar reformations produces quality imaging of pancreatic and peripancreatic tissues.[7]

Magnetic resonance imaging (MRI) of the pancreas[8,9] is increasingly used in children because it does not require ionizing radiation

---

*We acknowledge and thank Sue C. Kaste, Paritosh C Khanna, and Sumit Pruthi for contributions to the current chapter from prior editions.

## Abstract:

The pancreas is an important retroperitoneal organ with key exocrine and endocrine functions responsible for digestion and blood glucose regulation. The pediatric pancreas is subject to developmental variants; infections; inflammation and tumors. In our chapter, we explore the entire gamut of developmental and acquired conditions of the pancreas in the pediatric age group. We discuss congenital and hereditary pancreatic abnormalities; pancreatic tumors including solid-cystic papillary tumor; pancreatoblastoma; neuroendocrine tumors among others. We discuss the role of various imaging modalities with advantages and disadvantages in imaging pancreatic abnormalities in children with interesting illustrations demonstrating these abnormalities.

## Keywords:

congenital pancreatic abnormalities
pancreatoblastoma
hereditary pancreatitis
primary alveolar rhabdomyosarcoma of the pancreas
primary pancreatic neuroblastoma

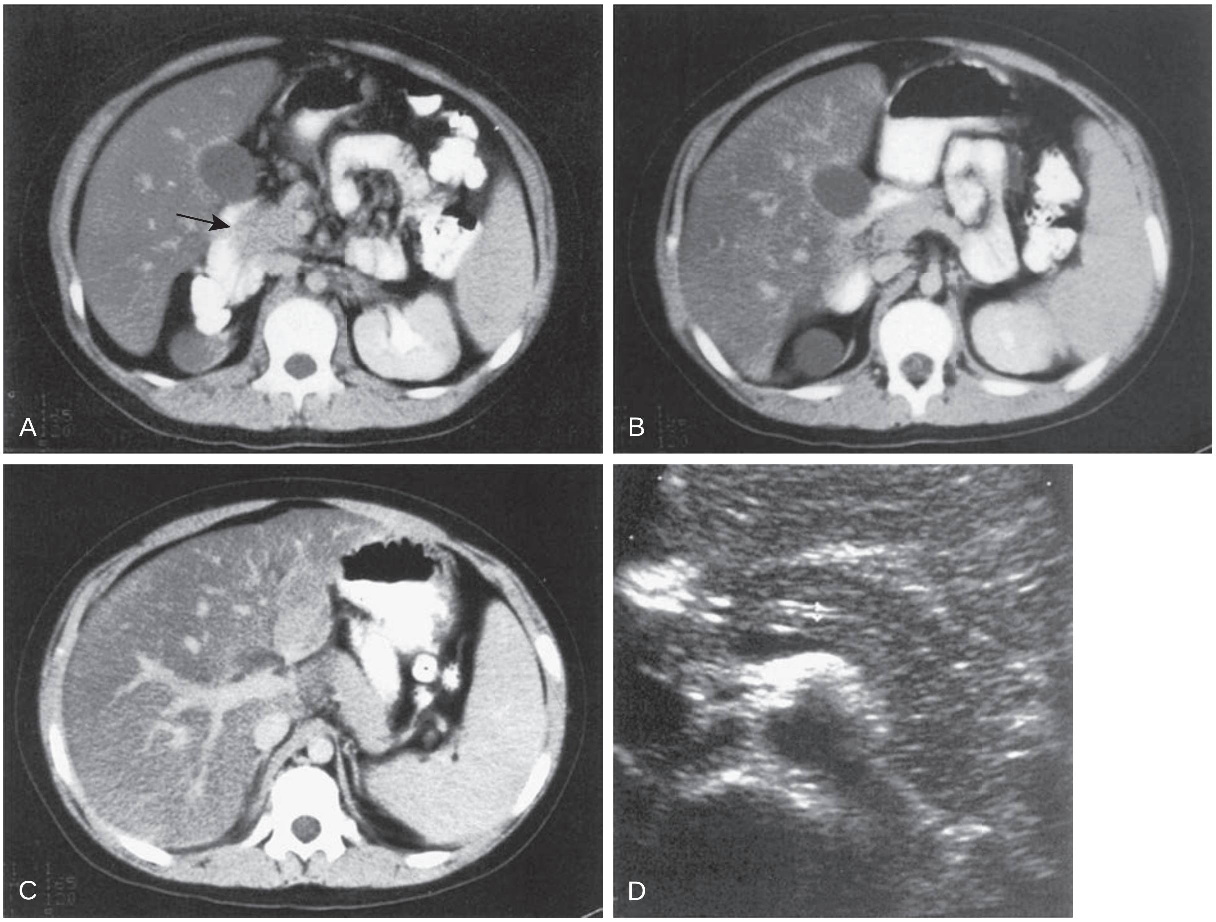

**Figure 95.1. Normal pancreas in an 11-year-old boy.** (A–C) Computed tomography (CT) sections of the pancreas. The head of the pancreas (*arrow* in A) is slightly bulbous and distinct from the contrast-filled duodenal sweep. The body of the pancreas (B) is narrower than the head or tail and is seen anterior to the aorta, from which the superior mesenteric artery arises. The tail of the pancreas (C) is thicker in children than in adults and extends to the spleen. (D) Transverse ultrasound shows the double track of a normal pancreatic duct.

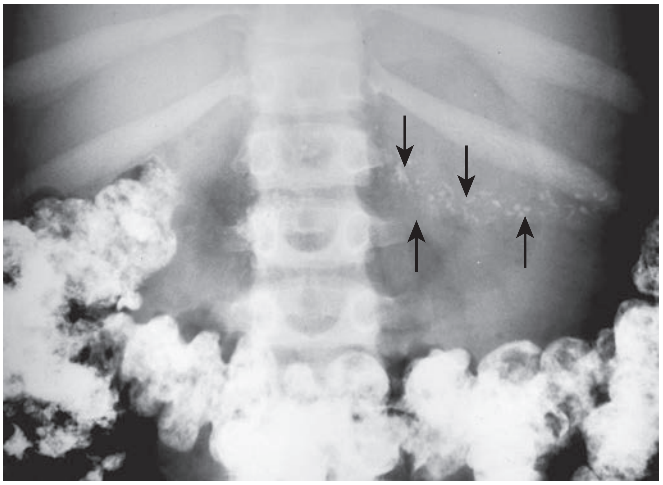

**Figure 95.2. Cystic fibrosis in a 9-year-old girl.** Multiple pancreatic calcifications *(arrows)* are seen on radiography.

and has high soft tissue contrast for characterizing the pancreatic parenchyma and ductal system.[8] Magnetic resonance (MR) images of the pancreas in children can be degraded by motion artifacts from respiration and patient movement, as well as susceptibility artifacts from air within bowel.[10] However, advances in rapid MR image acquisition, motion correction, and image reconstruction have greatly improved image quality in infants and young children.[11,12] On T1-weighted MRI, the pancreas demonstrates uniformly high signal intensity related to high protein content of the acinar cells.[13] The pancreas typically demonstrates similar signal intensity to the liver on T2-weighted images. Respiratory motion in older children is minimized by acquiring images during breath-holding, whereas in infants and young children, respiratory triggering or signal averaging techniques are typically required[11] (Fig. 95.3). T1-weighted imaging with fat suppression is very helpful for detection of focal pancreatic pathology, while T2-weighted imaging with fat suppression is helpful for detection of fluid collections and edema associated with pancreatitis or pancreatic masses.

Because of its noninvasive nature, magnetic resonance cholangiopancreatography (MRCP)[14] may be more useful than endoscopic

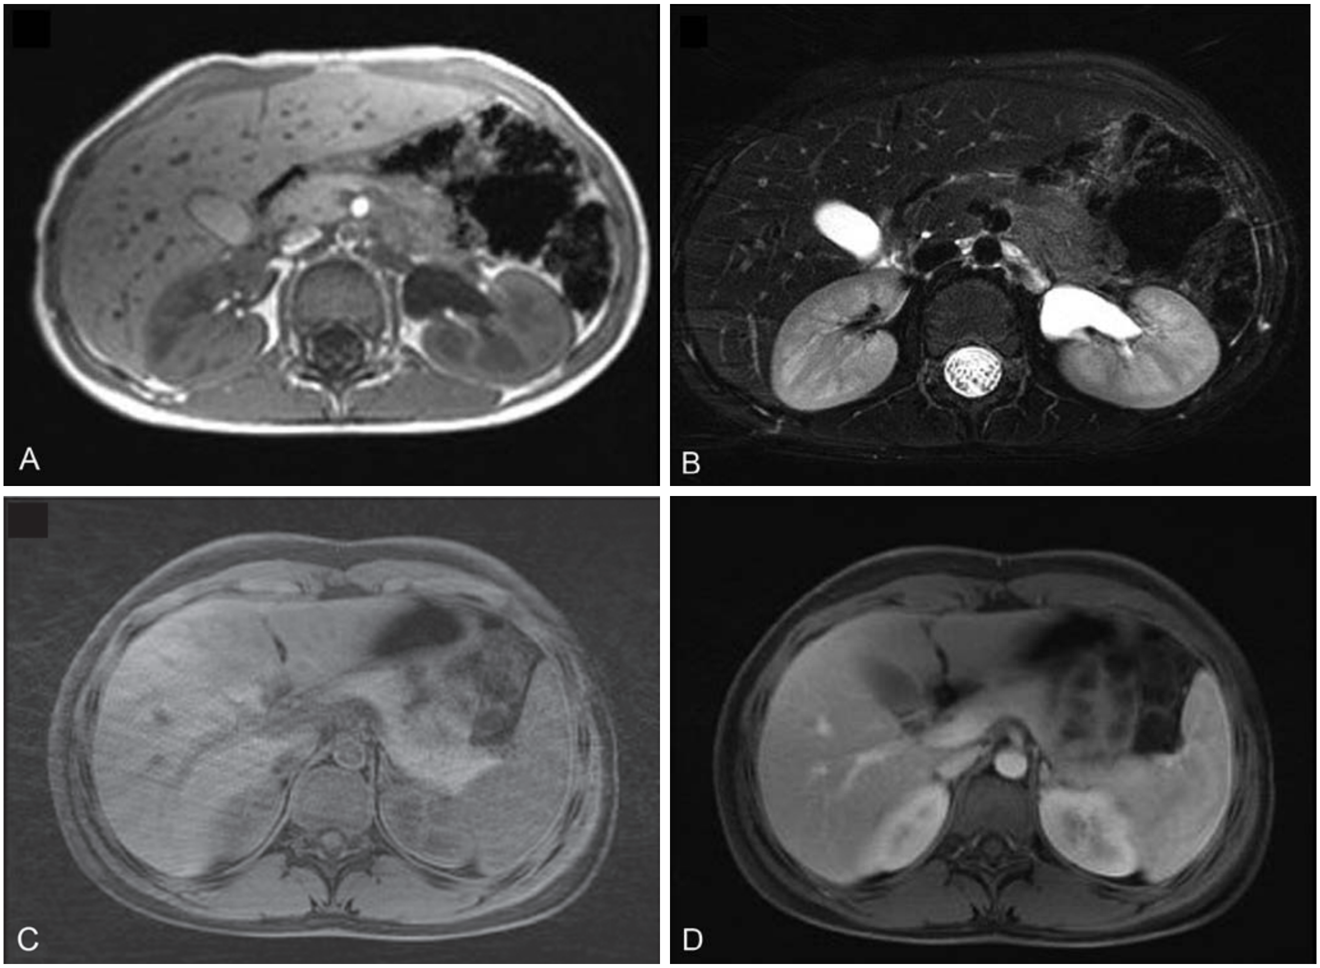

**Figure 95.3. MRI of normal pancreas in a 10-year-old girl.** (A) Axial T1-weighted, (B) T2-weighted fat-saturated, (C) T1-weighted fat-saturated precontrast, and (D) T1-weighted fat-saturated postcontrast images in a normal 10-year-old. Note that the normal pancreas is the brightest organ on T1-weighted images (with or without contrast) in the upper abdomen.

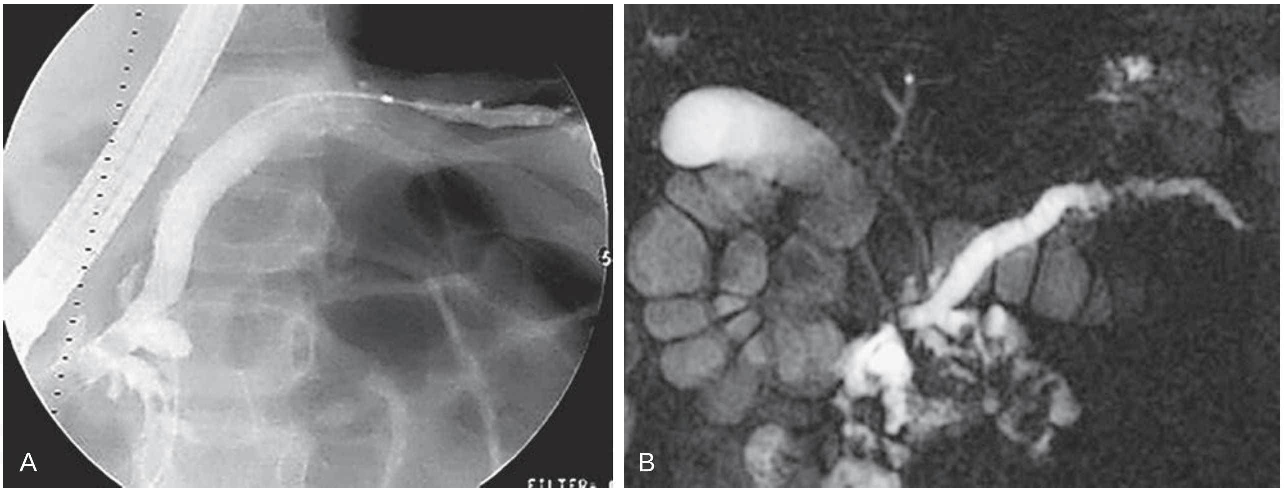

**Figure 95.4. Endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP) in a 9-year-old with recurrent pancreatitis and stones.** (A) Anteroposterior image from ERCP shows abnormal dilation of the proximal pancreatic duct and narrowing, irregularity, beading, and an undulating caliber of the distal pancreatic duct. (B) Anterior MRCP image of the same patient exquisitely defines the abnormal caliber and irregularity of the pancreatic duct, consistent with recurrent pancreatitis. The common bile duct is normal. *(Courtesy Dr. Kimberly Applegate, Indianapolis, IN.)*

retrograde cholangiopancreatography (ERCP)[15] in children (Fig. 95.4). Reported sensitivity, specificity, and accuracy are 87%, 90%, and 89%, respectively, for stones; 100%, 98%, and 98% for cholangitis; 92%, 97%, and 96% for bile duct tumors; and 89%, 96%, and 95% for periampullary stenosis.[16] MRCP is useful in congenital abnormalities such as pancreas divisum, after pancreatic trauma to identify duct of Wirsung transections, in delineating postoperative anatomy after choledochal cyst repair, pancreatobiliary maljunction, common channel,[17] and pancreatic duct.[18] Similarly, MRCP accurately depicts the postoperative anatomy and complications after liver transplantation.[19] A normal MRCP may obviate the need for ERCP or percutaneous transhepatic cholangiography, and abnormalities visualized with MRCP can direct the modality and route for further intervention. An overview of MRCP pitfalls has been provided by Van Hoe and colleagues.[20]

Secretin stimulation with MRCP further enhances the imaging information obtained, because it gives additional valuable, functional, and anatomic information about the pancreatic duct and pancreatic excretory capacity. Secretin-enhanced MRCP has been described in detail in recent years[21–25] and may be useful for detection and diagnosis of a variety of congenital, inflammatory, and neoplastic pancreatic conditions.[26] Secretin stimulates pancreatic exocrine secretion, which in turn leads to transient pancreatic duct dilation and fluid excretion into the duodenum. Imaging the distended pancreatic duct during secretin stimulation can improve sensitivity for detecting anatomic abnormalities such as pancreas divisum. In addition, the volume and location of secretin-stimulated duodenal fluid production during MRCP has been shown to be an accurate surrogate marker of pancreatic exocrine function in patients with pancreatitis.[27] MRI can be used as a noninvasive tool to detect pancreatic iron overload and endocrine function due to magnetic susceptibility effects of iron.[28]

## CONGENITAL AND HEREDITARY PANCREATIC ABNORMALITIES

### Congenital Pancreatic Abnormalities[29,30]

#### Pancreas Divisum

***Overview.*** Pancreas divisum occurs in 4% to 14% of the population when the dorsal and ventral ducts fail to fuse, although the pancreas is otherwise anatomically normal. This fusion abnormality leads to the smaller minor papilla and duct of Santorini draining the major portion of the pancreas and is associated with an increased risk of pancreatitis.

***Clinical Presentation.*** Pancreas divisum is present in 12% to 50% of cases of acute pancreatitis in patients whose pancreatitis would otherwise be considered idiopathic.[31]

***Imaging.*** MRCP has been shown to be highly sensitive and specific for pancreas divisum (Fig. 95.5). The most commonly observed finding is a main pancreatic duct entering the duodenum at a location that is superior to the common bile duct and major papilla. Increased thickness of the pancreatic head has also been described.[32] Thin-section CT can demonstrate the unfused ducts and two distinct pancreatic moieties separated by a fat cleft in some patients.[33] Pancreas divisum may be associated with minor papilla adenoma beyond childhood. Secretin MRCP may be useful in better demonstration of pancreas divisum[34]

***Treatment.*** Minor papilla sphincterotomy to facilitate normal egress of pancreatic enzymes and duct stenting has been attempted.[35]

#### Congenital Short Pancreas

***Overview.*** Congenital short pancreas, also known as *agenesis of the dorsal pancreatic anlage*,[36] occurs when the portion of the pancreas derived from the dorsal embryonic bud is absent, and only the smaller portion, derived from the ventral anlage, is present. Thus the pancreatic neck, body, and tail are absent. This anomaly has been described in patients with polysplenia syndrome or as a sporadic finding.

***Clinical Presentation.*** Patients may have variable symptoms of abdominal pain and epigastric discomfort to diabetes.[37]

***Imaging.*** Only the globular pancreatic head can be identified on CT (Fig. 95.6). Size is variable, ranging from an enlarged or prominent pancreatic head, to a normal-sized or even mildly atrophic and small pancreatic head. The diagnosis of agenesis of the dorsal pancreas is inconclusive without demonstration of the absence of the dorsal pancreatic duct, either with MRCP or ERCP. Patients with this abnormality have an increased risk of developing diabetes mellitus[38] because of the paucity of islet cells, most of which are located in the distal pancreas. This condition may also be associated in later life with pancreatic tumors[39] such as intraductal papillary mucinous neoplasms.

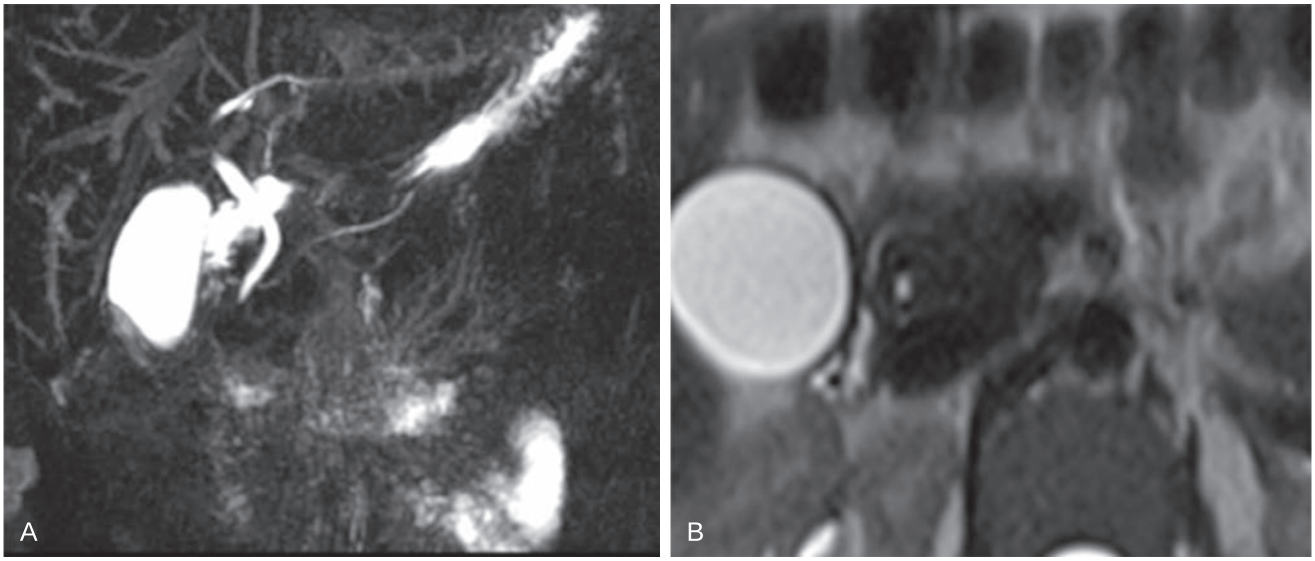

**Figure 95.5. Pancreas divisum.** (A) Coronal T2-weighted MR image shows the pancreatic body and tail draining through minor papilla. (B) Axial T2-weighted MR image shows separate ducts of Santorini (anterior duct) and Wirsung (posterior duct) in the pancreatic head.

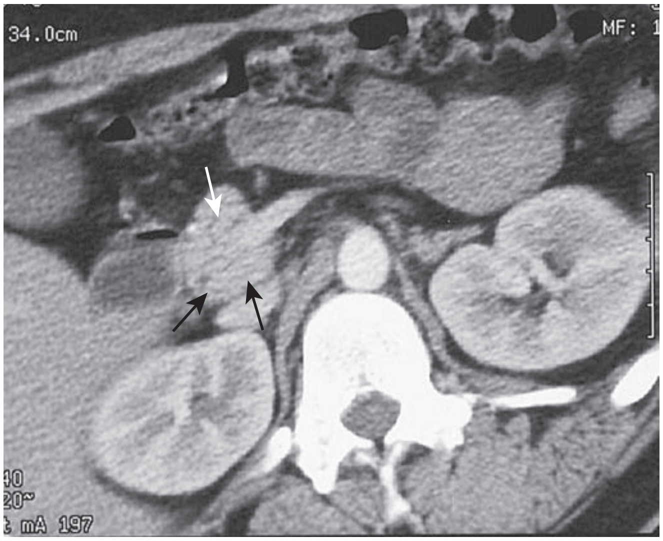

**Figure 95.6. Congenital short pancreas.** Axial contrast-enhanced abdominal CT image through the pancreatic bed shows a congenital short pancreas, with only a bulbous pancreatic head present *(arrows)*. *(Courtesy Dr. George Taylor, Boston, MA.)*

***Treatment.*** Treatment is supportive and is directed at the abdominal pain, pancreatitis, and diabetes.

## Ectopic Pancreas

***Overview.*** Ectopic pancreatic tissue[40] is an aberrant rest of normal pancreatic tissue remote from the pancreatic body that occurs in 1% to 13% of the population. The vast majority of pancreatic rests (about 70%) are located in the stomach, duodenum, and jejunum,[41] but they can occur elsewhere, such as omphaloenteric duct rests.[42] An association with Beckwith-Wiedemann syndrome (BWS)[43] and noncommunicating gastric duplication cyst containing ectopic pancreatic ducts and islet cells without acini has been described.[44]

***Clinical Presentation.*** Most pancreatic rests are incidental findings and are asymptomatic.

***Imaging.*** Detection of ectopic pancreatic tissue needs a high index of suspicion. Kim et al.[45] have described CT findings of ectopic pancreas and CT features to differentiate it from other common tumors found in these locations.

***Treatment.*** Laparoscopic gastric wedge resection is a safe and effective treatment for symptomatic pancreatic rests located in the stomach.

## Annular Pancreas

***Overview.*** Several theories of embryonic dysgenesis have been proposed for annular pancreas, but most suggest some form of rotational anomaly of the ventral bud. The pancreatic annulus, or the portion surrounding the duodenum, frequently has a separate duct entering the duodenum opposite the ampulla of Vater. Duodenal contents may reflux through this duct into the annulus. Affected patients present with duodenal stenosis or obstruction in infancy, but adults present with pancreatitis.[46] Other associated abnormalities (especially in patients with trisomy 21) include intestinal malrotation, tracheoesophageal fistula, anal atresia, and cardiac abnormalities and has been described in de Lange syndrome.

***Clinical Presentation.*** Infants frequently present because of associated duodenal obstruction. However, in approximately half the cases, the diagnosis is made beyond infancy. Annular pancreas has also been a cause of extrahepatic biliary obstruction.[47]

***Imaging.*** It is easier to detect and characterize the tissue surrounding the duodenum as pancreatic on MRI than CT. Diagnosis by US has also been described.[48] ERCP and MRCP are used to investigate ductal anatomy (Fig. 95.7).

***Treatment.*** Treatment requires bypass of the obstructed segment of duodenum usually by duodenoduodenostomy or gastrojejunostomy.[49]

## Congenital Pancreatic Cysts

***Overview.*** Congenital cysts of the pancreas are rare and are often confused with choledochal,[50] omental, or mesenteric cysts. Single congenital pancreatic cysts are very rare and occur predominantly in females.[51]

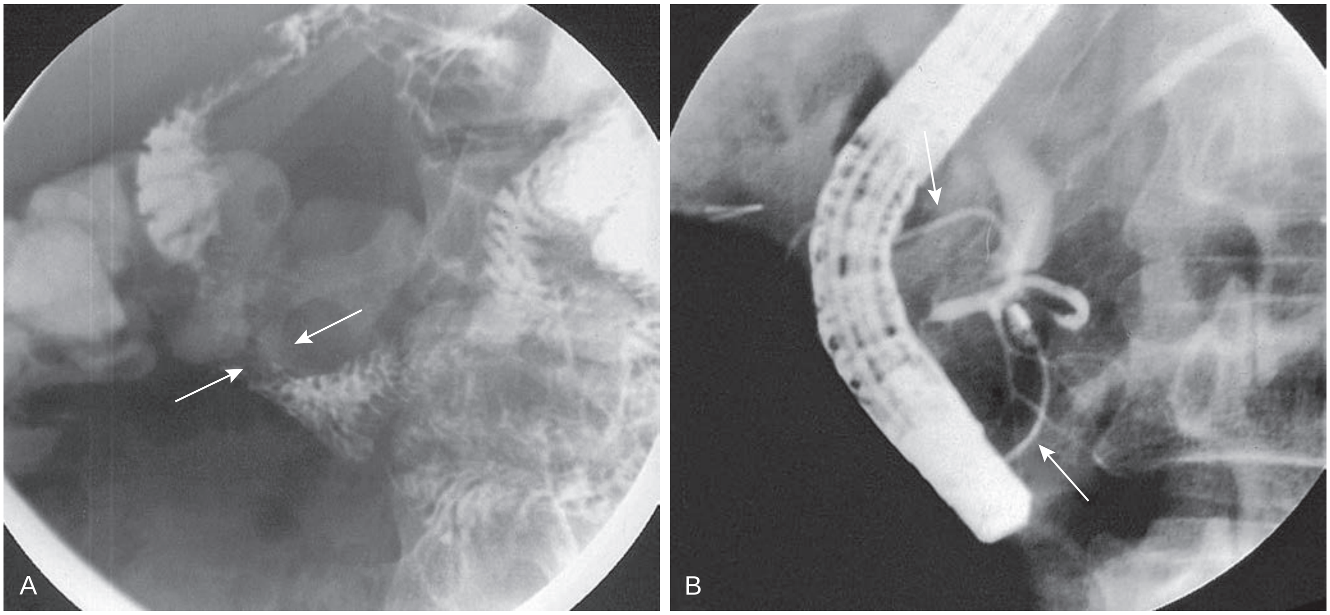

**Figure 95.7. Annular pancreas.** (A) Oblique view during an upper gastrointestinal series shows extrinsic narrowing of the duodenal C-loop *(arrows)*. (B) Endoscopic retrograde cholangiopancreatography confirms the presence of small ducts *(arrows)* encircling the duodenum, consistent with an annular pancreas.

***Clinical Presentation.*** Usually asymptomatic, but when symptoms do occur, they are related to mass effect and compression of adjacent structures.

***Imaging.*** Congenital cysts are anechoic on US. They are usually unilocular, located in the pancreatic tail, and range in size from microscopic to 5 cm.[52] Rarely, they may communicate with the ductal system. In contrast to single congenital pancreatic cysts, multiple congenital cysts may be associated with a polycystic disorder such as von Hippel-Lindau disease.[53] Juxtapancreatic gastrointestinal (GI) duplication cysts occur as abnormalities of the developing foregut and therefore usually have an alimentary tract epithelial lining. Most of these cysts arise from the stomach or duodenum but may rarely be sequestered within the pancreas.[54]

***Treatment.*** Surgical removal is usually only necessary for symptomatic cysts or those concerning for neoplasia.

## Hereditary Systemic Conditions With Pancreatic Involvement

### Cystic Fibrosis

***Overview.*** CF, an autosomal recessive genetic disease related to chloride channel dysfunction, leads to exocrine pancreatic insufficiency in 80% of affected patients. The etiology of pancreatic pathology in CF is multifactorial but is thought to include a combination of increased intra-acinar pressure from retained viscous pancreatic secretions, precipitation of proteins, and increased pancreatic enzyme concentration.[55]

***Clinical Presentation.*** Patients have pancreatic insufficiency, mainly exocrine, with failure to thrive, abdominal distension, steatorrhea, and occasional rectal prolapse. Patients with pancreatic cystosis (see the following text) are usually asymptomatic.

***Imaging.*** Four general imaging patterns of the pancreas have been observed, including normal, atrophic, lipomatous, and cystotic appearances.[56] In young patients with CF, US[57] shows a normal pancreas or pancreatic enlargement, but chronic obstruction ultimately results in atrophy of the gland with fatty infiltration and fibrosis, leading to increased echogenicity. CT shows reduced attenuation secondary to fatty infiltration (Fig. 95.8). Fibrosis without fatty infiltration is found infrequently. Unenhanced scans may show pancreatic calcifications, ductal dilation, and pancreatic cysts.[58] MRI findings are variable but can accurately depict the changes of fatty infiltration, fibrosis, and atrophy.[59,60]

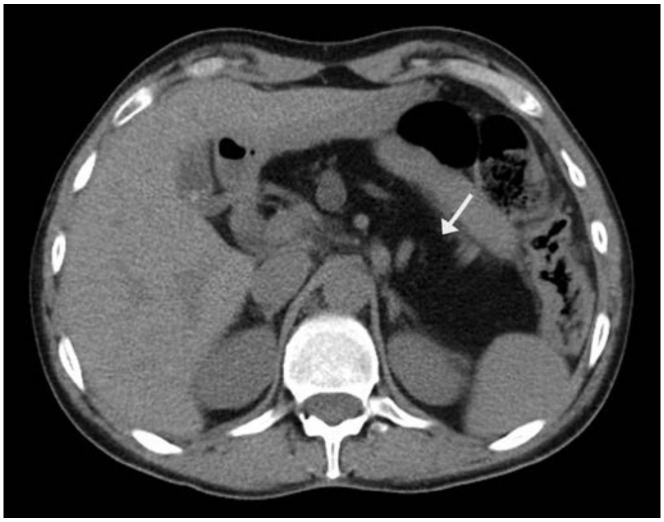

**Figure 95.8. Cystic fibrosis (CF) with diffuse fatty replacement of the pancreas.** Axial noncontrast CT of the abdomen in an 18-year-old girl with CF demonstrates diffuse fatty replacement *(arrow)*.

Cystic transformation of the pancreas, or *pancreatic cystosis*, in children and young adults may occur.[61] Here, the pancreas is replaced by macrocysts that are rarely more than 1 cm in diameter. These are true, epithelium-lined cysts that result from the accumulation of inspissated mucus, produced as a result of residual exocrine secretory function in the acinar cells, proximal to ducts obstructed from inflammation. This can be imaged with US, CT (Fig. 95.9), and MRI. Secretin-stimulated MRI with diffusion-weighted imaging is being investigated for assessment of exocrine pancreatic insufficiency in patients with CF.[62]

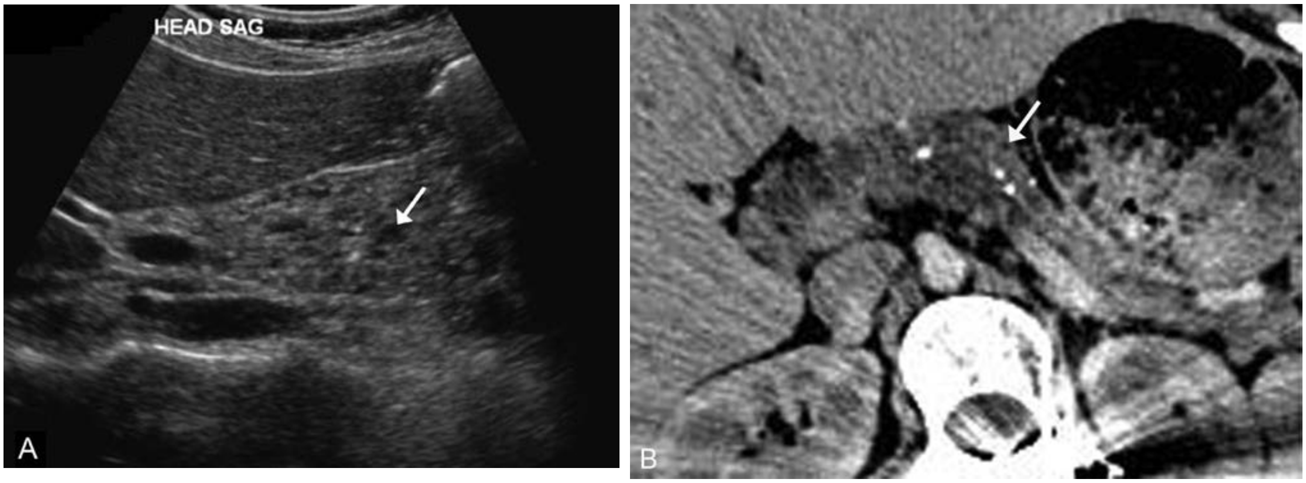

**Figure 95.9. Cystic fibrosis with pancreatic cystosis.** A 13-year-old girl with CF demonstrates pancreatic cystosis *(arrows)* on (A) US and (B) contrast-enhanced axial CT.

***Treatment.*** Exocrine pancreatic insufficiency is treated by supplementation with pancreatic enzyme products. Treatment otherwise is supportive and directed toward the underlying CF.

## Shwachman-Diamond Syndrome

***Overview and Clinical Presentation.*** Shwachman-Diamond syndrome is an autosomal-recessive disorder that results in short stature, exocrine pancreatic insufficiency, metaphyseal chondrodysplasia, and bone marrow dysfunction.

***Imaging.*** US and CT evaluations of the pancreas demonstrate fatty replacement (pancreatic lipomatosis)[63] as described earlier in patients with CF (e-Fig. 95.10). Other causes of pancreatic lipomatosis include chronic pancreatitis, prolonged steroid use, obesity, Cushing syndrome, hemochromatosis, obstruction of the duct of Wirsung, and Johanson-Blizzard syndrome.

***Treatment.*** Exocrine pancreatic insufficiency is treated by supplementation with pancreatic enzyme products. Other current treatment strategies include surgery for skeletal deformities, granulocyte colony-stimulating factor for neutropenia, and bone marrow transplantation for marrow failure.

## von Hippel-Lindau Disease

***Overview and Clinical Presentation.*** von Hippel–Lindau disease (VHL) is an autosomal-dominant disorder characterized by hemangioblastoma in multiple organs (especially the retina and central nervous system), skin lesions, and cysts of numerous organs, including the pancreas. Pancreatic involvement is seen in approximately 21% of patients.[64] Up to 75% of these multiple pancreatic lesions (e-Fig. 95.11) likely originate from progenitor cells, not mature endocrine cells as previously thought.[65]

***Imaging.*** VHL-associated cysts are typically anechoic on US and have reduced attenuation on CT compared with the surrounding pancreatic tissue. Multiple cysts—as well as serous and mucinous cystadenomas of the pancreas, carcinoma, adenocarcinoma, and islet cell tumors—are also associated with VHL.[64]

***Treatment.*** Although symptoms are rare, specific treatment of pancreatic lesions is required in selected patients, mainly those with large neuroendocrine tumors that require surgical resection.[66]

## Autosomal-Dominant Polycystic Kidney Disease

***Overview.*** Autosomal-dominant polycystic disease is a hereditary disorder with 100% penetrance but variable expressivity. The genetic mutations underlying the disease are in *PKD1* and *PKD2* that encode for components of a calcium channel receptor within primary cilia.[67] This ciliary defect leads to problems with mechanical stimulus sensing and membrane reception signal transmission, giving rise to tissue degeneration and cyst formation in a number of organs including the pancreas.[68]

***Clinical Presentation.*** Symptoms of large pancreatic cysts include abdominal pain, jaundice, and fever.

***Imaging.*** Renal cysts are the dominant feature, but cysts may also be found in the liver, spleen, adrenal glands, and pancreas. Pancreatic cysts are present in about 10% of patients, and the gland is typically less involved than the kidneys or liver.

***Treatment.*** Large, symptomatic pancreatic cysts may require surgical or percutaneous intervention.

## Hereditary Pancreatitis

Hereditary pancreatitis is an autosomal-dominant disease in which patients have recurrent episodes of pancreatitis. This condition is discussed later in the chapter.

## Beckwith-Wiedemann Syndrome

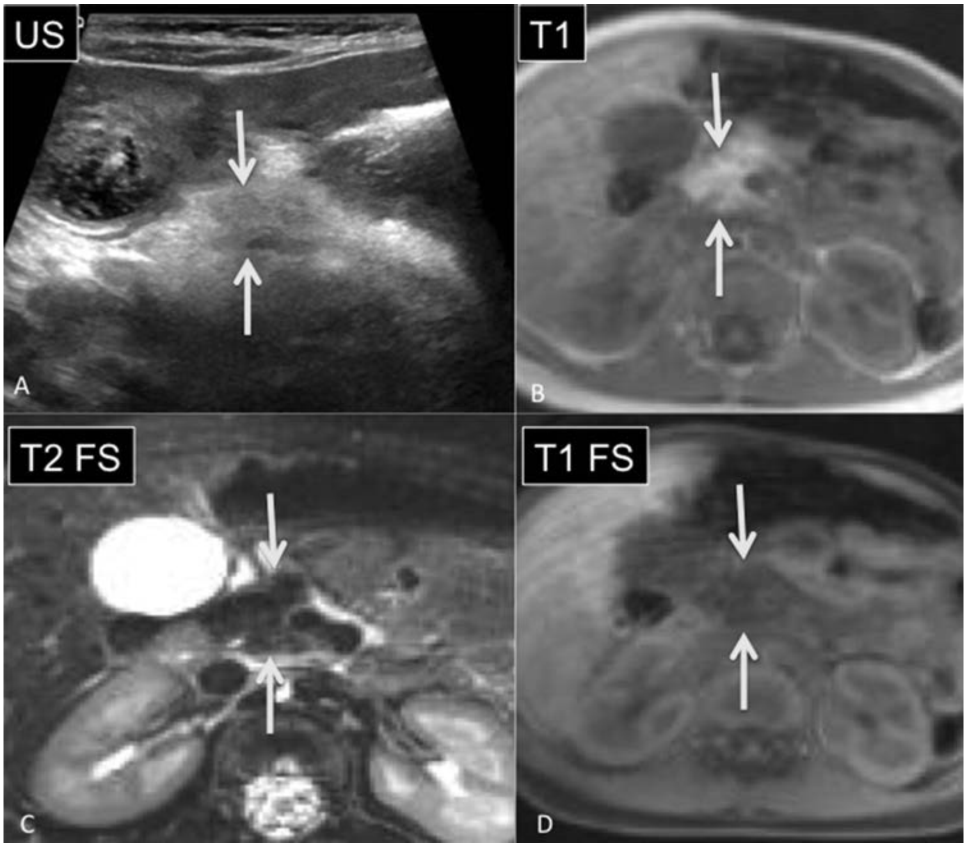
***Overview and Clinical Presentation.*** BWS is a relatively frequent overgrowth syndrome with an incidence estimated at 1 in 14,000 births. It is probably an autosomal-dominant disorder with variable transmission. The BWS gene has been identified on the short arm of chromosome 11 (11p15.5). The syndrome is characterized by visceromegaly, hemihypertrophy, and development of malignant tumors in 10% to 15% of affected patients; benign tumors are also found.

***Imaging.*** Imaging studies may show nonspecific pancreatic enlargement. Patients may develop pancreatoblastoma or focal adenomatosis, as discussed later under Pancreatic Neoplasms. Because of this risk, routine US screening is initiated at an early age.

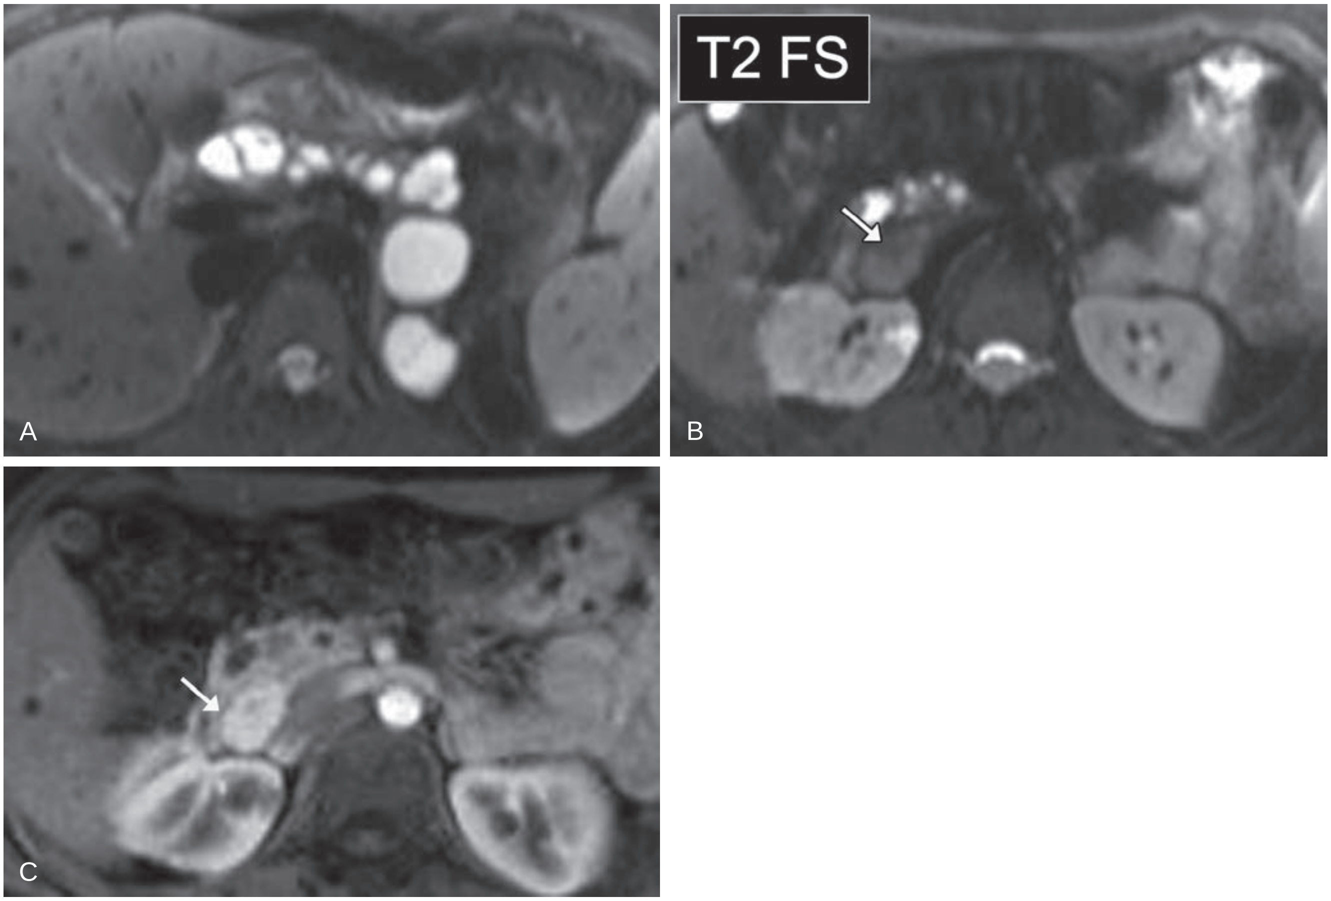
***Treatment.*** Surgical intervention is required for pancreatic tumors.

## Hemochromatosis

***Overview.*** Hemochromatosis is an autosomal-recessive disorder that manifests as iron accumulation mainly in the liver, pancreas, and heart secondary to excessive iron reabsorption from the intestine, leading to organ dysfunction (see also Chapter 89).



**e-Figure 95.10. Shwachman-Diamond syndrome.** (A) US demonstrates diffusely echogenic pancreas in a 9-year-old boy *(arrow)*. (B–D) Axial MR images demonstrate high signal pancreas on (B) T1-weighted images with (C) signal loss on T1-weighted and (D) T2-weighted fat-suppressed images *(arrows)*.



**e-Figure 95.11. von Hippel-Lindau (VHL) syndrome.** A 10-year-old girl with VHL demonstrates cysts on T2-weighted MR images (A and B). An arterial enhancing islet cell tumor is seen in the pancreatic head *(arrows)* on (B) T2-weighted fat-saturated and (C) T1-weighted fat-saturated images.

***Clinical Presentation.*** Symptoms referable to the pancreas may be absent or nonspecific, such as malaise and fatigue, or they may be those of insulin resistance due to pancreatic damage from iron deposition, culminating in diabetes.

***Imaging.*** The pancreatic changes from hemochromatosis are better appreciated with MRI, rather than CT, because of the magnetic susceptibility effects of iron. The liver and pancreas appear diffusely hypointense on T2*- and T2-weighted sequences. Distinction should be made from acquired transfusional iron overload (hemosiderosis), in which iron accumulates in the reticuloendothelial cells causing T2 hypointensity in the liver and spleen, but typically spares the pancreas.

***Treatment.*** Treatment is directed toward the resultant diabetes, and supportive treatment—such as phlebotomy, iron chelation therapy, and restriction of oral intake of iron-rich foods and beverages—is undertaken to prevent further damage from iron overload.

## PANCREATITIS

### Acute Pancreatitis

***Overview.*** Recent studies have reported an increasing incidence of acute pancreatitis in the pediatric age group.[69–71] This has been proposed to be secondary to both better detection as well as a rising incidence of obesity, which in turn is considered a risk factor for acute biliary pancreatitis.[72] Other demonstrated factors include multisystem disease, including sepsis, shock, hemolytic uremic syndrome, and viral infection, specifically mumps. Blunt trauma is the cause in 15% of patients (including bicycle handlebar injuries), congenital anatomic abnormalities in 10%, metabolic diseases in 10%, and drug toxicity in 3%. No cause may be identified in 25% of patients.[73]

Anatomic abnormalities associated with pancreatitis include pancreas divisum, congenital bile duct dilation, cysts with pancreatobiliary malunion/maljunction (40%–50%),[74] duodenal web, and congenital pancreatic cyst. An anomalous pancreatobiliary ductal junction may cause pancreatitis, by facilitating reflux of bile into the pancreas.[75–77] The frequency of acute pancreatitis in children with a choledochal cyst is reportedly as high as 68%. Associated metabolic disorders include hypercalcemia, hyperlipidemia, and CF; the drugs implicated most frequently are L-asparaginase (e-Fig. 95.12), steroids, and acetaminophen. A reported increased incidence of biliary sludge in adult patients with pancreatitis suggests that biliary sludge may be the probable cause in as many as 70% of patients with idiopathic pancreatitis.[78]

Autoimmune pancreatitis is a part of IgG4-related disease affecting the pancreas but is uncommon in the pediatric population.[79] Diffuse, focal, and multifocal involvement of the pancreas has been described; the diffuse type being the most common leading to “sausage”-shaped enlargement of the gland.[80]

***Clinical Presentation.*** Patients with nontraumatic acute pancreatitis typically present with epigastric pain, nausea, and vomiting. Elevation of serum concentrations of pancreatic enzymes—amylase, lipase, and trypsinogen—is common. Although abnormal laboratory values are typically considerably more sensitive than imaging in identifying acute pancreatitis, imaging studies are useful to confirm the diagnosis and to determine the extent of associated inflammatory changes and complications. Very rarely, pancreatitis may be the presenting symptom of a pancreatic malignancy in children and adolescents.

***Imaging.*** Abdominal radiographic findings are nonspecific. Reactive ileus or localized ileus from focal dilation of the duodenal loop (“sentinel loop”) and asymmetric left pleural effusion are suggestive findings.

US is the best initial imaging study for evaluation of acute pancreatitis and biliary abnormalities in children.[80] Pancreatic parenchymal echogenicity and size are unreliable indicators of acute pancreatitis. The edema that accompanies acute pancreatitis often results in a diffusely enlarged hypoechoic gland, although some will appear normal. A minority of affected patients have increased pancreatic echogenicity (see e-Fig. 95.12). The pancreatic duct may be dilated,[2] but this is an inconsistent finding. Masses may be identified in the pancreas that represent focal areas of fluid, hemorrhage, or phlegmon formation. US is sensitive in detecting peripancreatic fluid collections and assessing feasibility for image-guided interventions. The most commonly involved areas are the lesser sac, anterior pararenal space,[81] transverse mesocolon, and perirenal space. US can also detect vascular complications, including pseudoaneurysms and venous thromboses.

CT with IV contrast is more sensitive in detecting acute pancreatitis and its complications compared with US. CT features include focal or diffuse pancreatic enlargement, presence of hemorrhage, peripancreatic fluid collections, thickening of adjacent fascial planes, and ascites. Abscesses, necrosis, and vascular complications are particularly well delineated on CT.[82] Presence of gas locules without prior intervention is an indicator of underlying infection.

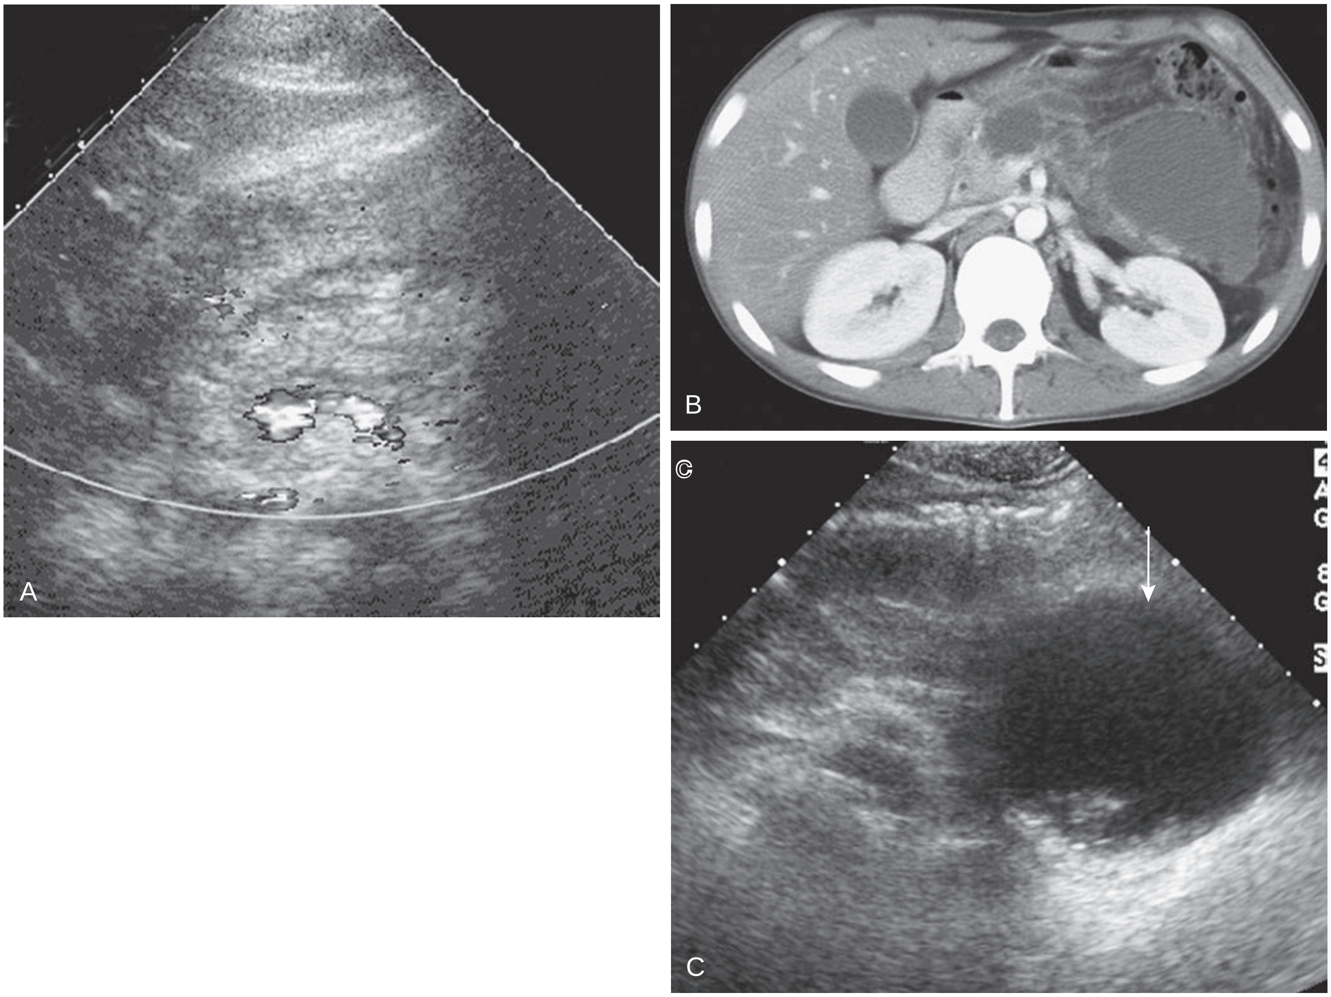
The CT severity index (CTSI), originally developed by Balthazar et al. for the adult population, has been shown to be a better indicator of acute severe pancreatitis than clinical scores in the pediatric population.[83] CT findings help triage early institution of antibiotics, ICU transfer in anticipation of renal or respiratory complications, or early administration of parenteral nutrition. However, serial follow-up with CT should be limited due to the risk of radiation exposure.

ERCP has no role in acute pancreatitis except when a therapeutic intervention is planned due to a known biliary etiology. ERCP is more useful to evaluate complicated or recurrent pancreatitis[84] and in cases of unusual pseudocyst formation. The findings range from mild irregularity of the duct to ductal narrowing with wall ectasia and acinar enlargement, which has been likened to a “string of beads.” Marked ductal ectasia is usually not seen in acute pancreatitis.

MRCP[85] is preferred to ERCP in the evaluation of childhood pancreatitis because it is noninvasive (see Fig. 95.4). MRCP is more sensitive in detection of choledocholithiasis compared with US, and pancreaticobiliary ductal anomalies are better evaluated. Secretin administration may help in visualizing the pancreatic duct and structural abnormalities.

MRI features of acute pancreatitis include low T1 signal intensity of the pancreatic parenchyma as well as heterogeneous or diminished parenchymal enhancement on the postcontrast imaging. T2-weighted and diffusion-weighted images are sensitive for detection of parenchymal edema and fluid collections as well as surrounding inflammation. Gas and calcification are better visualized on CT when compared with MRI.

Complications of acute pancreatitis can broadly be divided into vascular and nonvascular complications, the latter including collections and fistulizing disease. The latest revised version of the Atlanta classification[86] can be extrapolated to the pediatric population as the nature of collections is the same in adults and children. Acute edematous interstitial pancreatitis is associated with acute peripancreatic fluid collections that do not demonstrate a well-delineated wall and are seen up to 4 weeks from the start of inflammation, compared with pseudocysts that take 4 or more weeks to develop. Although most pseudocysts are in the region of the pancreas itself (see e-Fig. 95.12), they can appear nearly anywhere in the abdomen and in the mediastinum.[75,76] About 13% of pediatric patients with acute pancreatitis develop pseudocysts.[80] Although most pseudocysts resolve spontaneously within an average of 5 months,[87] some persist and require intervention.[88,89] Features associated with spontaneous resolution include a pseudocyst diameter less than 7.5 cm, absence of internal debris, and total pseudocyst volume less than 250 mL.



**e-Figure 95.12. Asparaginase-induced pancreatitis and pseudocyst formation.** (A) Transverse US in a 17-year-old boy undergoing treatment for acute lymphoblastic leukemia who developed acute pancreatitis. The body of the pancreas is enlarged and mildly hyperechoic, with indistinct margins. Doppler signal indicates the splenic vein dorsal to the pancreas. (B) Axial contrast-enhanced CT scan 2 days later shows peripancreatic edema and two pseudocysts in the body and tail. (C) Additional follow-up with US shows a large pseudocyst *(arrow)* involving the pancreatic tail and containing complex debris.

Collections associated with necrotizing pancreatitis are classified as acute necrotic collections in the first 4 weeks and walled off necrosis thereafter. Although contrast-enhanced CT is sensitive in diagnosing fluid collections, US or MRI is more sensitive in characterizing fluid composition. They frequently cause mass effect on adjacent structures, especially the stomach and duodenum, and this may be seen on radiographs or upper GI studies performed for unexplained abdominal pain. Pseudocysts are typically anechoic, although some may contain debris. ERCP usually shows the irregular ductal dilation of chronic inflammation (see Fig. 95.3A). Skeletal changes, particularly bone marrow infarcts, have long been recognized as a complication of pancreatitis, possibly related to increased levels of circulating lipase and to generalized enzymatic dysfunction of the pancreas.[90]

***Treatment.*** Primary treatment includes analgesia and bowel rest with parenteral nutrition.[91,92] Postpyloric enteral feeds may be begun before oral refeeding to prevent relapse and to provide nutritional support while preventing gut mucosal atrophy. Antibiotic use is recommended for necrotic pancreatitis. Surgery and interventional procedures are indicated for infected necrotic pancreatitis and complications such as pseudocyst and abscess formation, splenic artery and vein thrombosis, hemorrhage, and pseudoaneurysms.

## Chronic Pancreatitis

***Overview.*** Chronic pancreatitis in children is less common than acute pancreatitis. Although it occurs as a sequela of the acute disease, chronic pancreatitis can also be found in association with other entities, such as CF. Familial hereditary pancreatitis is an autosomal-dominant disease that usually presents during childhood or the teenage years.

***Clinical Presentation.*** Patients with chronic pancreatitis usually present with persistent abdominal pain; some have constant, debilitating pain, whereas others have pain related to food intake, especially fats and protein-rich meals. Steatorrhea as a result of fat malabsorption is common, and weight loss is attributed to malabsorption and a reduction in food intake secondary to pain and food aversion. Diabetes may result from chronic pancreatic damage, and chronic pancreatitis may result in obstructive jaundice secondary to biliary strictures.[93]

***Imaging.*** Ductal dilation with strictures and visibility of pancreatic duct side branches, pseudocysts, and calcifications are the most common imaging abnormalities in chronic hereditary pancreatitis,[94] and pancreatic atrophy may also occur. Chronic fibrosing pancreatitis is characterized by bands of collagen enclosing normal acini[95]; the resulting mass simulates a tumor.

***Treatment.*** Pancreatic enzyme supplementation is used for treatment of malabsorption and steatorrhea. Dietary fat restriction, analgesics and opiates for pain, and insulin for diabetes are other treatment strategies. Therapeutic endoscopy and surgery may also be used.[96]

## Trauma

***Overview.*** Traumatic pancreatic injury in children is typically caused by blunt abdominal injury. Bicycle handlebar injuries and motor vehicle trauma account for the majority of pancreatic trauma; however, pancreatic injury can also be seen with nonaccidental trauma, and this mechanism should always be excluded in children.[97] Please refer to Chapter 109 on abdominal trauma for further details.

# PANCREATIC NEOPLASMS

Primary pancreatic tumors, both benign and malignant, are very rare in childhood and adolescence (Table 95.3).[98] Pancreatic tumors that occur in pediatric patients include solid-cystic pseudopapillary tumor (Frantz tumor), pancreatoblastoma, and islet cell tumors with carcinomas being rare. Other tumors that typically occur elsewhere, but can arise within the pancreas, include lymphoma,[99] rhabdomyosarcoma, and rare cases of pancreatic neuroblastoma. Secondary involvement of the pancreas by adjacent tumor, especially neuroblastoma, may be difficult to distinguish from a primary pancreatic tumor.

**TABLE 95.3** Classification of Common Pancreatic Tumors of Childhood

| Location | Benign | Malignant |
|---|---|---|
| **EXOCRINE PANCREAS** | | |
| | Pancreatic cysts | Pancreatoblastoma |
| | Papillary-cystic tumor | Duct cell adenocarcinoma |
| | Duct adenoma | Acinar cell carcinoma |
| | Mucinous cystadenoma | |
| | Serous cystadenoma | |
| | Intraductal papilloma | |
| **CONNECTIVE TISSUE** | | |
| | Hemangioendothelioma | Sarcoma |
| | Lymphangioma | Lymphoma |
| | Teratoma | Leiomyosarcoma |
| **SECRETORY/ENDOCRINE** | | |
| | Islet cell hyperplasia | Insulinoma (10%) |
| | Insulinoma (90%) | Gastrinoma (60%) |
| | Gastrinoma (40%) | Gastrinoma (60%) |

*Modified from Enríquez G, Vázquez E, Aso C, et al. Pediatric pancreas: an overview.* Eur Radiol. *1998;8:1236–1244.*

## Solid-Cystic Papillary Tumor

***Overview.*** Solid-cystic papillary tumor is also known by many other terms: Frantz tumor, solid pseudopapillary tumor, papillary epithelial neoplasm (PEN), solid pseudopapillary epithelial neoplasm (SPEN), solid and cystic acinar cell tumor, papillary and solid neoplasm, papillary-cystic epithelial neoplasm, papillary-cystic carcinoma, solid and cystic tumor, solid and papillary neoplasm, papillary cystic tumor, and low-grade papillary neoplasm.[100] Recent studies have shown that this is the most common pancreatic neoplasm in children.[101,102] It accounts for about 0.2% to 2.7% of all nonendocrine pancreatic tumors. Solid-cystic papillary tumor is histologically low grade, with a reported 5-year survival of 97%.

***Clinical Presentation.*** This tumor has a predilection for women[103] and for persons of Asian origin; it is the most common pancreatic tumor in Asian children. Girls between the ages of 12 to 16 are commonly affected, although 10% do occur in males.[104] Children usually have a better prognosis than adults, owing to less frequent metastatic disease. Abdominal pain is the presenting symptom in about one-third of cases, with a palpable abdominal mass or as an incidental finding.

***Imaging.*** US shows a solid and cystic mass. CT findings include a large, well-defined, solid mass with varying degrees of cystic components that usually represent necrosis but are unrelated to tumor size (Fig. 95.13A and B).[105] Calcifications may also be present. On T1-weighted MR sequences, a low signal rim may represent either a fibrous capsule or compressed pancreatic parenchyma; central high-signal areas that represent debris or hemorrhagic necrosis have also been reported. Almost half of all lesions occur in the pancreatic head. Invasion of adjacent structures occurs and is often associated with liver and lymph node metastases.[106,107]

## Pancreatoblastoma

***Overview.*** Pancreatoblastoma, or pancreaticoblastoma,[108] arises from the pancreatic acinar cells, usually in the head or tail of the gland. The cells of these tumors represent persistence of the fetal anlage containing immature pancreatic acinar cells.

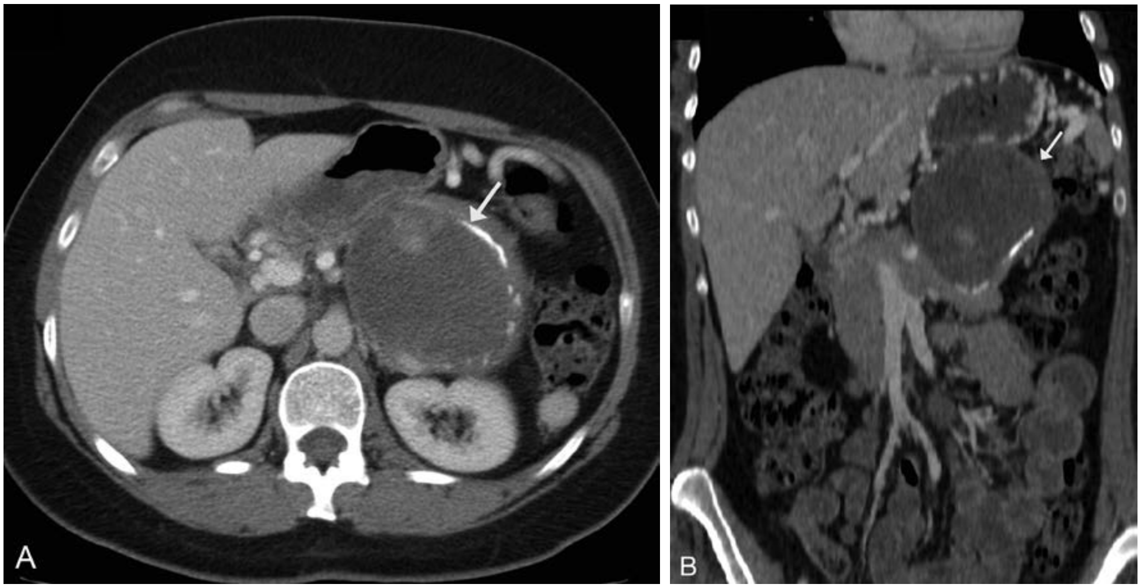


**Figure 95.13. Solid-cystic papillary tumor.** (A) Contrast-enhanced axial and (B) coronal reformatted CT in an 18-year-old girl presenting with an enlarging palpable abdominal mass demonstrates a hypoattenuating mass in the pancreatic tail with rim calcification and enhancing solid nodules.

Pancreatoblastoma is one of the most common exocrine tumors in pediatric patients and represents about 0.5% of all pancreatic epithelial tumors.

***Clinical Presentation.*** These tumors are found in boys twice as often as in girls. The incidence is higher in East Asia. Serum α-fetoprotein is elevated in 25% to 55% of cases, and an association with Beckwith-Wiedemann syndrome has been reported. A review of 153 patients with pancreatoblastoma found that the median age at presentation was 5 years, although this tumor has been diagnosed in patients as old as 68 years.[109] Seventeen percent of patients have metastatic disease, mostly involving the liver (88% of metastatic sites). Factors associated with a worse prognosis include metastatic or nonresectable disease and age older than 16 years at diagnosis. Pancreatoblastomas are often large at presentation, up to 12 cm, and may have central necrosis.

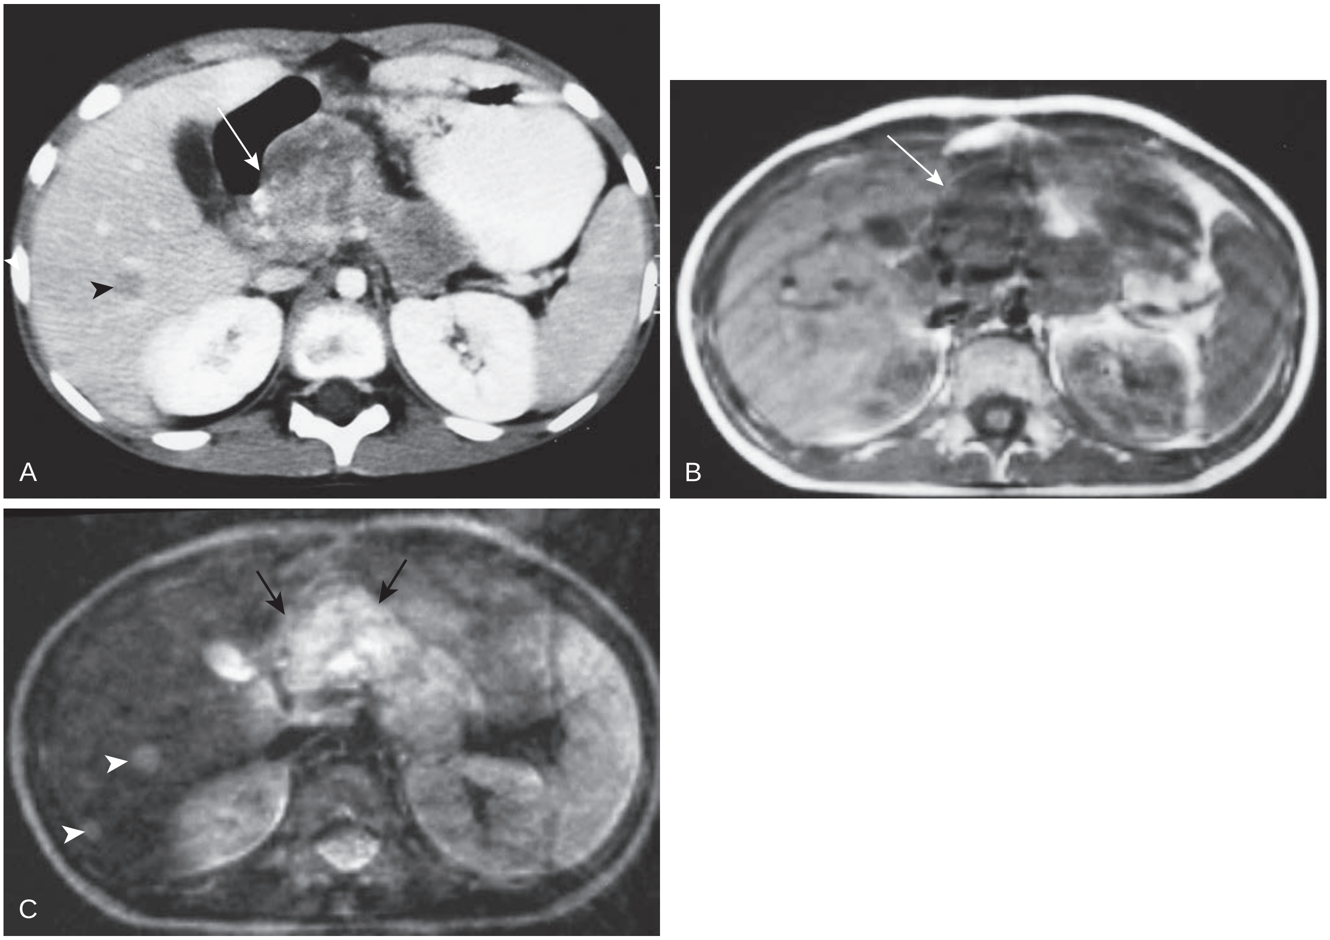
***Imaging.*** US and CT findings of pancreatoblastoma are often indistinguishable from those of pancreatic adenocarcinoma. Masses are typically hypoechoic and heterogeneous on US.[109] On CT, pancreatoblastoma is hypodense and appears to be multiloculated with enhancing septa (Fig. 95.14). Calcifications are not uncommon. When vascular encasement is present, it usually involves the inferior vena cava or mesenteric vessels. Despite the typically large size of pancreatoblastomas, obstruction of the biliary system is infrequent. Although variable, MRI characteristics include typically low signal intensity compared with the liver on T1-weighted images and isointensity to hyperintensity on T2-weighted images; enhancement varies.[110] Although findings are nonspecific as to tumor type, imaging suggests the malignant nature of the tumor and can clearly exclude the kidney and adrenal glands as organs of origin.

## Neuroendocrine Tumors

***Overview.*** Pancreatic neuroendocrine tumors arising from the pancreatic islet cells may be functioning (hormone-producing) or nonfunctioning.[97,104] In general, functioning neuroendocrine tumors tend to grow undiagnosed and present at a larger size at the time of diagnosis, while functioning tumors tend to be detected at a smaller size due to clinical symptoms related to hormone production (Fig. 95.15 and e-Fig. 95.16). Functioning neuroendocrine tumors produce increased amounts of polypeptide hormones such as insulin, gastrin, glucagon, VIP, and somatostatin.[104] Congenital hyperinsulinism (CHI, formerly called nesidioblastosis[111]) is due to beta-islet cell hyperplasia or adenomatosis and comes in two patterns: *diffuse adenomatosis*, where the gland is diffusely involved, and *focal adenomatous hyperplasia* due to a hyperfunctioning focal lesion.

***Clinical Presentation.*** Pancreatic neuroendocrine tumors present more commonly in adults but can present in older children. Pancreatic neuroendocrine tumors are observed in higher frequency in children with some genetic syndromes (e.g., multiple endocrine neoplasia type 1, Beckwith-Wiedemann, von Hippel-Lindau, tuberous sclerosis complex).[112] Nonfunctioning neuroendocrine tumors typically present with abdominal pain or distension, while patients with functioning tumors usually present with symptoms related to hormone production. Patients with insulinoma are seen initially with hypoglycemia, which typically manifests in children as erratic behavior and seizures. Tumors that secrete vasoactive intestinal peptide (VIP), so-called VIPomas, are associated with the syndrome of secretory diarrhea, hypokalemia, and achlorhydria. VIPomas are rare, with an estimated annual incidence of 0.2 to 0.5 per million population.

***Imaging.*** The most common site for pancreatic neuroendocrine tumors is in the pancreatic body and tail, where the majority of the islet cells reside.[113] These tumors are round or oval and are well circumscribed on US. They are hypoechoic but may have a hyperechoic rim; isoechoic and hyperechoic lesions have also been described in children and young adults. Endoscopic ultrasound (EUS) is more sensitive in detection of these tumors; however, it requires sedation/anesthesia and hence is less favored in children. On CT, these tumors demonstrate marked IV contrast enhancement particularly in the arterial phase (see Fig. 95.15, e-Fig. 95.16). Because these tumors are hypervascular, arteriography may be necessary in high-risk patients in whom US and CT are nondiagnostic, although magnetic resonance angiography (MRA) may replace this invasive technique. Intraoperative US has been used successfully to locate functioning islet cell tumors in children.[114] Selective venous sampling in children with hyperinsulinism can also help diagnose and localize tumors.[115] Indium-111-pentetreotide (Octreoscan) scintigraphy may also be useful in the diagnosis of primary or metastatic tumors.[116]



**e-Figure 95.16. Insulinoma.** (A) Axial contrast-enhanced CT through the pancreas of a 10-year-old girl with hypoglycemia. A large, heterogeneously enhancing mass involves the pancreatic head *(arrow)*. The remainder of the pancreas is also somewhat enlarged. Note the low-density hepatic metastasis *(arrowhead)*. (B) Axial T1-weighted MR image at the same level shows the intermediate-intensity pancreatic mass *(arrow)*. (C) T2-weighted sequence shows intensely increased signal *(arrows)*. Note also the conspicuity of the liver metastases on T2 weighting and a second, smaller metastatic focus located more peripherally *(arrowheads)*.

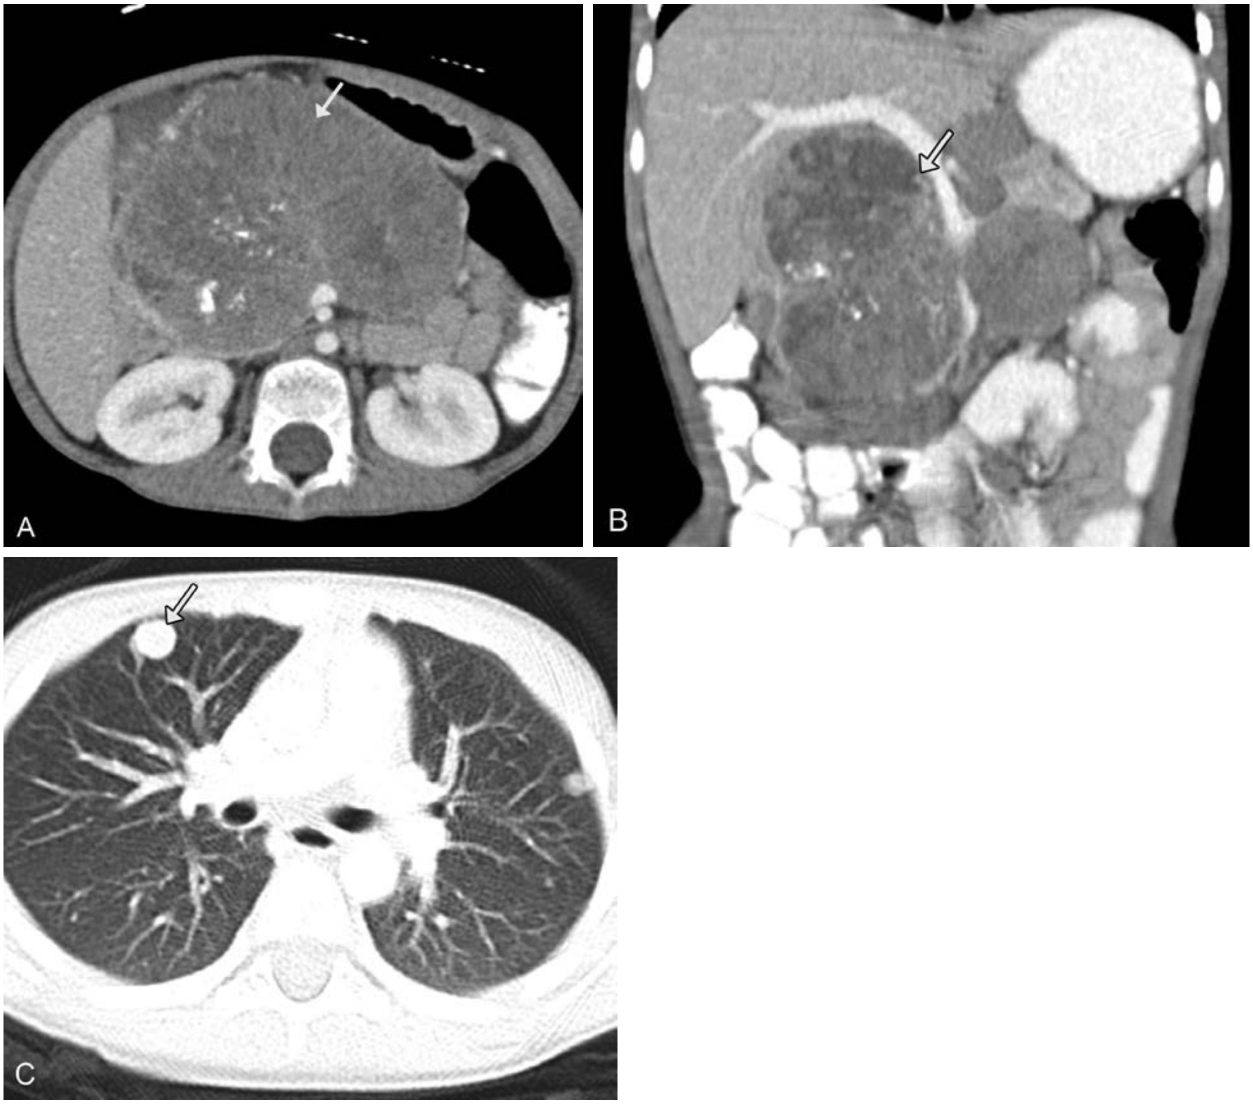


**Figure 95.14. Pancreatoblastoma.** (A) Axial contrast-enhanced and (B) coronal reformatted CT in a 3-year-old boy demonstrate a large, heterogeneously enhancing mass *(arrows)* arising from the pancreatic head and body. (C) Pulmonary metastases *(arrow)* are seen on the axial CT chest in lung windows.

Other islet cell tumors are rare in children, but they may be found in association with tumors in other organs as part of a genetic syndrome, in which case multiple synchronous neuroendocrine tumors can be observed.[104] Gastrinomas may be found in children with Zollinger-Ellison syndrome. In one series, 2 of 56 reported cases of VIP-producing tumors in children were islet cell tumors; neurogenic tumors generated the hormone in the other patients.[117] Pancreatic neuroendocrine tumors in the setting of tuberous sclerosis complex may be functioning or nonfunctioning but typically are diagnosed at a small size[118] incidentally on imaging performed to evaluate renal involvement of disease.

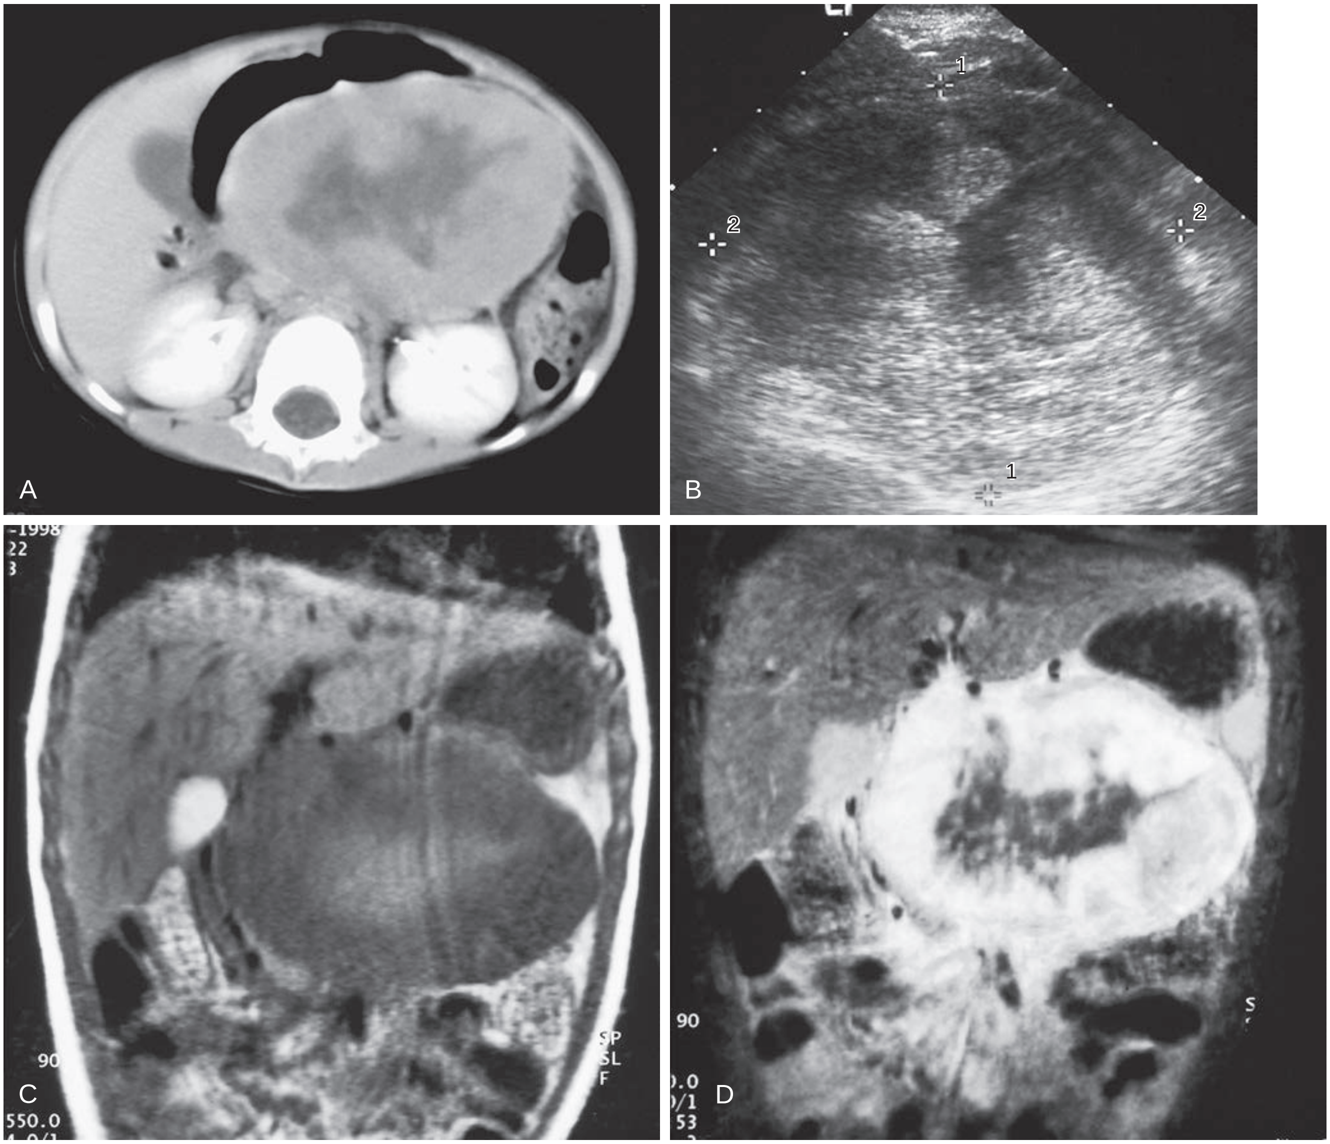
## Other Pancreatic Tumors

***Overview.*** The exocrine tissues of the pancreas give rise to benign and malignant tumors that are hormonally inactive, such as cystadenoma, adenocarcinoma, and adenosarcoma.

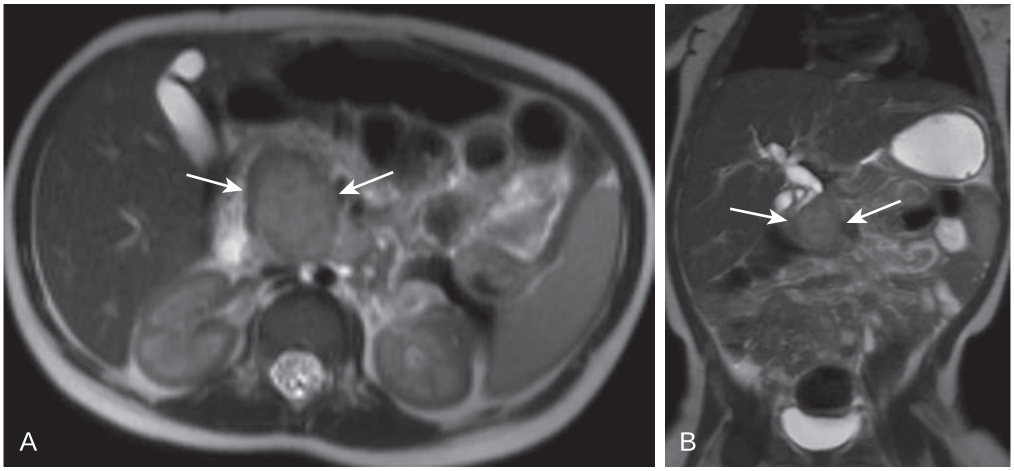
***Clinical Presentation.*** The most common presenting symptoms include abdominal pain in 55.8%, nausea or vomiting in 32.6%, fatigue in 25.6%, and an abdominal mass in 23.3%.[119] Cystadenomas and adenocarcinomas of the pancreas rarely occur in children and have been described in infants as well.[120] Pancreatic adenocarcinoma has been described in an adolescent boy with Peutz-Jeghers syndrome,[121] which carries a 100-fold increased risk.[122]

***Imaging.*** On US, solid tumors are typically hyperechoic, and cystic lesions are anechoic or hypoechoic. Adenocarcinomas may have cystic or hemorrhagic areas that result in mixed echogenicity. CT usually identifies a pancreatic mass of variable size, often causing biliary obstruction. In a recent study, pancreatic duct adenocarcinomas were identified in only 3 patients younger than 20 years among a total cohort of 439 cases.[123] Such tumors are often associated with a genetic predisposition. Because the diagnosis of pancreatic carcinoma is so rare in children (only about 50 cases have been reported), imaging evaluation is often delayed, and vascular invasion and metastases to lymph nodes and liver may be noted on imaging.[123]

Rhabdomyosarcoma may arise primarily in the pancreas (e-Fig. 95.17), as may lymphoma (Fig. 95.18). Neuroblastoma has been reported in the pancreas either as primary (e-Fig. 95.19) or secondary to direct extension. A single case of abdominal desmoid tumor presenting in the pancreas was reported in a 17-year-old boy with familial adenomatous polyposis syndrome.[124]



**e-Figure 95.17. Primary alveolar rhabdomyosarcoma of the pancreas in a 3-year-old boy.** (A) Axial, contrast-enhanced abdominal CT shows a large midabdominal mass that arises from the pancreatic body with a central hypodense area. (B) Axial US through the upper abdomen shows the mass *(between cursors)* to be of heterogeneous echogenicity. (C) Coronal, noncontrast, T1-weighted MR image shows irregular high signal centrally, surrounded by decreased signal in the bulk of the mass. (D) Coronal, contrast-enhanced, T1-weighted MR image with fat saturation shows diffuse, intense peripheral enhancement of the bulk of the mass around the central area in addition to surrounding edema.



**e-Figure 95.19. Primary pancreatic neuroblastoma in a 15-month-old boy with intermittent jaundice.** Axial (A) and coronal (B) T2-weighted MR image of the abdomen demonstrates a gently lobulated, T2-hyperintense mass in the head of the pancreas *(arrows)*. Pathology after a pylorus-sparing Whipple pancreaticoduodenectomy revealed a poorly differentiated primary pancreatic neuroblastoma.

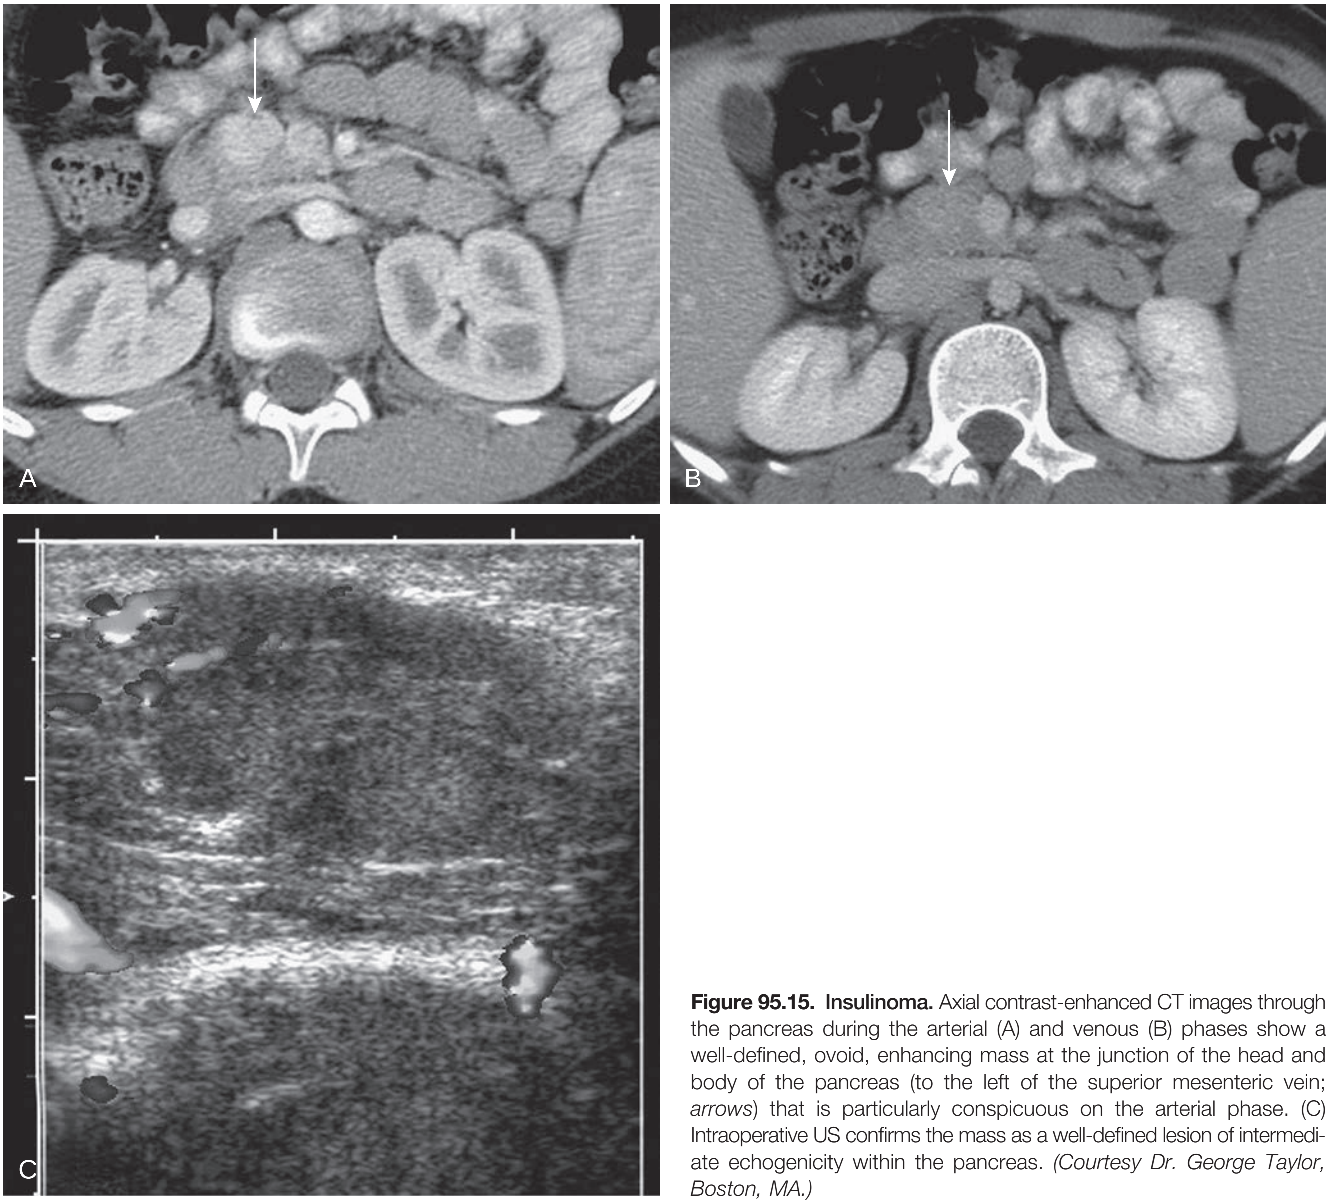


**Figure 95.15. Insulinoma.** Axial contrast-enhanced CT images through the pancreas during the arterial (A) and venous (B) phases show a well-defined, ovoid, enhancing mass at the junction of the head and body of the pancreas (to the left of the superior mesenteric vein; *arrows*) that is particularly conspicuous on the arterial phase. (C) Intraoperative US confirms the mass as a well-defined lesion of intermediate echogenicity within the pancreas. *(Courtesy Dr. George Taylor, Boston, MA.)*

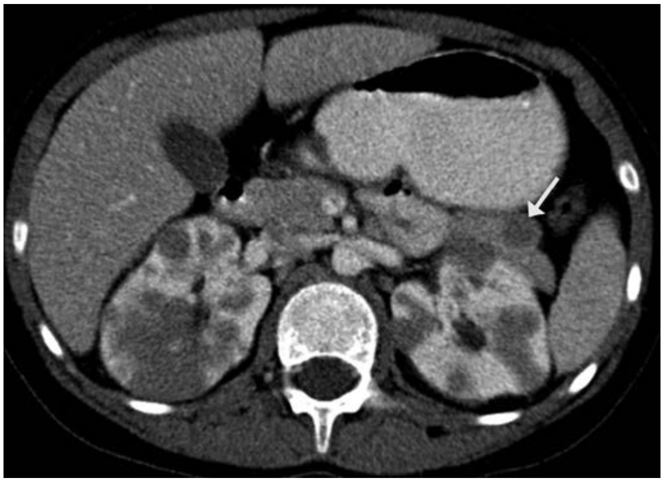

**Figure 95.18. Widely disseminated non-Hodgkin lymphoma involving the pancreas.** Axial contrast-enhanced CT image through the abdomen show, multiple rounded lymphomatous deposits in both kidneys and the pancreatic tail *(arrow)*.

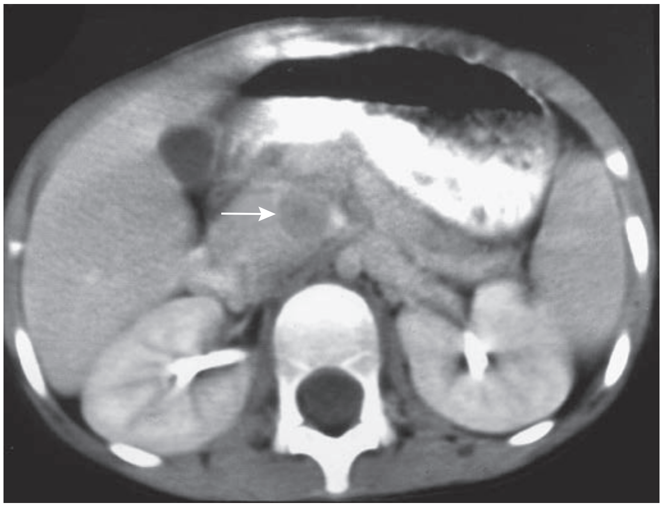
Lymphatic malformations of the pancreas are extremely rare and account for less than 1% of cases.[125] They may occur in any portion of the pancreas at any age and are more frequent in females. On imaging, lymphatic malformations appear as septated, fluid-filled masses. Clinical presentation is nonspecific and includes nausea, vomiting, vague abdominal pain, and a palpable mass.

Exceptionally rare tumors of the pancreas include anaplastic large cell lymphoma,[99] infantile myofibromatosis,[126] and mature cystic teratoma.[127] Cystic teratoma of the pancreas has been reported in at least seven pediatric patients, who ranged in age from 2 to 16 years. These tumors arise from pluripotent cells of ectodermal cell lines and, like other extragonadal teratomas, likely originate from aberrant germ cells. Such tumors may be indistinguishable from other cystic abdominal masses.

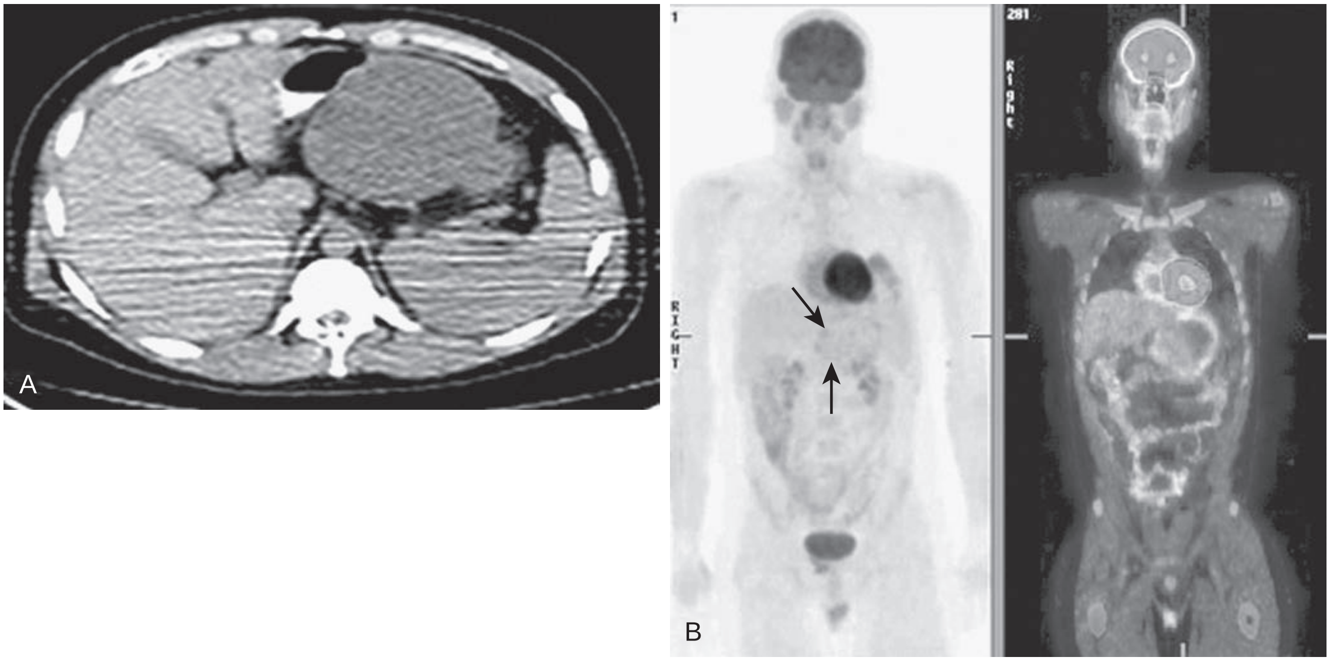
Pancreatic involvement with metastatic disease is also rare but includes malignant melanoma, lymphoma (e-Fig. 95.20), rhabdomyosarcoma (Fig. 95.21), acute lymphoblastic leukemia, and osteosarcoma (e-Fig. 95.22).[128,129]

## Treatment of Pancreatic Neoplasms

Most pancreatic tumors are treated primarily with pancreatic resection and pancreatoduodenectomy. Resection is complete for



**e-Figure 95.20. Primary lymphoma of bone metastatic to the pancreas.** Axial computed tomographic image of the abdomen in an 8-year-old boy with known lymphoma of bone shows a focal, well-defined, hypoattenuating mass within the body of the pancreas *(arrow)*. This lesion showed mild gallium uptake on scintigraphy *(not shown)*.



**e-Figure 95.22. Recurrent osteosarcoma metastatic to the pancreas in a 19-year-old man.** Five years earlier, the patient had been treated with multi-drug chemotherapy and limb-sparing surgery for nonmetastatic primary femoral osteosarcoma. He had been well until coming to medical attention with abdominal pain and fatigue. (A) Noncontrast axial CT through the upper abdomen as part of a fluorodeoxyglucose PET scan shows a large, low-density midabdominal mass arising from the midbody of the pancreas. (B) Anterior planar attenuation-corrected PET image *(left)* shows a subtle blush of uptake in the distribution of the mass *(arrows)*. Fused FDG-PET CT image *(right)* shows minimal peripheral uptake in the mass and central photopenia consistent with central necrosis; this was confirmed by aspiration and biopsy.

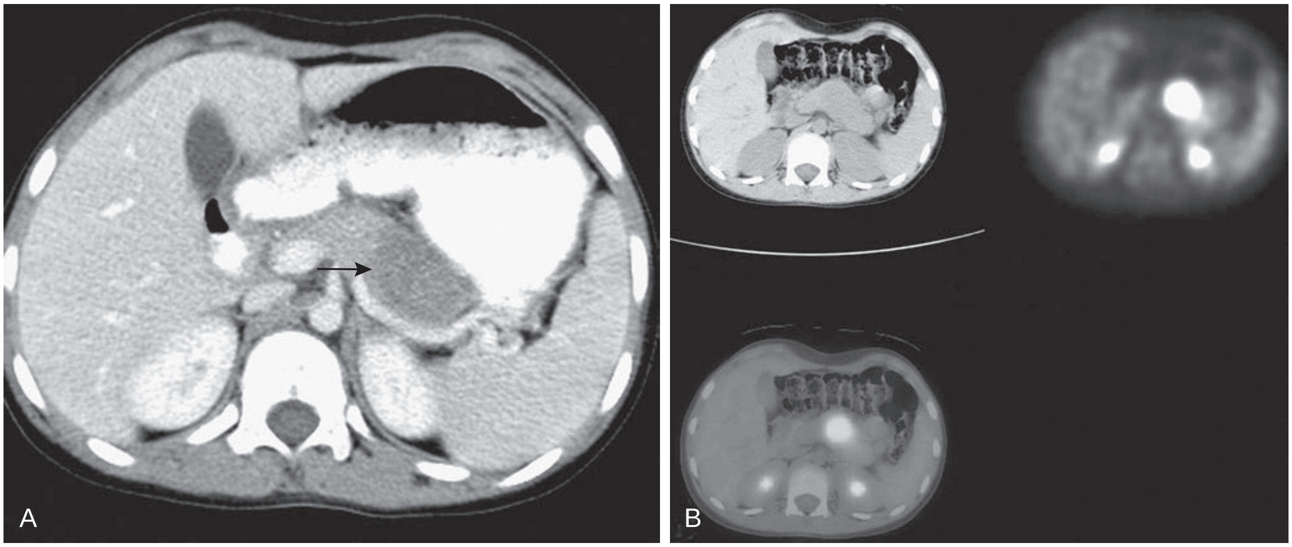


**Figure 95.21. Recurrent rhabdomyosarcoma metastatic to the pancreas.** Three years earlier, this 10-year-old girl had been treated for alveolar rhabdomyosarcoma of the calf. (A) Axial contrast-enhanced abdominal CT shows a well-defined low-density mass in the pancreas *(arrow)*. (B) Axial fluorodeoxyglucose PET CT image shows the lesion as a focal mass with intense uptake of radiopharmaceutical in the midbody of the pancreas.

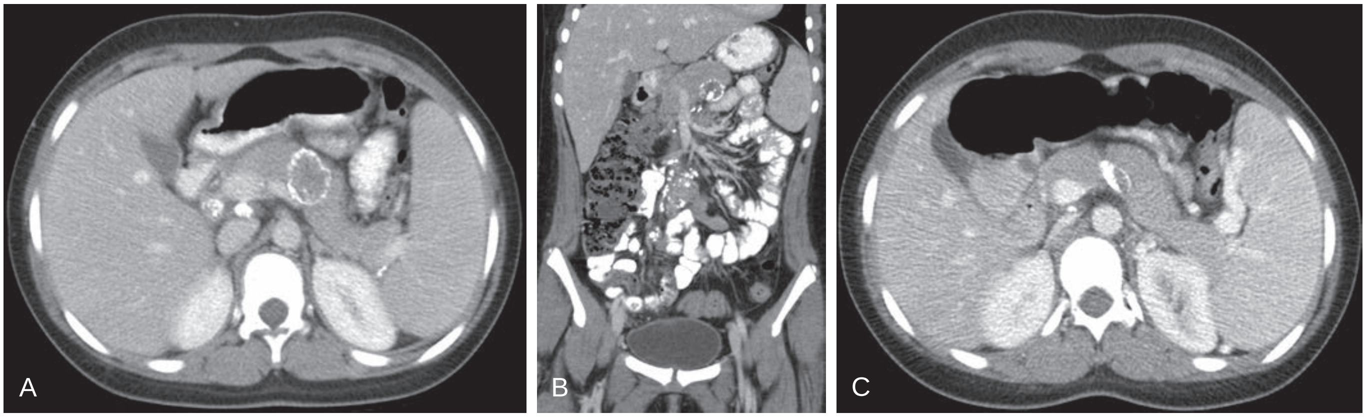

**Figure 95.23. Pancreatic tuberculosis in an HIV-positive teen.** (A) Axial contrast-enhanced CT through the upper abdomen shows a large, peripherally calcified, relatively hypodense lesion in the pancreatic body. (B) Coronal CT image through the abdomen demonstrates this lesion again; both axial and coronal images demonstrate calcified retroperitoneal lymph nodes. This patient was on multidrug therapy for abdominal tuberculosis. (C) Axial CT through the upper abdomen 2 years later demonstrates interval shrinkage of the peripherally calcified pancreatic body lesion; calcific foci appear more coarse and chunky as a result.

aggressive and advanced tumors; partial pancreatectomy[130] and enucleation may be indicated for less aggressive or small neoplasms. Radiotherapy or chemotherapy is less frequently indicated in the pediatric population.[104] Supportive medical therapy may be indicated, such as IV glucose for insulinoma or adenomatosis-induced hypoglycemia and for gastrinoma-induced Zollinger-Ellison syndrome.

## PANCREATIC INFECTIONS

### Hydatid Disease

***Overview.*** Pancreatic hydatid disease, or echinococcosis, is extremely rare and can result from parasitic infestation with *Echinococcus granulosus*, a parasite that affects humans and other mammals, most notably dogs and sheep.[131] The disease manifests as cysts in the affected organ.

***Clinical Presentation.*** Jaundice and abdominal pain may be the first symptoms of hydatid disease of the pancreas, and hydatid disease may also be a rare cause of recurrent pancreatitis.[132]

***Imaging.*** Abdominal CT demonstrates a complex, cystic pancreatic mass, most commonly in the pancreatic head.[131] Larger cysts may have smaller "daughter" cysts within them.

***Treatment.*** Conservative therapy with albendazole and surgical procedures such as subtotal cystectomy, distal pancreatectomy, cystoenteric anastomosis, Whipple resection, marsupialization, and external drainage have been used.

### Tuberculosis

***Overview and Clinical Presentation.*** Patients with abdominal tuberculosis are human immunodeficiency virus positive or otherwise immune compromised, or are from areas endemic for tuberculosis.

***Imaging.*** Abdominal tuberculosis (Fig. 95.23) can result in focal pancreatic parenchymal lesions or tuberculous abscesses, usually with one or more calcified components and imaging evidence of abdominal tuberculosis elsewhere (retroperitoneal adenopathy that is usually matted and may or may not be centrally necrotic or calcified; tuberculous ascites; matting of bowel loops or omentum, so-called omental cake; and intraperitoneal adhesions).[133]

***Treatment.*** Antituberculous multidrug therapy is recommended for up to 1 year; three to four drugs are given for the first 2 months, and then two drugs are given for up to 10 months. Surgical intervention is used for complicated cases.

## KEY POINTS

- Pancreas divisum is a normal variant due to failure of fusion of the dorsal and ventral anlage. The incidence of pancreatitis is slightly higher in individuals with pancreas divisum.
- Annular pancreas typically presents with duodenal obstruction in the neonatal period or pancreatitis/extrahepatic biliary obstruction in adults. There are often associated abnormalities.
- Imaging of patients with CF may reveal a spectrum of findings, from a normal to mildly enlarged pancreas in early stages of the disease to complete fatty replacement with calcification or “pancreatic cystosis” in advanced stages.
- Nonaccidental trauma should be considered as a potential etiology in children with unexplained pancreatic trauma or pancreatitis.
- Complications of acute pancreatitis evident by imaging include pseudocysts, splenic vein thrombosis, and splenic artery pseudoaneurysms.
- Direct evidence of pancreatic trauma at imaging includes contusion, transection, laceration, and comminution. Indirect findings include findings of acute pancreatitis and/or duodenal hematoma.
- Solid-cystic papillary tumor is the most common pancreatic tumor in children.
- Pancreatoblastoma and focal adenomatosis are pancreatic tumors associated with BWS.

## PART 5 Esophagus

# 96 Congenital and Neonatal Abnormalities

Wendy Drew Ellis

## OVERVIEW

Severe congenital esophageal malformations, such as esophageal atresia, are usually diagnosed in the neonate; other congenital lesions, such as isolated tracheoesophageal fistulae (TEF), may remain undetected until later in life. Others, such as duplication cysts, may remain asymptomatic and identified incidentally later in life or even in adulthood.

## ESOPHAGEAL ATRESIA WITH AND WITHOUT TRACHEOESOPHAGEAL FISTULA

***Overview.*** Esophageal atresia with and without TEF is part of a heterogeneous spectrum of anomalies that ranges from isolated esophageal atresia to isolated fistula without atresia. Lesions are typically classified according to the association and location of the fistulous connection between the esophagus and the airway (Fig. 96.1). First described in 1670, esophageal atresia was a universally fatal anomaly until the fifth decade of the 20th century, when pediatric surgeons began successfully treating these children.[1,2] The incidence of esophageal atresia is approximately 1 in 3500 to 5000 births worldwide, with a tendency to occur more commonly in boys, although the gender difference varies with the type of lesion. Maternal risk factors include white race, first pregnancy, and advanced maternal age. There is also an increased risk in the siblings of affected patients.[1,3,4]

***Etiology.*** The development of esophageal atresia is poorly understood and still debated. Dominant theories in the past have been based on the model of a tracheoesophageal septum, a lateral ridge of tissue believed to separate the foregut into a dorsal component (the esophagus) from a ventral component (the trachea) in a caudocephalic direction. However, more recent investigations have suggested that this process does not occur in humans and instead suggest that the formation of the esophagus and trachea is the result of "a system of folds" in the cranial and caudal ends of the tracheoesophageal space that move toward each other, thus separating the space into the ventral trachea and dorsal esophagus. Following this theory, esophageal atresia with fistula results from an abnormally ventral position of the dorsal fold; isolated esophageal atresia is attributed to a vascular accident rather than abnormal separation of the alimentary and respiratory canals.[1,4–6] The association of the esophageal atresia complex with conotruncal anomalies and anomalies associated with DiGeorge syndrome suggests that abnormal development of pharyngeal arches may be related to this malformation.[1]

Further research with animal models concerns the investigation of genes that influence the temporal and spatial sequence of expression of molecular and genetic pathways, including retinoic acid receptors, and sonic hedgehog pathway effectors. Human teratogens that have been associated with this anomaly include abnormal maternal hormonal milieu (including estrogen, progesterone, and thyroid hormones), intrauterine exposure to thalidomide and diethylstilbestrol, and maternal diabetes.[1,7]

***Clinical Presentation.*** Patients with esophageal atresia with or without fistula typically come to medical attention prenatally or soon after birth. At prenatal evaluation patients with isolated esophageal atresia are most likely to be seen in the setting of maternal polyhydramnios with findings of a small or absent stomach bubble. Esophageal atresia and TEF may be suspected during pregnancy with similar findings. Neonates generally come to medical attention in the first few hours of life with excessive salivation and drooling, choking and regurgitation during feeds, and sometimes with cyanosis and/or respiratory distress.[1,3,4]

The incidence of associated congenital anomalies has been reported to be between 50% and 70%; it is most common in infants with isolated esophageal atresia and less common in children with isolated TEF.[3] The most common associated anomalies, in descending order of frequency, include cardiac, genitourinary, gastrointestinal, musculoskeletal, and neurologic anomalies. Approximately half of the children with esophageal atresia who have associated anomalies can eventually be classified as having a known syndrome, either chromosomal or named, such as VACTERL (*v*ertebral anomaly, *a*norectal atresia, *c*ardiac lesion, *t*racheo*e*sophageal fistula, *r*enal anomaly, *l*imb defect) (Fig. 96.2), CHARGE (*c*oloboma, *h*eart malformation, choanal *a*tresia, mental *r*etardation, *g*enitourinary and *e*ar malformations), Fanconi anemia, Opitz, and Goldenhar syndromes. VACTERL alone is present in approximately 20% of patients with esophageal atresia; patients with isolated esophageal atresia have an increased incidence of trisomy 21 (11%) and duodenal atresia (10%).[4,8,9]

***Imaging.*** Imaging is used in both the prenatal and neonatal diagnosis of esophageal atresia. Esophageal atresia is a cause of polyhydramnios. Fetuses with esophageal atresia may also have a small or absent stomach bubble.[4] These ultrasound findings alone lack specificity, with a reported 20% to 40% positive predictive value, and prenatal diagnosis may be made in as few as 10% of patients.[4,10] Diagnostic accuracy is improved when a blind-ending pouch is visualized in the fetal neck, and newer data suggest that fetal magnetic resonance imaging (MRI) may play an increasingly important role in prenatal diagnosis.[11,12] More commonly, the diagnosis is made in the immediate neonatal period. If the diagnosis of esophageal atresia is suspected in the first few hours of life, placement of a flexible feeding tube or enteric tube should be attempted (see Fig. 96.2). Introduction of contrast into the pouch is not typically necessary for confirmation of the diagnosis and can result in aspiration, although air may improve its identification and elucidate proximal pouch length.[4] Careful introduction of contrast into the pouch may reveal the rare patient who has a proximal fistula with or without atresia, but the danger of aspiration remains, and this diagnosis is typically made endoscopically.

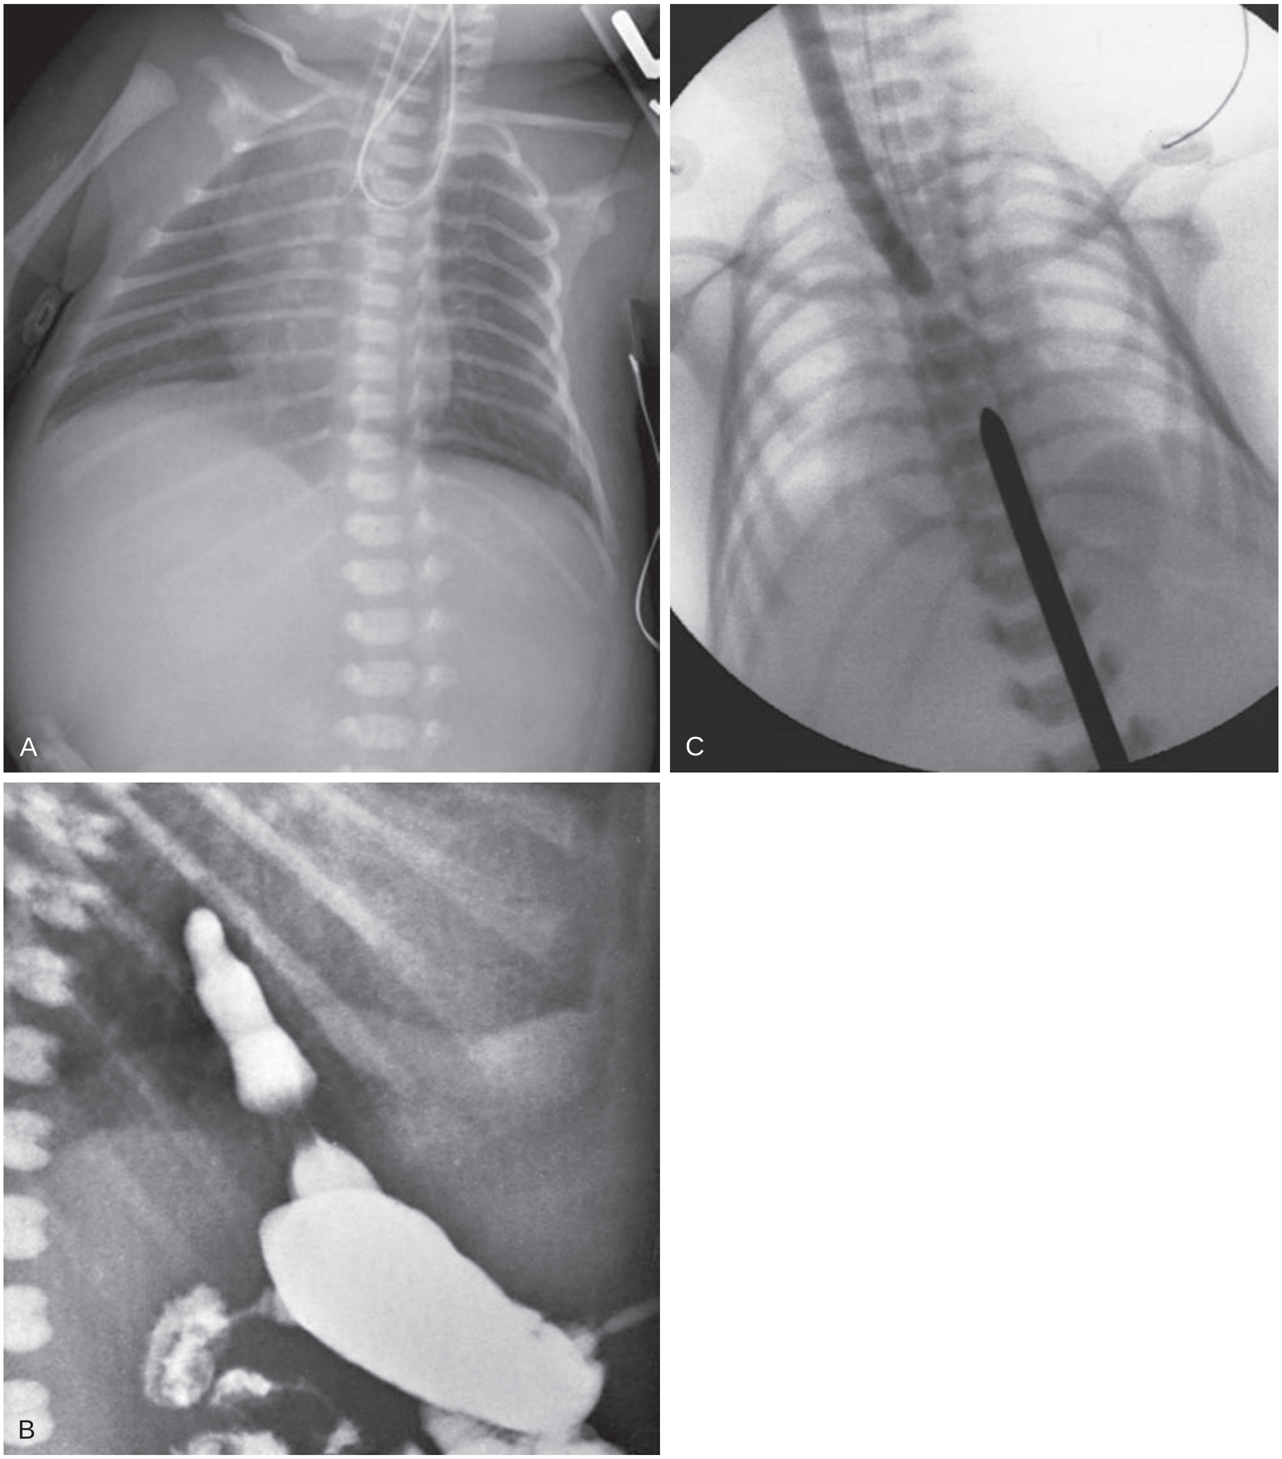
On radiographs of the abdomen, absence of bowel gas indicates esophageal atresia without a distal TEF (e-Fig. 96.3), while the presence of gas in the abdomen indicates that there is a distal TEF (see Figs. 96.2 and 96.4). TEF from the proximal pouch cannot be excluded with chest radiographs and requires endoscopy for diagnosis. In patients who are on assisted ventilation, air may be forced into the stomach through the fistula, resulting in gastric overdistension and even perforation, particularly in infants who are intubated or have duodenal atresia. Approximately 2.5% of patients will have a right-sided aortic arch that should be identified on preoperative echo or ultrasound as esophageal repair is performed on the side opposite the arch.[1,4,13,14]

## Abstract:

Esophageal abnormalities of the newborn represent a diverse group of conditions, and include congenital anomalies ranging from various types of atresia, duplications and enteric fistulae, duplications as well as acquired conditions such as pharyngeal and esophageal perforation.

## Keywords:

esophageal atresia
tracheoesophageal fistula
foregut duplication
pharyngeoesophageal perforation
neurenteric cyst



**e-Figure 96.3. Isolated esophageal atresia.** (A) Newborn boy born at 37 weeks' gestation with isolated esophageal atresia. The enteric tube turns cephalad in the blind-ending proximal esophageal pouch, and abdominal bowel gas is absent. (B) Gastrostomy injection with reflux into the short distal esophageal segment in a patient with esophageal atresia without a distal fistula. (C) Esophageal atresia with the gap between the segments confirmed at surgery. Frontal view reveals bougies in both the proximal and distal segments, showing a long gap between them.

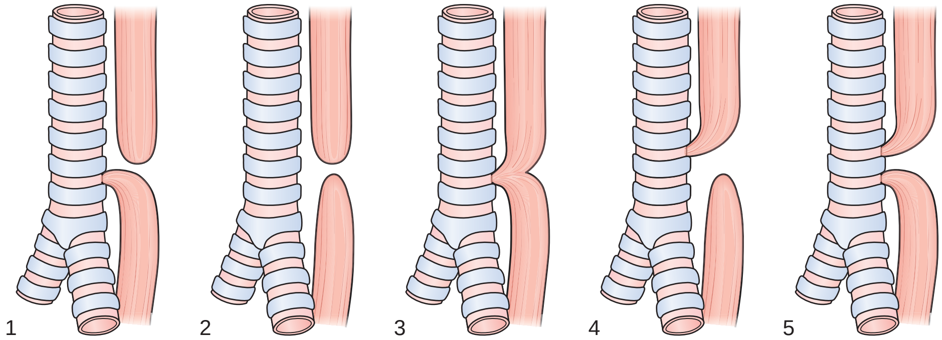


**Figure 96.1. Types of esophageal atresia, with and without tracheoesophageal fistula.** *Type 1* represents esophageal atresia with a distal fistula and is the most common form, occurring in approximately 84% of patients. *Type 2* illustrates esophageal atresia without a fistula, seen in about 6%. *Type 3* is an isolated H-type fistula (4%), and *type 4* describes esophageal atresia with the fistula arising from the proximal pouch (5%); *type 5,* with fistulae arising from both the proximal and distal pouch, is the least common (~1%).[1]

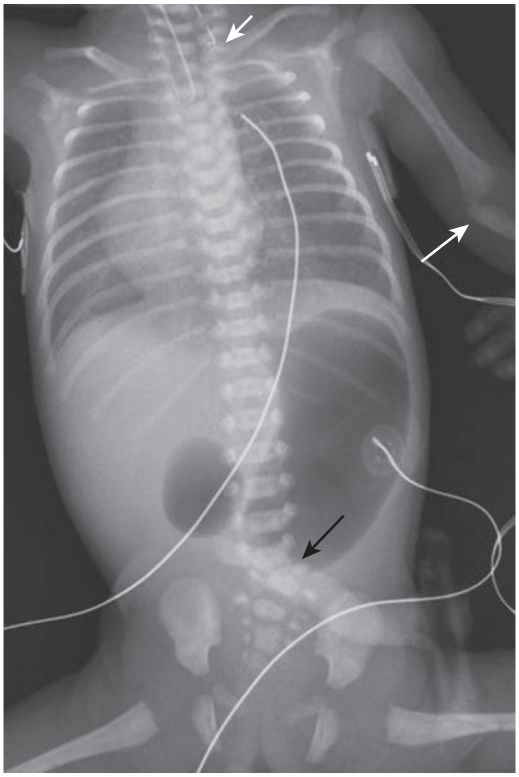

**Figure 96.2. VACTERL (*v*ertebral anomaly, *a*norectal atresia, *c*ardiac lesion, *t*racheoesophageal fistula, *r*enal anomaly, *l*imb defect) syndrome.** Newborn girl born at 32 weeks' gestation demonstrates the abnormalities seen with the VACTERL association. The patient is intubated because of the lung disease of prematurity. The enteric tube *(short white arrow)* ends just above thoracic inlet in the proximal esophageal pouch, and abdominal bowel gas indicates a distal tracheoesophageal fistula, whereas a "double bubble" sign and absence of distal bowel gas indicate duodenal atresia. There are 13 pairs of ribs, and a hemivertebra between L5 and S1 *(black arrow)*. Note the absent radius in the left arm (*white arrow* points to the ulna).

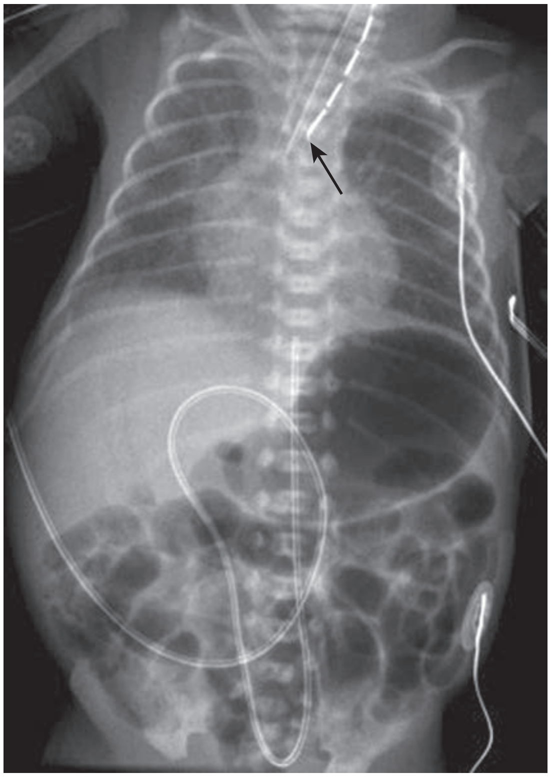

**Figure 96.4. Esophageal atresia with tracheoesophageal fistula.** Radiograph of a newborn preterm girl shows that the enteric tube *(arrow)* ends in the proximal esophageal pouch with abundant distal gas.

***Treatment/Follow-up.*** Surgical repair is typically undertaken within 1 to 2 days, after the clinical workup is complete, including treatment of more emergent medical issues. Open or thoracoscopic division/ligation of the fistula and primary esophageal anastomosis is the treatment of choice. Long-gap atresia, which accounts for approximately 25% of patients with esophageal atresia, is defined as a separation between the proximal and distal segments of greater than 2.5 cm. For these patients, a staged approach is employed, including early placement of a gastrostomy tube for nutritional support while mechanical traction is used to more closely appose the proximal and distal pouches before repair.[4] Isolated esophageal atresia is typically associated with a small proximal pouch and almost no thoracic esophagus (see e-Fig. 96.3), and patients are typically palliated with a gastrostomy in the first 24 to 48 hours of life, followed by delayed repair. Alternatively, if these procedures fail, a gastric pull-up or an esophageal substitute (usually jejunum or colon) can be interposed between the proximal and distal

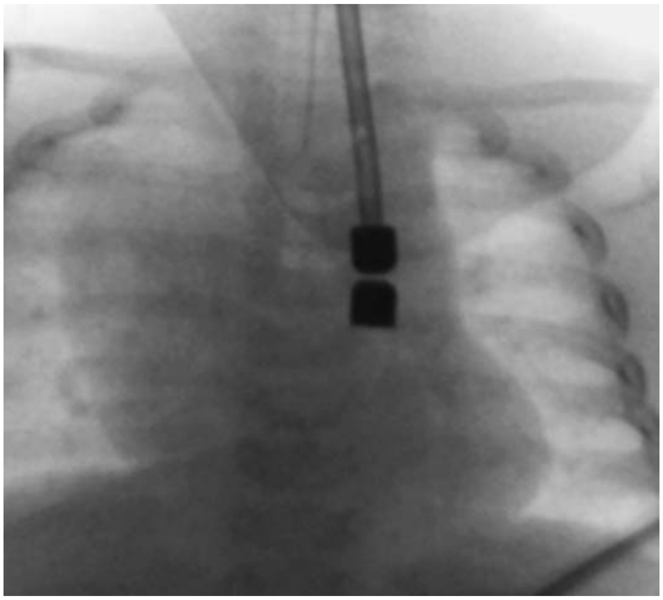

**Figure 96.5. Magnets in esophageal atresia.** Single fluoroscopic image demonstrates the magnetic probes placed in the proximal esophageal pouch and into the distal segment through the gastrostomy.

segments.[1,4] More recently, some centers, particularly in Europe, have used magnets to approximate and unite long gap segments shorter than 4.5 cm (Fig. 96.5).[15,16]

Imaging also plays an important role in the evaluation of early and late complications of esophageal atresia repair. Complications include anastomotic leak, anastomotic stricture, and recurrent TEF[17]; these are evaluated with esophagram (e-Fig. 96.6). Because standard esophageal contrast studies reportedly may miss as many as 50% of recurrent fistulae, bronchoscopy may also be required if a recurrent fistula is suspected.[1]

## ISOLATED TRACHEOESOPHAGEAL FISTULA

***Overview.*** Congenital, isolated TEF without atresia of the esophagus (type 3 in Fig. 96.1) is often termed an *H-type fistula*, and it differs significantly from the other types of tracheoesophageal malformations. Large fistulae usually present very early in life and are relatively easy to see on an esophagram (Fig. 96.7). More commonly, the fistulae are small, inconstantly patent, difficult to identify both clinically and radiographically, and may require repeated examinations and/or endoscopy for diagnosis.[4,18,19] A major reason for inconstant patency of a fistula is that normal esophageal mucosa can be redundant, which can transiently occlude the esophageal side.[20] Although rare, multiple fistulae can be present.[21]

Rarely, a bronchus originates directly from the esophagus, termed an *esophageal bronchus* (see also Chapter 52). If the connection is to the entire lung rather than a segment or lobe, it is termed *esophagotrachea* or *esophageal lung*.[22,23] This anomaly may be associated with esophageal atresia, TEF, or both.[22]

***Clinical Presentation.*** These patients typically present with recurrent episodes of coughing or choking and may progress to recurrent pneumonias, either in infancy or later in childhood; very rarely the presentation may be in early adulthood.[4,22,24,25] Patients with unexplained, intermittent respiratory distress and recurrent pneumonia should always be considered at risk for the presence of a TEF, and radiographic examination is warranted. Esophageal bronchus likewise presents with respiratory distress and pneumonia.

***Imaging.*** The term *H-type fistula* refers to its appearance on esophagram: the fistula courses cephalad from the esophagus posteriorly to the trachea anteriorly as it connects these two structures (see Fig. 96.7).

The examination should begin as a single-contrast esophagram using digital, pulsed fluoroscopy in the right lateral to slightly right anterior oblique position. The position should be optimized during the examination to allow the best view of the anterior wall of the esophagus and posterior wall of the trachea. A key element to the success of this examination is achieving full distension of the esophagus, to optimize filling and visualization of the fistula. If the esophagus does not distend optimally and no abnormality is detected while the patient is swallowing, an esophageal catheter may be placed for introduction of contrast under fluoroscopic guidance. This is considered especially in patients with normal prior examinations in whom a fistula remains suspect or in those in whom contrast is seen within the trachea from an unclear source (i.e., patients in whom aspiration versus fistulous connection cannot be differentiated).[26,27] The examiner slowly withdraws the catheter from the distal esophagus in the cephalic direction, while carefully injecting contrast material with enough velocity and volume to distend the esophagus maximally under constant fluoroscopic monitoring. The catheter should have an end hole, without more proximal side holes, for adequate control of the contrast infusion. Even if a fistula is noted, the injection should continue until the catheter is withdrawn into the hypopharynx, but care must be taken not to allow contrast material to spill over into the trachea. Although there is a danger of spilling contrast material into the airway with injection of the high cervical esophagus, it is important to examine this area because many fistulae occur at the level of the lower cervical or upper thoracic spine (see Fig. 96.7C).[28] Slow retraction of the catheter and careful fluoroscopic monitoring allow constant visualization and help to prevent overflow into the trachea.[28] Esophageal bronchus is well outlined on upper GI examination, and also with cross-sectional imaging, particularly computed tomography (CT) (Fig. 96.8A and e-Figs. 96.8B and 96.8C).[29]

***Treatment/Follow-up.*** Surgical correction of the connection between the esophagus and the airway is the treatment of choice. Endoscopic, thoracoscopic, and open thoracotomy surgical techniques can be used.[30,31]

Esophageal dysmotility, stenosis at the anastomotic site, and gastroesophageal reflux are common long-term issues in patients who require repeat imaging and often additional treatments.[4,31]

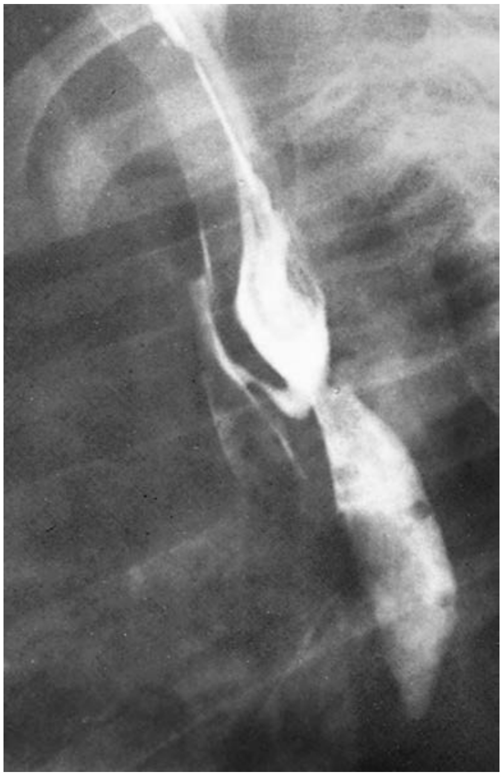
## LARYNGOTRACHEOESOPHAGEAL CLEFTS

***Overview.*** Laryngotracheoesophageal clefts occur in approximately 1 in 10,000 to 20,000 live births and consist of fistulous communications between the alimentary canal and the airway, either confined to the hypopharynx and larynx (Fig. 96.9) or extending inferiorly to include the esophagus.[32,33] Several related classifications have been proposed based on the extent of the communication between the respiratory and alimentary pathways.

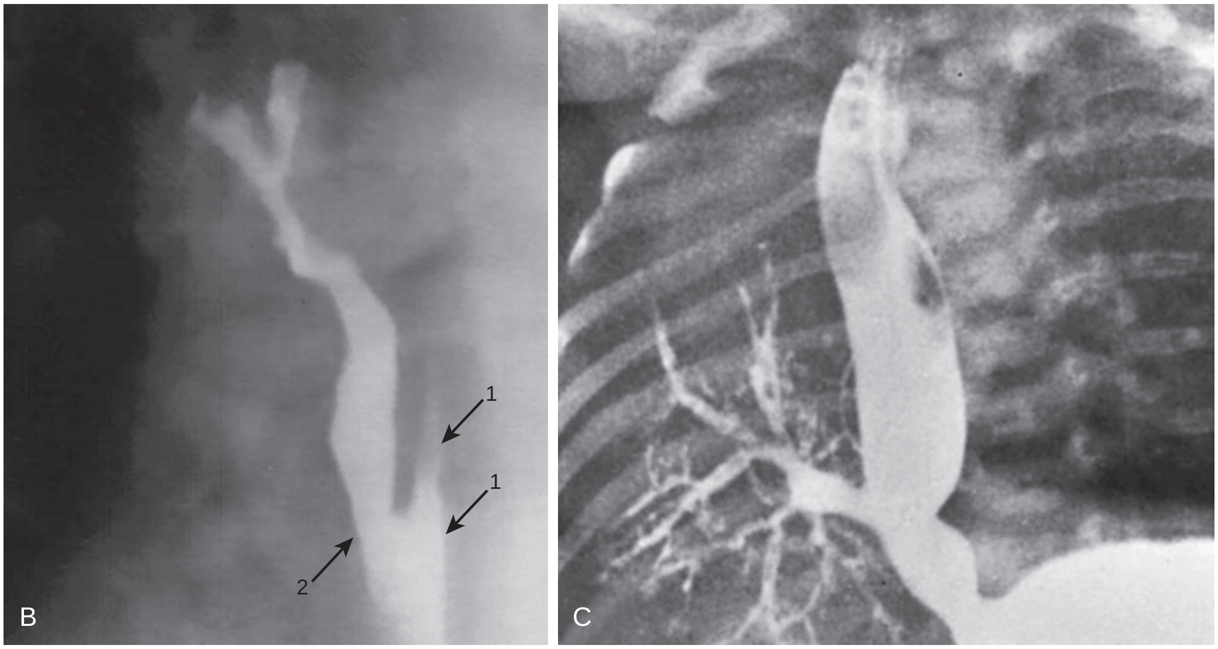
The Benjamin-Inglis classification system, first published in 1989 and since modified to include therapeutic implications, describes four basic lesions (Table 96.1) that are classified on the length and location of the cleft.[32,33]

***Etiology.*** The larynx forms from the endoderm of the foregut caudally and from the mesenchyme of branchial arches four and six cranially.[32,34] Incomplete separation and/or incomplete midline fusion of these concurrent processes during early gestation is believed to result in the persistent midline defect with varying extent and severity.

***Clinical Presentation.*** The clinical presentation varies with the extent of the cleft; varying degrees of respiratory distress that begin early in infancy are aggravated during feeding with choking, stridor, aspiration, recurrent pneumonia, and cyanosis.[32,34] Patients with smaller defects, particularly type I, may present and come to diagnosis later; infants with type III and IV lesions typically present very soon after birth. In some patients, esophageal mucosa



**e-Figure 96.6. Recurrent tracheoesophageal fistula.** Contrast esophagram demonstrates a fistulous connection with the airway at the site of the anastomosis, a finding typical of fistula developing as a postoperative complication.



**e-Figure 96.8.** (B) Congenital esophagobronchial fistula. Oblique view shows esophagus (*arrows* with 1) and bronchus to right upper lobe (*arrow* with 2). (C) Esophageal bronchus. Frontal view from an esophagram demonstrates the origin of the right main bronchus from the distal esophagus.

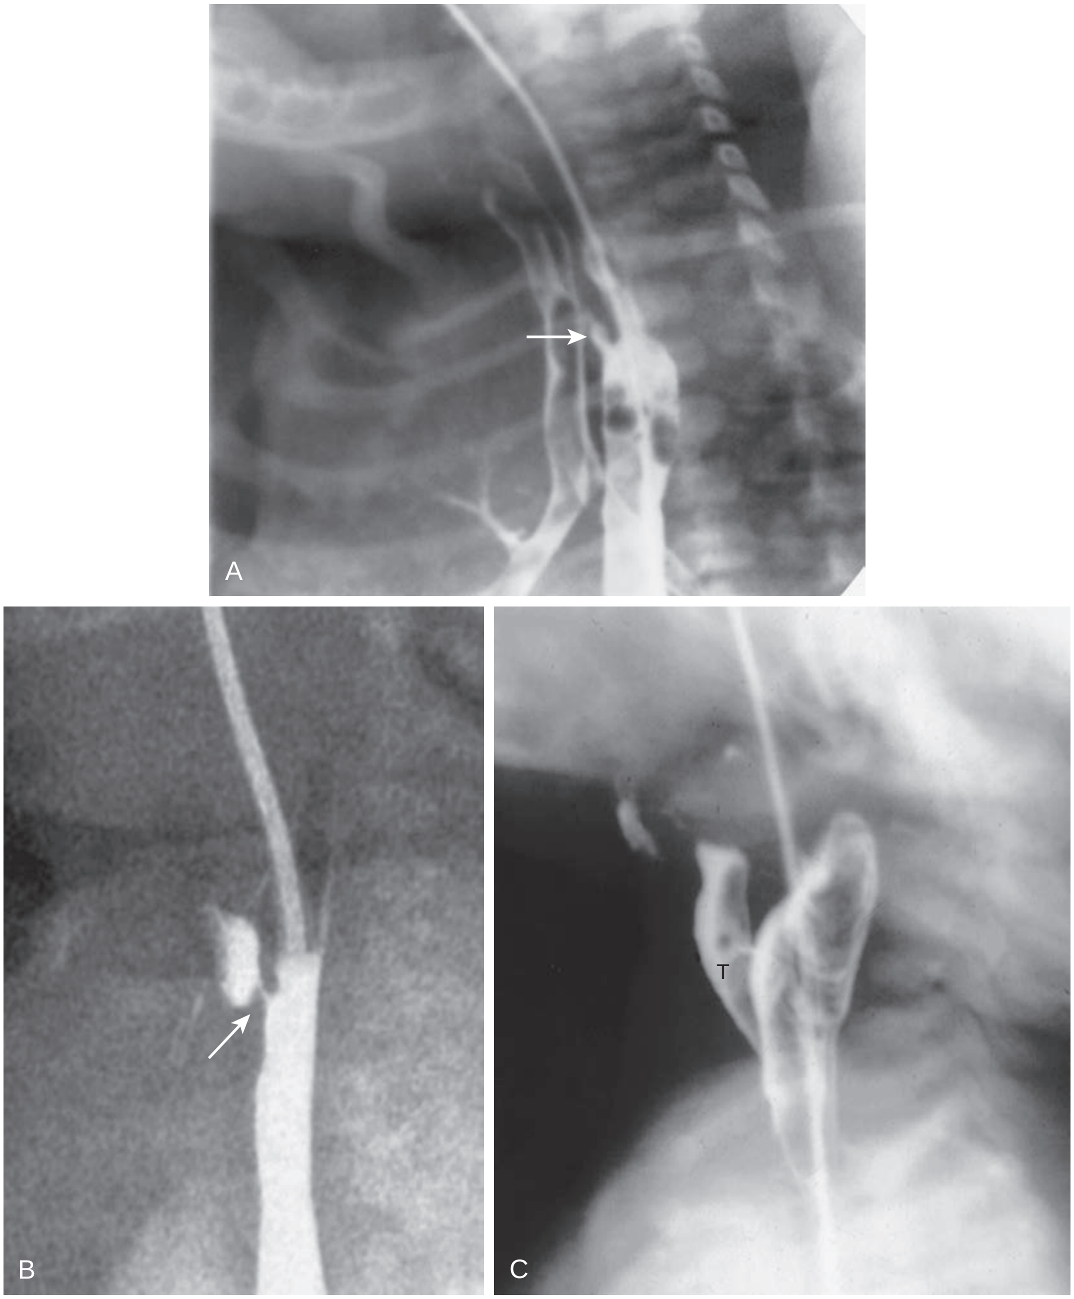


**Figure 96.7. H-type tracheoesophageal fistula.** (A) Tracheoesophageal fistula *(arrow)* in a 7-day-old boy with imperforate anus. (B) Demonstration of another H-type fistula *(arrow)* from the upper cervical esophagus to the trachea, using the technique of contrast injection through a feeding tube with very careful volume control. (C) Large H-type fistula from the upper cervical esophagus to the trachea *(T)*.

**TABLE 96.1** Benjamin-Inglis Classification of Laryngotracheoesophageal Clefts

| **Lesion Type** | **Type I** | **Type II** | **Type III** | **Type IV** |
|---|---|---|---|---|
| **Description** | Interarytenoid defect to the level of the vocal cords | Extension below vocal cords with incomplete extension through posterior cricoid | Complete extension through the posterior cricoid cartilage to the cervical trachea and esophagus | Extension to the intrathoracic trachea and esophagus |

herniates into the defect and offers some protection against aspiration, but symptoms of respiratory distress secondary to compromise of the airway typically worsen.[32] Associated anomalies such as esophageal atresia, VACTERL association, and other abnormalities such as anal atresia, bronchial or tracheal stenosis and pulmonary hypoplasia, hypospadias, and coarctation of the aorta may occur. Laryngotracheoesophageal clefts may also occur as part of syndromes such as CHARGE, Opitz G/BBB (laryngeal malformations, craniofacial anomalies, genitourinary anomalies, and ventral midline anomalies), and Pallister-Hall (laryngeal, gastrointestinal [GI], cardiopulmonary, limb, and neurologic malformations) syndromes.[32–34]

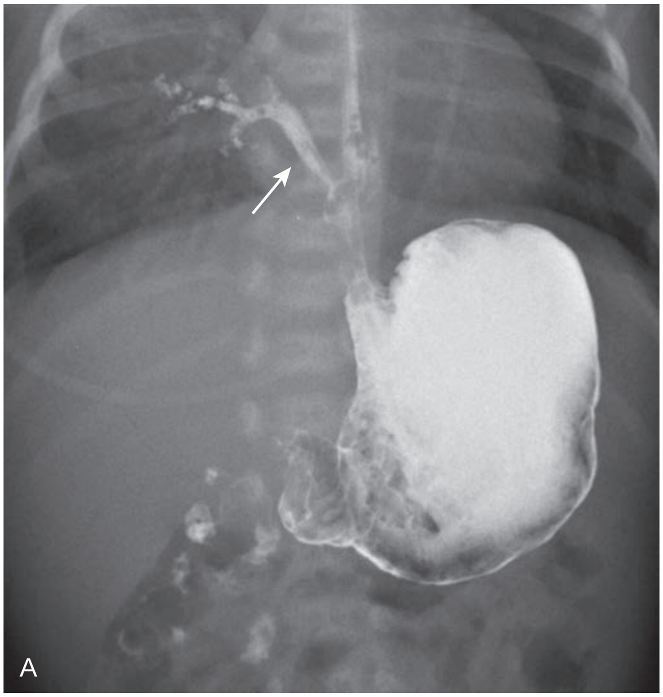

**Figure 96.8. Connections between esophagus and airway.** (A) Spot radiograph from an esophagram in a neonate with recurrent coughing/choking during feeds shows an esophageal bronchus *(arrow)* extending to the right lower lobe. *(Courtesy Alex Towbin, MD, Cincinnati, OH.)*

***Imaging.*** Diagnosis is usually made by direct laryngoscopy (see Fig. 96.9B). In some patients, such as those with type III and IV clefts, the diagnosis may be made during bronchoscopy undertaken to investigate symptoms of respiratory distress. On chest radiography, findings of chronic aspiration such as pneumonia, peribronchial wall thickening, and scarring can be seen.[34] On contrast esophagram (see Fig. 96.9A), contrast is seen within the airway, although this can be confused with aspiration or with TEF. If CT is performed, a common tracheoesophagus may be seen in extensive lesions, containing both the endotracheal and orogastric tubes, or expected tissue between trachea and esophagus may be absent.[32]

***Treatment Follow-up.*** The goal of treatment is to maintain the airway and ventilation while minimizing aspiration and allowing adequate nutrition. For minor clefts, medical therapy may be attempted initially.[33,34] Endoscopic surgical repair should be considered for types I, II, and some type III clefts. The remaining type III and IV are usually corrected with an open surgical approach,[34,35] and extensive clefts may require both cervical and thoracic approaches.[1,34] Postoperative survival rates range between 50% and 75%, depending on the extent of the cleft and severity of associated anomalies.[1,34] Late complications include anastomotic leaks, pharyngeal and esophageal dysfunction, and gastroesophageal reflux.[1,34]

## ACQUIRED PHARYNGOESOPHAGEAL PERFORATION

***Overview.*** Iatrogenic perforation of the pharynx and esophagus was first reported more than 40 years ago and, while reportedly rare, may occur more frequently than is recognized by the literature.

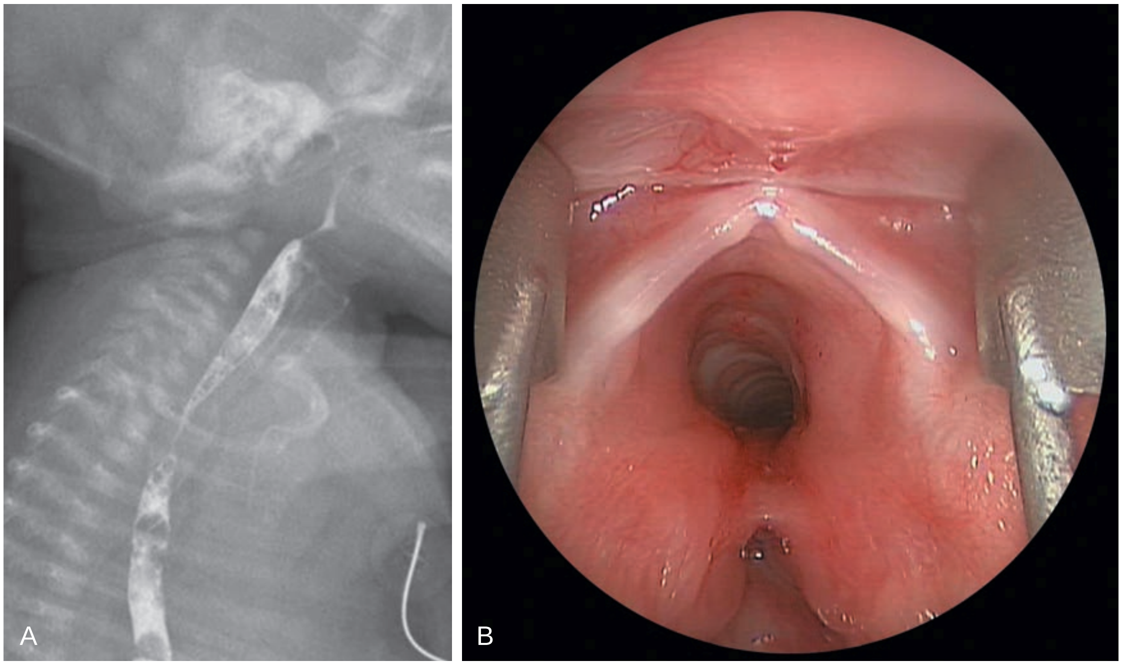

**Figure 96.9. Laryngotracheal cleft.** (A) Laryngotracheal cleft. Contrast swallow demonstrates large-volume aspiration from a posterior laryngeal wall defect. (B) Endoscopic photograph from the same patient shows a posterior laryngeal wall defect and type 2 or 3 laryngotracheal cleft.

It is typically secondary to manipulation, such as intubation and enteric tube placement. The imaging findings may overlap with those of esophageal atresia and can lead to misdiagnosis.[4,36,37]

***Etiology.*** This injury is more common among premature infants.[38] The mechanism of injury to the pharynx and upper esophagus is believed to relate to reflexive contraction of the cricopharyngeus muscle and narrowing of the esophageal introitus as it is compressed against the cervical vertebrae with hyperextension of the infant's neck. This leads to formation of a retroesophageal tract, which descends along the posterior mediastinum. The path of the catheter, or that of subsequently inserted catheters, may follow the perforation and enter the blind-ending tract in the prevertebral space; this may resemble the appearance of esophageal atresia on radiographs.[36,39] Alternatively, the catheter may pass into the right pleural space, presumably as the tube passes above the cricopharyngeal "roll bar" (the posterior and transverse hypopharyngeal portions of the cricopharyngeal muscle) and is deflected to the right by the brachiocephalic vessels. Saliva, formula, and gas collect in the pleural space.[40,41]

***Imaging.*** On chest radiographs, the findings of air or of a coiled enteric tube over the cervicothoracic junction may resemble the findings in esophageal atresia; distinguishing features include an unusually long blind pouch representing the false lumen, with irregular outline. Alternatively, an abnormal course of an enteric tube may be diagnostic (Fig. 96.10A–C). Esophagrams should be performed with water-soluble contrast at or near iso-osmolar concentration. Contrast extravasates into the newly created retroesophageal space (Fig. 96.10D). Introduced contrast material with time dissipates along adjacent tissue. Coexisting pneumomediastinum and pneumothorax or hydropneumothorax are helpful signs in detecting this complication and in differentiating it from esophageal atresia (see Fig. 96.10).[36–38]

***Clinical Findings.*** Although the initial clinical presentation may be relatively silent, patients typically manifest increased secretions with episodes of choking and cyanosis associated with feeding, and the development of crepitus and clinical deterioration follows. There is inability to easily pass a feeding catheter. Early diagnosis is critical as delay leads to increased morbidity and mortality.[4,38]

***Treatment/Follow-up.*** Once the injury has been recognized, the majority of these patients can be managed conservatively, with withdrawal of enteral feedings, broad spectrum antibiotics, and drainage of pleural effusion or pneumothorax if present. This management is successful in the vast majority of patients, and surgical treatment is reserved for complications, such as mediastinal abscess.[36–38]

## ESOPHAGEAL STENOSIS

***Overview.*** Congenital esophageal stenosis is a rare condition that occurs in 1 in 25,000 to 50,000 live births. The three histologic subtypes are fibromuscular stenosis, membranous web, or tracheobronchial remnants.[42]

Membranous stenosis is considered one of the rarest forms of this rare lesion and is usually located in the middle or distal third of the esophagus; it typically demonstrates an eccentric opening and is covered with squamous epithelium. Fibromuscular stenosis demonstrates subepithelial proliferation of smooth muscle and fibrosis. Stenosis associated with tracheobronchial remnants demonstrates cartilaginous tissue proliferation that partially or completely encircles the esophagus—usually in the lower third, within 3 cm of the gastroesophageal junction—and is often associated with esophageal atresia and TEF.[1,43,44]

***Etiology.*** The etiology of fibromuscular stenosis is uncertain, whereas that of membranous stenosis may be similar to that of membranous stenosis elsewhere in the GI tract. Stenosis as a result of tracheobronchial rests is thought to arise from incomplete separation of the tracheoesophageal septum during gestation with sequestration of the tracheal cartilage in the esophageal wall; this is carried distally by the growth of the esophagus.[1,44,45]

***Clinical Presentation.*** The typical presentation is that of dysphagia later in infancy, especially after introduction of solids.[1,46] Older patients may present with regurgitation, choking, vomiting, or failure to thrive.[42,44] Patients may also come to medical attention with retention of a foreign body outside of the cervicothoracic junction, the aortic arch, the left bronchial crossing, or the gastroesophageal junction, which are the typical locations in which foreign bodies lodge in the normal esophagus.[42]

***Imaging.*** Esophagram in patients with esophageal stenosis demonstrates an area of narrowing with partial obstruction. Stenoses secondary to web or to fibromuscular hypertrophy may be seen in the upper or mid portion of the esophagus. Stenoses secondary to tracheobronchial remnants appear as a discrete narrowing of the esophagus along its distal portion, typically within 3 cm of the gastroesophageal junction (Fig. 96.11A and e-Fig. 96.11B), particularly in a patient with esophageal atresia. The diagnosis may be confirmed by endoscopy and histopathology.[4,42,47]

Because of the rarity of congenital esophageal stenosis, the findings at esophagram may be misinterpreted as stricture, such as secondary to gastroesophageal reflux, or as achalasia, if located very close to the gastroesophageal junction.[45,47] In such cases, specific reflux studies and manometric studies to exclude the diagnosis of achalasia may be helpful.[47]

If the diagnosis is delayed, cross-sectional imaging may demonstrate marked thickening of the wall of the esophagus, resembling esophageal leiomyomatosis.[47]

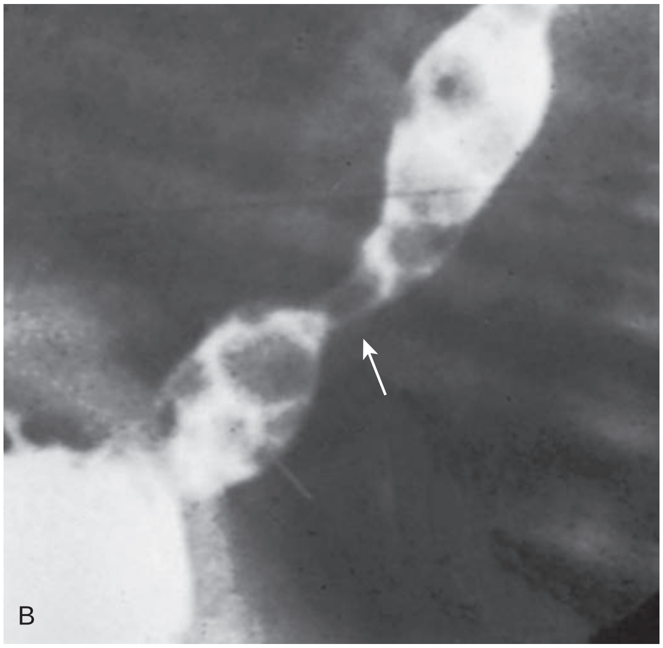
***Treatment/Follow-up.*** It is essential that a stricture as a result of gastroesophageal reflux be excluded before the diagnosis of esophageal stenosis is made.[1] Endoscopic balloon dilatation can be used as a primary and therapeutic procedure and is most successful in those patients without a true cartilaginous component of the stenosis.[42,48,49] Membranous stenoses are amenable to endoscopic dilation and resection, although surgical resection of the stenotic segment is reserved for strictures that are not amenable to dilation or that recur.[42,50] A follow-up esophagram can be performed to assess for perforation, recurrent stenosis, or stricture after dilation or surgical resection.[42]

## ESOPHAGEAL DUPLICATION CYSTS

***Overview.*** Duplication cysts of the esophagus represent part of the spectrum of foregut duplication cysts, which in addition to esophageal duplication cysts, also include bronchogenic cysts and neurenteric cysts. Bronchogenic cysts typically include mural cartilage or respiratory glands and are discussed in Chapter 53. Neurenteric cysts communicate with the spinal canal through a vertebral defect and are additionally discussed in Chapters 43 and 58.

Esophageal duplication cysts represent approximately 10% of mediastinal masses in children and approximately 20% of alimentary tract duplications, being the most common site of duplications after the ileum.[51,52] They are found most commonly in the chest associated with the thoracic esophagus; however, they also may occur in the neck, associated with the cervical esophagus, or they may involve the thorax and the upper abdomen as in a thoracoabdominal duplication cyst. Approximately two-thirds occur in the right side of the mediastinum.[52–54]

Diagnostic criteria met by esophageal duplication cysts include attachment to the esophagus, two muscular layers enveloping the cyst, and lining by squamous, columnar, cuboidal, pseudostratified, or ciliated epithelium, or epithelium that "demonstrates some level of the gastrointestinal tract."[4,53] The vast majority of esophageal duplications are of the cystic, noncommunicating type; true tubular duplications of the esophagus are rare.[55–57] These cysts may extend below the diaphragm to involve the stomach, and they may communicate with the stomach or esophagus.[51]



**e-Figure 96.11.** (B) Esophagram on another patient demonstrates stenosis in the distal portion of the esophagus (*arrow*) secondary to cartilaginous remnants. *(Courtesy Dr. E. Afshani, Buffalo NY.)*

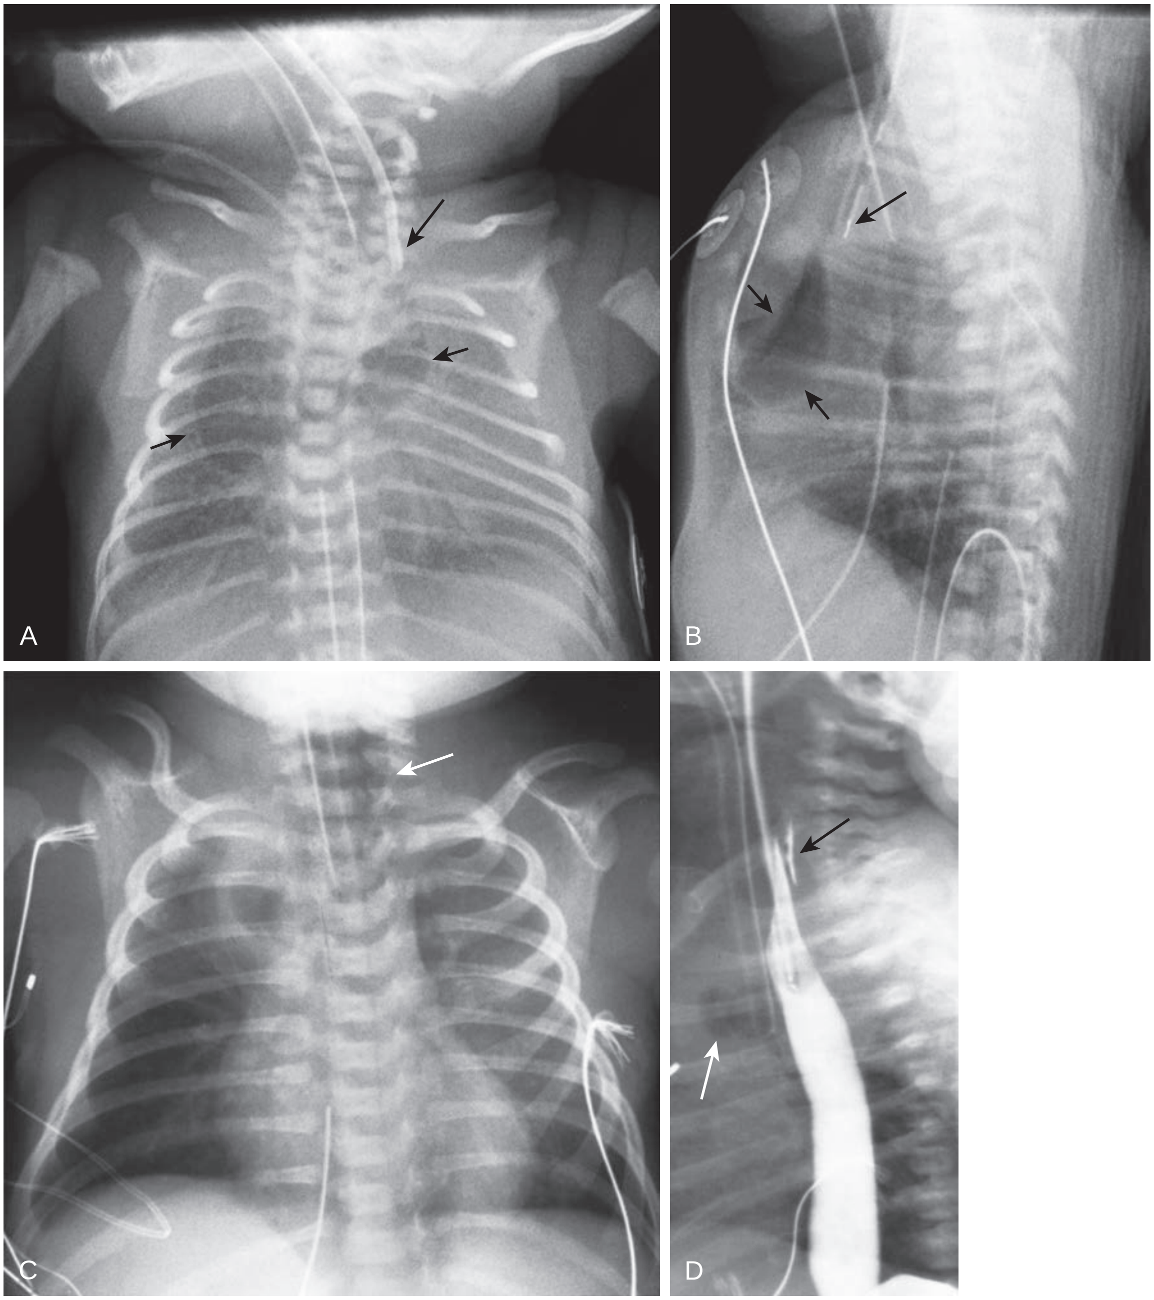


**Figure 96.10. Traumatic pharyngoesophageal perforation.** (A) Frontal chest in a 24-week premature infant reveals an unusual course of the enteric tube, terminating at a level that might suggest esophageal atresia *(long arrow)*. However, there is also an abnormal gas collection in the mediastinum *(short arrows)*. (B) Lateral view on same infant shown in A illustrates an abnormally anterior course of the enteric tube *(long arrow)* and anterior location of the loculated gas collection *(short arrows),* confirming traumatic pharyngeal perforation. This case is unusual in the anterior location of the collection, which clearly excludes esophageal atresia. The perforation healed spontaneously and the patient did well. (C) Frontal chest radiograph reveals an opacity in the right upper lobe with air in its center, consistent with hydropneumothorax. Note the hyperlucency in the lower neck, resembling the findings of an esophageal pouch in esophageal atresia *(arrow)*. (D) Esophagram shows air in the mediastinum *(white arrow)* and contrast extending behind the esophagus, a more typical location for perforation *(black arrow)*.

Neurenteric cysts are duplication cysts that communicate with the spinal canal. The typical example of this spectrum of anomalies is the dorsal enteric fistula, a patent communication between the gut and the dorsal midline skin surface, which traverses the vertebral body or the interspace, spinal canal and its contents, and the posterior vertebral elements (Fig. 96.12) (see also Chapter 58).

***Etiology.*** Esophageal duplication cysts are believed to be the result of a budding error of the dorsal portion of the foregut between the third and sixth weeks of gestation. These cysts arise from the posterior portion of the foregut and contain mucosa that, by histologic examination, is usually gastric or, more rarely, intestinal.[53] True tubular esophageal duplications likely develop

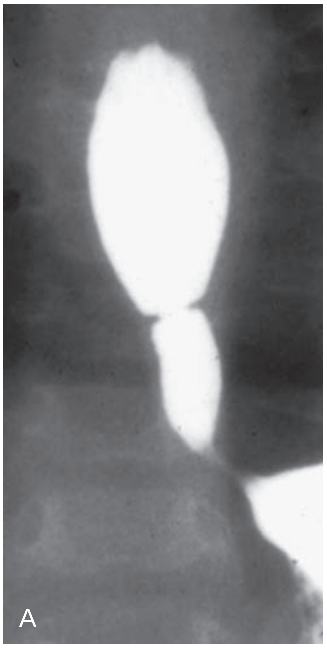

**Figure 96.11. Esophageal stenosis.** (A) Weblike narrowing of the distal esophagus with proximal dilatation secondary to esophageal cartilaginous rests. The diagnosis is suggested by the location of the narrowed segment.

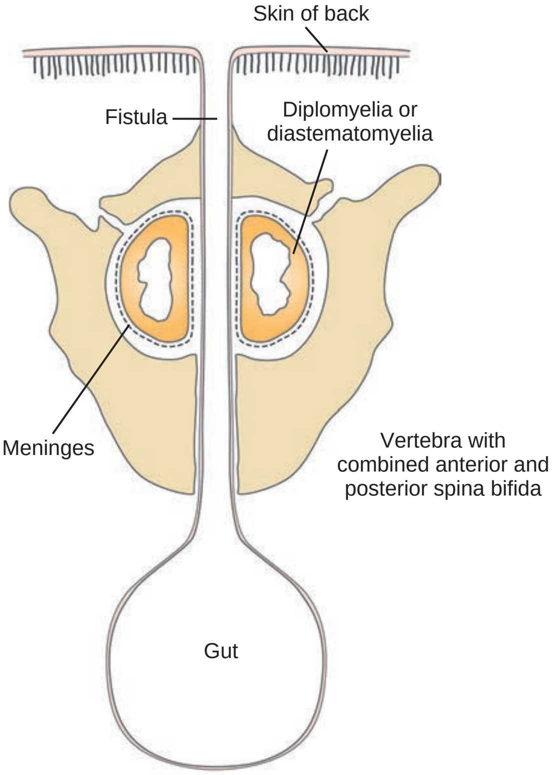

Skin of back
Fistula
Diplomyelia or diastematomyelia
Meninges
Vertebra with combined anterior and posterior spina bifida
Gut

**Figure 96.12. Diagrammatic representation of a typical dorsal enteric fistula.** *(From Naidich TP, McLone DG, Harwood-Nash DC. Spinal dysraphism. In: Newton TH, Potts DG, eds.* Computed Tomography of the Spine and Spinal Cord*. San Anselmo, CA: Clavadel Press; 1983:299–353.)*

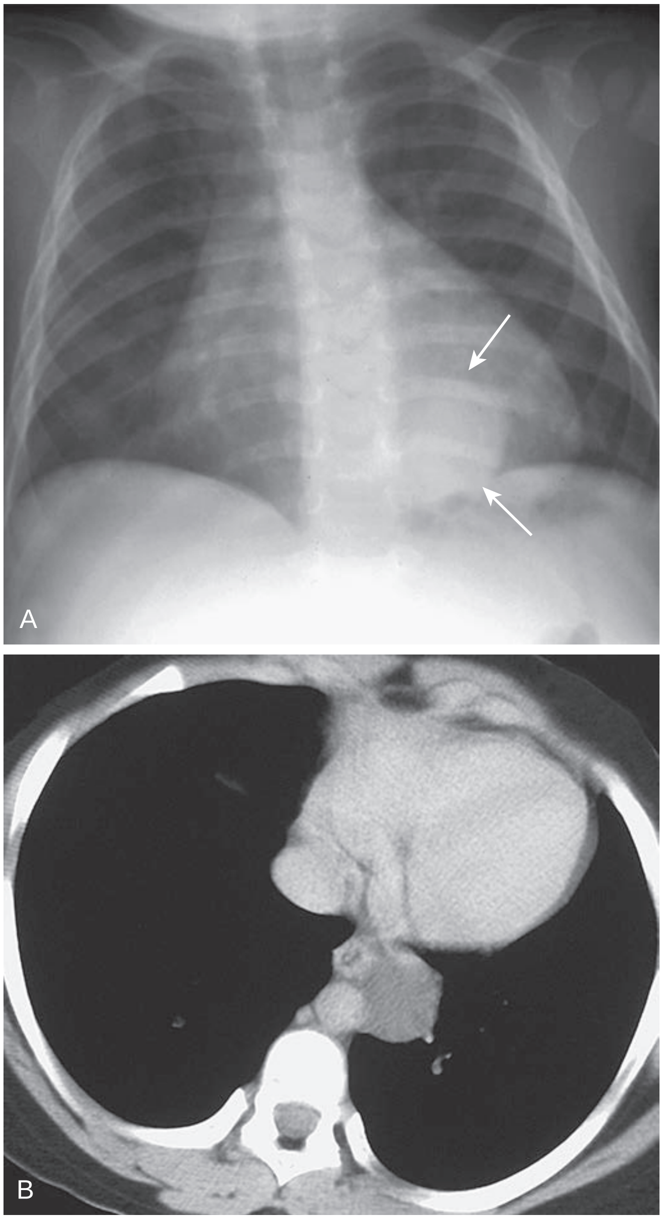

**Figure 96.14. Lower esophageal duplication cyst.** (A) Frontal chest radiograph reveals a paraspinal retrocardiac mass at the left base *(arrows)*. (B) Contrast-enhanced CT image demonstrates the persistently low attenuation of the duplication and its relationship to the esophagus.

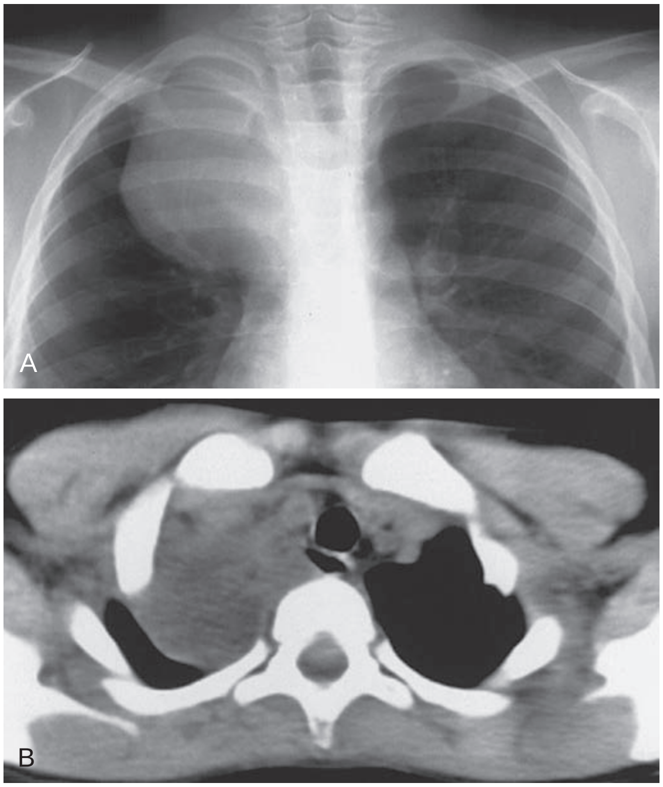
from faulty recanalization of the esophageal lumen during the tenth week of gestation. They may or may not communicate with the esophageal lumen.[51,54–56,58]

***Clinical Presentation.*** Cervical duplication cysts are usually symptomatic very early in life, and patients come to medical attention with respiratory distress. Potential for respiratory compromise may be evident in fetal life, and an ex utero intrapartum treatment may be needed at delivery.[53] Thoracic duplication cysts that occur in the superior mediastinum may be found incidentally, but, if large, the patient may present with respiratory distress or dysphagia because of compression of adjacent structures (e-Fig. 96.13).[52] Duplication cysts that occur in the lower esophagus are often asymptomatic and may be discovered incidentally (Fig. 96.14), although they may become symptomatic as a result of inflammation,



**e-Figure 96.13. Upper esophageal duplication cyst.** (A) Chest radiograph demonstrates a large mass projecting over the right thoracic apex, without evidence of effect upon the adjacent ribs. (B) CT demonstrates the low-attenuation cystic lesion and its relationship to the mediastinum and the adjacent, air-filled esophagus seen posterior to the airway.

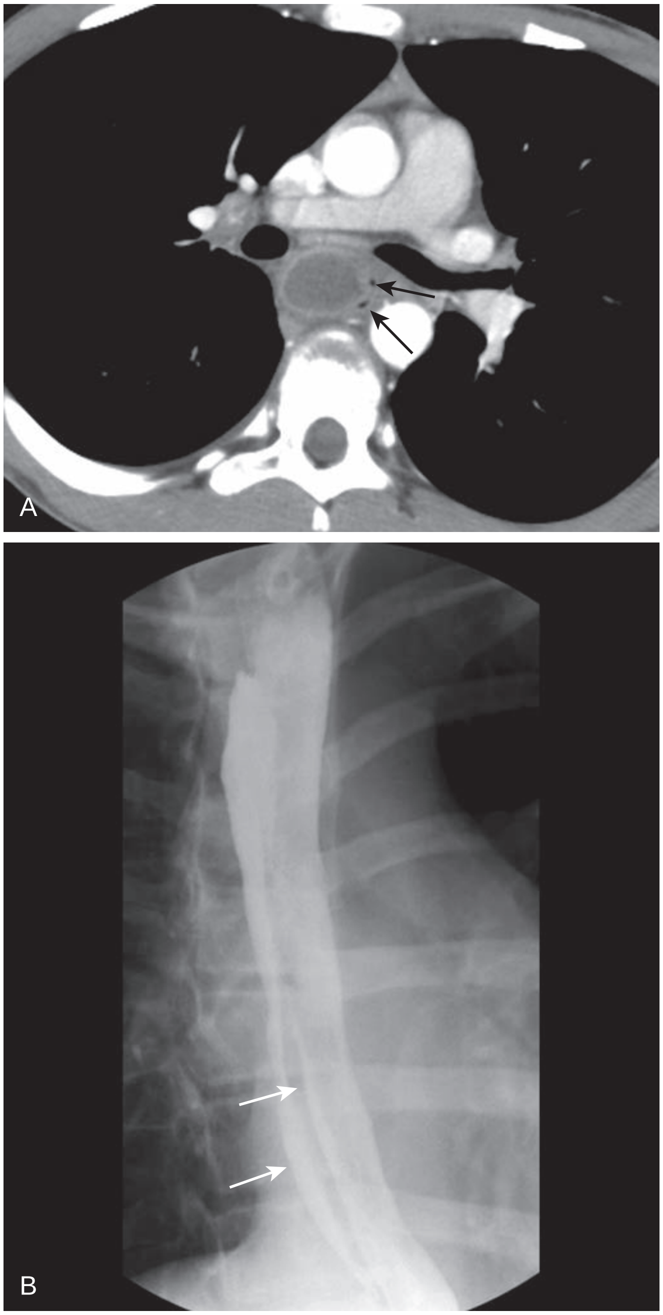


**Figure 96.15. Esophageal duplication cyst complication.** (A) CTA performed to evaluate for pulmonary embolus in a 17-year-old boy presenting with fever, vomiting, and chest pain shows a cystic structure with mildly enhancing walls to the right of the attenuated esophageal lumen *(arrows)*. (B) Subsequent water-soluble esophagram shows a filling defect *(upper arrow)* separating the lumen of the true esophagus from that of the duplication *(lower arrow)*. Duplication became superinfected, leading to symptoms at presentation and to erosion, allowing communication with the lumen of the esophagus.

if they contain gastric mucosa, or as a result of superinfection or hemorrhage (Fig. 96.15).[59]

Neurenteric cysts may present with back pain and progressive neurologic deficit if not diagnosed prenatally or in early infancy.[60] Infants may be brought to medical attention with meningitis. These defects are typically associated with midline vertebral lesions such as spina bifida, other dysraphic defects, or scoliosis (see Fig. 96.12 and e-Figs. 96.16 and 96.17).[60,61]

The combination of esophageal duplication with other anomalies, such as spinal defects, should prompt a search for additional duplications along the alimentary tract, which can be found in up to one-third of cases.[52]

***Imaging.*** Radiographs may demonstrate a sharply demarcated middle or posterior mediastinal mass and associated vertebral anomalies in cases of neurenteric cyst (see Fig. 96.14 and e-Fig. 96.16A).

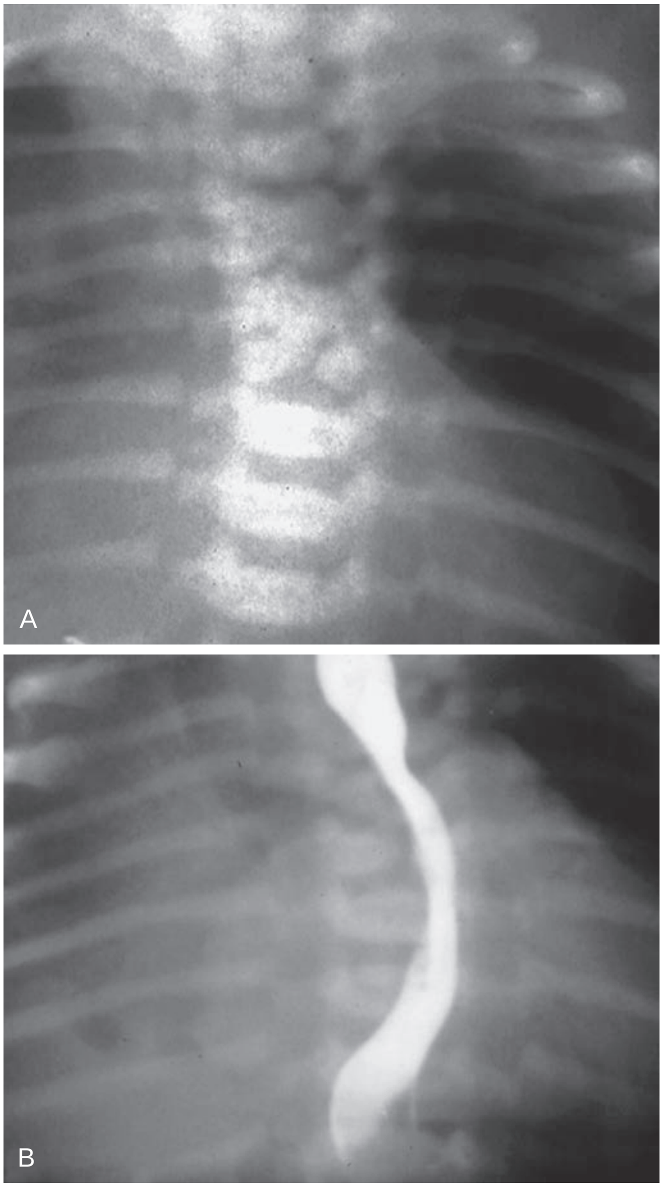
Esophagrams (e-Fig. 96.16B) will suggest an intramural mass, but typically no connection between the two structures is seen.[58] Ultrasound can confirm the cystic nature of the mass in utero but is rarely utilized after birth.[62] CT and MRI are the modalities of choice to confirm the cystic nature of the mass and to best delineate the abnormality. The cyst fluid typically has the attenuation and signal characteristics of water, although this can be affected by hemorrhage or infection (see e-Fig. 96.13B and Figs. 96.14B and 96.15A).[58]

For neurenteric cysts, CT myelography (see e-Fig. 96.17) can demonstrate the extent of the lesion and any associated vertebral anomaly. MRI, however, is the current study of choice to evaluate the presence and extent of intraspinal abnormalities. These lesions are usually intradural and extramedullary.[63,64] Those enteric cysts that contain gastric mucosa with acid and pepsin secretion can be identified by nuclear imaging and are at risk for hemorrhage.[65]

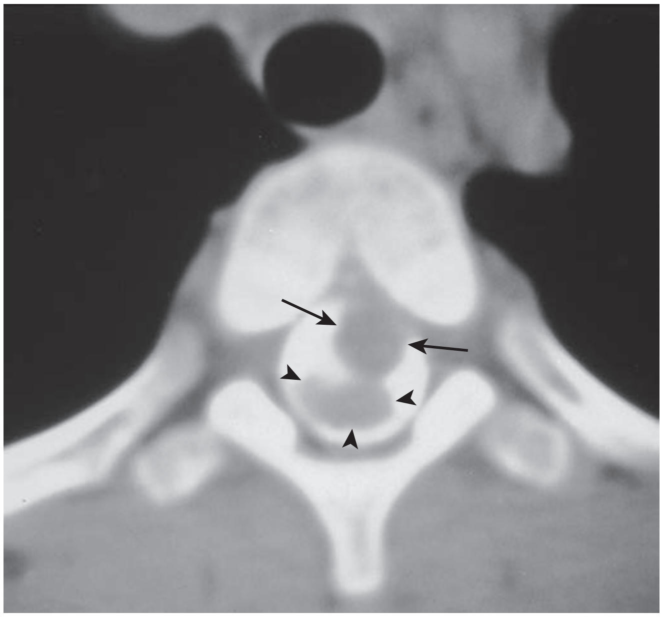
***Treatment/Follow-up.*** Complete surgical resection of cystic duplications is the rule, although this treatment may be modified in case of complications such as infection and erosion into the true lumen of the esophagus.[60] Even if asymptomatic at discovery, esophageal duplication cysts are at risk for development of bleeding, infection, and cancer.[54] Some cysts are amenable to endoscopic treatment.[57]

## KEY POINTS

- Patients with esophageal atresia and distal fistula will have air in the abdomen, whereas patients without a distal fistula will not have abdominal bowel gas.
- Approximately 2.5% of patients with esophageal atresia have a right-sided aortic arch, which is important to identify preoperatively for surgical planning.
- The majority of patients with esophageal atresia complex have associated anomalies, although this decreases to approximately 25% among those with isolated or H-type fistulae.
- Distinguishing features between esophageal atresia and traumatic pharyngoesophageal perforation include an unusually long pouch, irregularity of its lumen, presence of pneumomediastinum, and contrast on esophagram that outlines both true and false lumens.
- Laryngotracheoesophageal clefts may be confused with TEFs or mistaken for aspiration during esophagram.
- The clinical and radiographic diagnosis of an isolated TEF can be elusive, and repeat examination can be considered in difficult cases.
- Congenital esophageal stenosis with tracheobronchial remnants is typically located in the distal esophagus, and when abutting the esophagogastric junction, can be mistaken for achalasia.
- Duplication cysts in the esophagus are second only to the ileum in frequency and are most commonly intrathoracic and cystic. Thoracic duplication cysts are often asymptomatic, but cervical duplication cysts become symptomatic very early in life.



**e-Figure 96.16.** (A) Frontal chest radiograph demonstrates a right-sided mass lesion associated with a midthoracic vertebral segmentation anomaly. (B) Esophagram demonstrates the vertebral body malformations and paravertebral soft tissue mass and further outlines displacement of the esophagus. These findings in conjunction are suggestive of a neurenteric cyst.



**e-Figure 96.17. Intraspinal neurenteric cyst.** Axial CT image with intrathecal contrast demonstrates an intraspinal mass *(arrows)* anterior to the compressed spinal cord *(arrowheads)* surgically proven to represent an intraspinal neurenteric cyst. Note the associated congenital cleft in the vertebral body.

# 97 Disorders of Swallowing

Steven Kraus, Jayne M. Seekins, and Henrique M. Lederman

## OVERVIEW

Swallowing, the coordinated movement of liquids, purees, and/or solids, is a complex sensorimotor process that depends on integrated information from multiple levels of the central and peripheral nervous system. It involves complex excitatory and inhibitory signals from multiple regions of the cortex and subcortex, and ascending sensory signals from the oropharyngeal area that trigger the central pattern generator in the bulbar reticular formation. This makes up a network of premotor neurons and interneurons that drive motor neurons of swallowing in cranial nerves V, VII, IX, X, and XII. The muscles of the lips, submental muscle group, tongue, palate, larynx, pharynx, and esophagus that are innervated by these cranial nerves are then excited and inhibited sequentially to form an oral bolus and swallow. There are three phases of swallowing, (1) the oral phase, which is under voluntary control (preparing the food or liquid in the oral cavity to form a bolus on the tongue-including sucking liquids, manipulating soft boluses, chewing solid food, and moving or propelling the bolus posteriorly through the oral cavity); (2) the pharyngeal phase, which is under involuntary control (initiating the swallow and moving it through the pharynx); and (3) the esophageal phase, which is also under involuntary control (moving the bolus into and through the cervical and thoracic esophagus and into the stomach via esophageal peristalsis).[1,2] When swallowing function is abnormal (dysphagic) due to developmental disability; neurologic disorders (e.g., cerebral palsy, meningitis, encephalopathy, traumatic brain injury, neuromuscular disease); factors affecting neuromuscular coordination (prematurity); complex medical conditions (e.g., heart disease, pulmonary disease, gastroesophageal reflux disease); structural abnormalities of the head and neck (e.g., cleft lip and/or palate, esophageal atresia, head and neck abnormalities); genetic syndromes (e.g., Pierre-Robin, Prader-Willi, Treacher-Collins); medication side effects; sensory issues as a primary cause or secondary to limited food availability in early development; behavioral factors; or social, emotional, and environmental issues; a radiologic study of swallowing function can assess and help therapists treat the dysphagia.[3] Most swallowing disorders in infants and children are secondary to developmental disorders, of which cerebral palsy is the most common.[4,5]

## GENERAL EXAMINATION PRINCIPLES

The Videofluoroscopic Swallow Study or VFSS is the radiographic study of deglutition performed in association with occupational therapists and/or speech pathologists, depending upon the institutional referral pattern. The primary purposes of the VFSS are (1) to assess the structure and function of swallowing and to assess the risk of aspiration; and (2) once a functional abnormality of swallowing is detected, to identify compensatory strategies and a management plan that enables the patient to feed functionally and safely. These strategies may include adjustments in bolus characteristics (e.g., volume or texture), method of presentation (cup, spoon, straw, suckle feeder, syringe), body posture or position, sensory input, or the use of active maneuvers to protect the airway (e.g., supraglottic swallow, Mendelssohn maneuver, coughing, and clearing the throat between swallows).[6]

As a prerequisite to performing the VFSS, the patient's history related to feeding and associated clinical conditions should be obtained and include data about the acuity of the clinical complaint, the child's feeding history, ability to suck, use of utensils, positioning and irritability during and after feeding, usual appetite, and signs of fatigue during feeding. Having this history can help streamline the evaluation and limit the duration of the examination to limit radiation exposure. The historical review should also include review of prior radiologic studies that may have already been performed including prior VFSS studies, upper gastrointestinal series (GIs), chest radiographs, high resolution computed tomography (HRCT) of the chest, etc., which may show radiologic evidence of dysphagia such as aspiration on a prior VFSS or upper GI, or secondary signs of aspiration on a chest radiograph or HRCT such as right upper lobe and bibasilar lung disease pattern.

The initial step in the evaluation of swallowing is to assess the anatomic structures of the naso- and oropharynx. Note the presence of a nasoenteric tube or tracheostomy tube and realize that the presence of a nasoenteric feeding tube has been shown to have no significant effect on the results of the VFSS.[7] For feeding, parents are asked to bring food and liquid that the child typically eats or drinks at home, as well as familiar utensils. The VFSS is then completed with this food or liquid mixed with contrast (usually barium). In some patients, flavoring can be added to the liquid to increase patient cooperation in swallowing although making sure not to modify the thickness of the standard thin and thickened liquids. The patient is placed in the true lateral position in a swallowing chair (or side-lying on the fluoroscopy table tilted at 15 degrees head up if neonate or small infant to simulate breast-feeding position) and is fed the liquid/contrast mixture of varying thickness by bottle with a nipple, sippy cup, cup with straw, or open cup depending on their level of development. Swallowing is evaluated in real time with video fluoroscopy (15–30 frames per second), examining mostly from the mouth through the cervical esophagus. At least one swallow should be followed to the gastroesophageal junction to detect any unexpected esophageal abnormality such as an unknown or recurrent H-type tracheoesophageal fistula or esophageal stricture that might occur in a patient with history of repaired esophageal atresia, a prominent vascular impression such as an aberrant subclavian artery (dysphagia lusoria) or esophageal achalasia in an older patient.[8–15] Imaging in the frontal projection may be done after lateral imaging, sometimes using a basal or Towne view.[12] This allows for evaluation of lateral wall movement, as well as correlation with the clinical evaluation of swallowing by fiberoptic endoscopic evaluation of swallowing, which is often performed as a complementary examination.[3,16,17]

If the infant will not take liquid/contrast from the nipple, it can be carefully introduced into the baby's mouth with a blunt-tipped syringe (between the cheek and the lateral aspect of the teeth or gums) or a feeding tube can be inserted through the nipple (e-Fig. 97.1) into the baby's mouth and controlled introduction of contrast under fluoroscopic guidance can be made to initiate swallowing. However, this type of "force-feeding" is artificial because it bypasses the oral phase of swallowing and so the results should be interpreted with caution. Force-feeding should be avoided and if a patient refuses to eat or drink; discontinuing the examination and performing when the infant or child is more cooperative is recommended for the best and most clinically relevant results. Contrast medium is mixed with increasingly thick food mixtures from puree to solid and swallowing of these are evaluated (if age-appropriate). Evaluation of the patient's ability to handle

## Abstract:

Swallowing is a complex sensorimotor process that depends on integrated information from multiple levels of the central and peripheral nervous system. It can be separated into the oral, pharyngeal, and esophageal phases. Swallowing can be evaluated radiologically by the Videofluoroscopic Swallow Study, VFSS, which is performed in conjunction with speech or occupational therapists. The purpose of the VFSS is not only to assess the structure and function of swallowing and the risk of aspiration; if an abnormality of swallow function including aspiration is detected, it is also important to attempt to identify compensatory strategies and a management plan that enables the patient to feed functionally and safely. Knowing the anatomy and physiology of swallowing and the patients clinical status can help predict which phase of swallowing will be abnormal. The most common causes of swallowing dysfunction in children include central neurologic dysfunction, congenital anomalies that cause mechanical interference in the swallowing apparatus, congenital and acquired retropharyngeal processes, and connective tissue disorders. In otherwise normal infants with dysphagia, gastroesophageal reflux (GER) is a common associated abnormality.

differently textured foods aids in planning appropriate diet to meet nutritional needs and for future therapy. If the patient needs a special diet or only eats certain foods, those can be brought to the examination and used. If aspiration is seen during the VFSS, the study is not usually discontinued. Rather, the therapist will modify feeding strategies to help the patient swallow without aspirating; for example, (1) pacing the swallow, allowing only several swallows with intervening breaks; (2) utilizing nipples with a smaller opening resulting in a slower flow rate; and (3) thickening the fluid. One or all of these strategies are sometimes utilized to obtain safe swallowing.

## ABNORMAL FINDINGS ON VIDEOFLUOROSCOPIC SWALLOWING STUDIES

Typical abnormal findings in the oral phase of swallowing on a VFSS include (1) loss of food out of the mouth due to reduced lip closure, tongue thrust, and reduced tongue control; (2) piecemeal deglutition (requiring multiple swallows to clear the oral cavity of a single bolus) due to reduced tongue movements or strength; (3) prolonged oral transport (liquid >3 seconds) and (4) oral transport of puree with no bolus formation, both due to reduced tongue coordination; and (5) prolonged presence of material in valleculae or pyriform sinuses preinitiation due to prolonged delay in pharyngeal initiation of swallowing.[2]

Typical abnormal findings in the pharyngeal phase of swallowing include (1) pharyngonasal backflow due to reduced velopharyngeal closure or incoordination of pharyngeal contraction (Fig. 97.2 and e-Fig. 97.3); (2) laryngeal penetration due to reduced or delayed closure of airway entrance (laryngeal vestibule) (Fig. 97.4 and Video 97.1); (3) aspiration: (a) before swallow due to delayed swallow initiation, (b) during swallow due to incoordination of pharyngeal contraction and airway closure or vocal fold paresis or paralysis, (c) after swallow due to reduced pharyngeal pressure or contractions from residue; and/or (4) postswallow residue: (a) in valleculae due to reduced tongue base contraction, (b) in pyriform sinuses or posterior pharyngeal wall due to reduced submental muscle group and pharyngeal contraction.[2]

Typical abnormal findings in the esophageal phase of swallowing include (1) postswallow residue in the upper esophageal sphincter region due to reduced contraction of submental muscle group, tongue base, and reduced pharyngeal contractions and (2) prominence of or incomplete relaxation of the cricopharyngeus muscle (cricopharyngeal bar) due to reduced upper esophageal sphincter (UES) opening or premature UES closure.[2]

## CAUSES OF SWALLOWING DYSFUNCTION

The most common causes of swallowing dysfunction in pediatric patients include central neurologic dysfunction, congenital anomalies that cause anatomic abnormalities with mechanical interference in the swallowing apparatus, congenital and acquired retropharyngeal processes, and connective tissue disorders.

### Central Neurologic Dysfunction

***Overview.*** Cerebral palsy[1] is the most common cause of swallowing dysfunction in infants and children. Other neuromuscular disorders to be considered are brainstem dysfunction, cranial nerve abnormalities, intracranial neoplasms, meningomyelocele, muscular dystrophies, and myasthenia gravis. Familial dysautonomia (Riley-Day syndrome) leads to autonomic dysfunction with esophageal

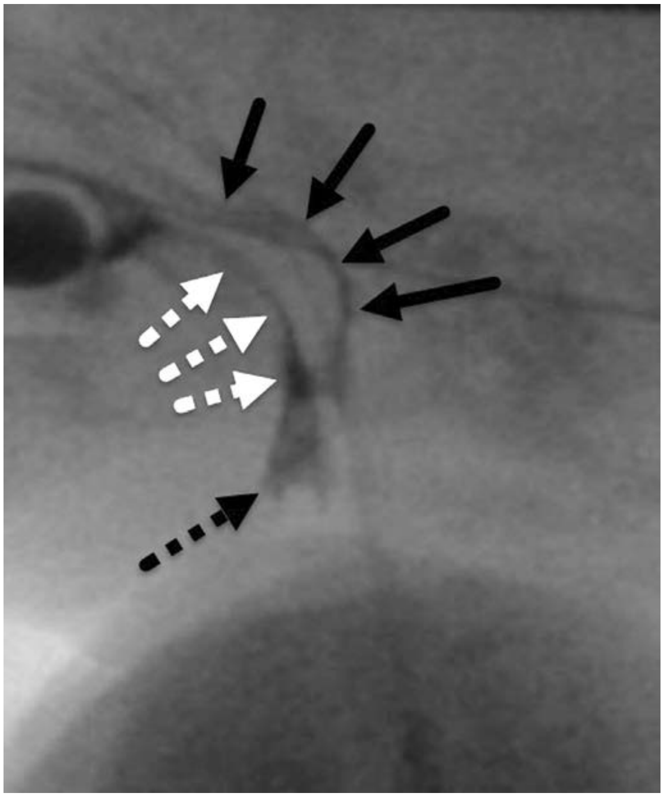

**Figure 97.2.** Pharyngonasal backflow. Lateral still image from a VFSS shows contrast from pharyngonasal backflow outlining the nasopharynx due to velopalatine insufficiency *(black arrows)*; contrast along the posterior tongue *(white dashed arrows)* and in the vallecula *(black dashed arrow)* is normal during swallowing.

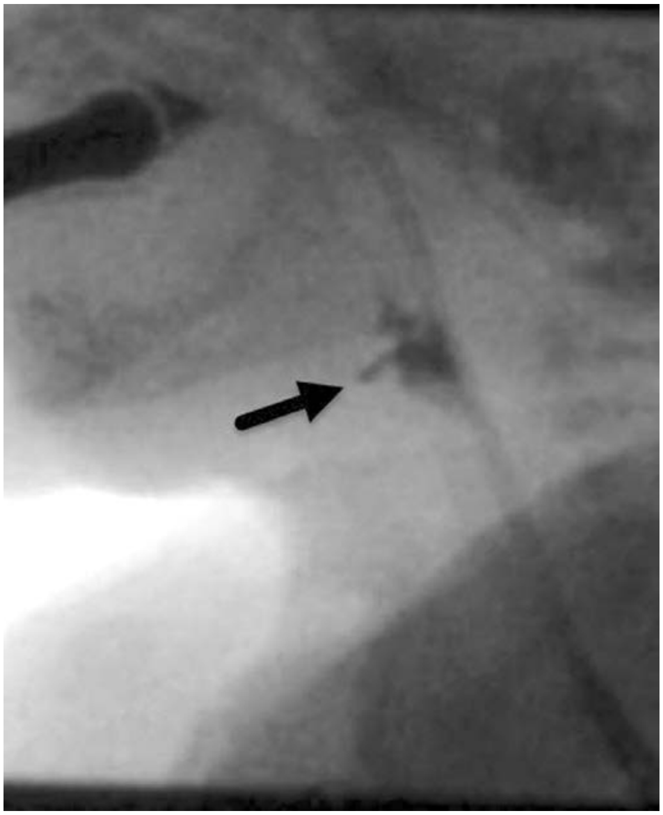

**Figure 97.4.** Shallow laryngeal penetration. Lateral still image from a VFSS shows contrast penetrating into the upper aspect of the laryngeal vestibule *(arrow)* but no contrast on the vocal cords or in the trachea.

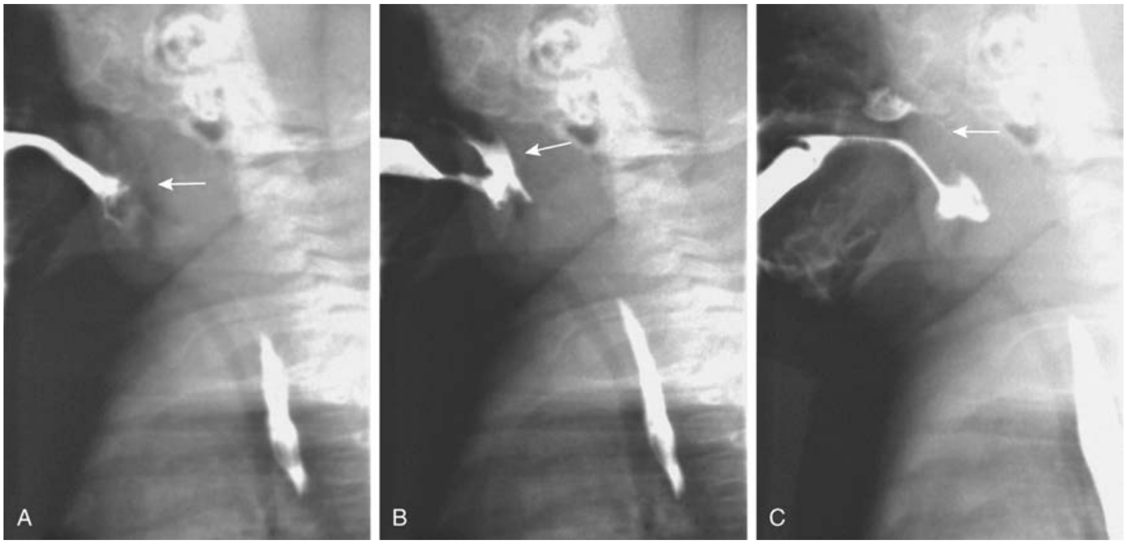

**e-Figure 97.3.** Pharyngonasal backflow. (A) As the nipple is inserted into the infant's mouth, the tongue and soft palate are relaxed and the nasopharynx opens *(arrow)*. (B) Normally, the tongue elevates, pushing the nipple to the roof of the mouth, and the soft palate elevates. In this example, the soft palate did not elevate and close off the nasopharynx, resulting in nasopharyngeal backflow *(arrow)*. (C) The infant finally did close the nasopharynx by elevation of the soft palate against the adenoid tissue *(arrow)*. Contrast material remains in the nose and in the hypopharynx.

dysmotility and frequent aspiration pneumonia. Abnormality of the neuromuscular mechanism elevating the soft palate (velopharyngeal closure) may lead to reflux of contrast material into the nasopharynx (pharyngonasal backflow or reflux), with subsequent pooling of contrast in the pharynx and potential aspiration into the airway. Abnormalities of other muscle groups lead to defective function of the epiglottis and upper esophageal sphincter, with aspiration into the airway being common.[18,19]

***Etiology.*** The etiology of swallowing dysfunction is related to dysfunction in one of the three phases of swallowing: oral phase with inability to deliver the food into the mouth (e.g., poor suck); pharyngeal phase with failure to move the food through the pharynx, elevation of the soft palate and closure of the epiglottis; or in the upper esophageal phase, with abnormal coordination of relaxation and contraction phase of the UES as previously detailed.[18] The coordination necessary to effect the swallowing process correctly is mediated through the cranial nerves responsible for both sensation and motor function, as well as osseous and muscular structures supplied by both the autonomic and voluntary nervous system. Thus depending on the level of the central nervous system (CNS) defect, one can predict which phase of swallowing will be most effected.

***Clinical Presentation.*** The severity of disordered swallowing and presence or absence of aspiration will depend on the level of neurologic deficit. Depending on the specific neurologic defect, any or all components of the swallowing mechanism may be affected. Symptoms may include pharyngonasal backflow, gagging, coughing and choking during feedings, recurrent pneumonia, malnutrition, and failure to thrive.[18,20] However, in some patients at risk for disordered swallowing and aspiration, the gagging and coughing reflex may itself be inherently absent or secondarily impaired, and these patients are at risk to aspirate without the protective cough reflex (silent aspiration). Due to the risk of silent aspiration in these patients, VFSS should be performed to aid nutritional management and to help reduce aspiration where possible.[21]

***Imaging.*** The abnormalities detected during VFSS will depend on the level of CNS defect. In upper cortical motor neuron dysfunction, oral phase dysfunction will dominate with loss of food from the mouth anteriorly, poor oral control of the bolus, fluid flowing off the tongue into the sulci of the mouth, and multiple small swallows required for a single bolus (piecemeal swallowing). In these patients, the pharyngeal phase is not as affected although if the oral phase of swallowing is markedly impaired, the pharyngeal phase will not be able to accommodate and contrast material may be seen within the nasopharynx or trachea (Fig. 97.5 and Video 97.2). Dysfunction in the pharyngeal phase may be related to brainstem dysfunction such as Chiari malformation, brainstem neoplasm, after resection of posterior fossa tumors, or demyelinating diseases involving brainstem structures. This may result in weak pharyngeal contraction or lack of adequate forward passage of pharyngeal contents resulting in pharyngeal residue or findings of a cricopharyngeal bar suggestive of cricopharyngeal achalasia.[18,22,23] It is also important to note if the patient can spontaneously clear the residue by repetitive dry swallows and if a cough reflex is present during episodes of aspiration.[21]

***Treatment and Follow-up.*** Treatment can begin at the time of the study as previously described by altering the liquid or food presentation or by altering the density of liquid by thickening agents to prevent aspiration, or treatment can extend to complete oral restriction with enteric tube feeding or total parenteral nutrition. VFSS can be repeated as the patient's clinical status improves or deteriorates further to assess the effect of any interval medical or surgical treatment.

## Congenital Anomalies

***Overview.*** Multiple congenital anomalies can lead to abnormal swallowing. Mechanical problems such as seen in the Pierre-Robin sequence with a small mandible can lead to significant feeding difficulties. Macroglossia as seen in patients with Beckwith-Wiedemann syndrome or trisomy 21 can present with similar problems. Disorders of the mouth and jaw such as cleft lip and cleft palate can lead to difficulties with oral and pharyngeal phases of swallowing.[16] These disorders are usually physically apparent or diagnosed prenatally. Disorders of the palate and tongue can be seen with both ultrasound and magnetic resonance imaging (MRI).[24–26]

***Etiology.*** The etiologies of the various congenital anomalies that can result in abnormal swallowing are obviously quite different. As an example, cleft palate is a result of partial or total lack of

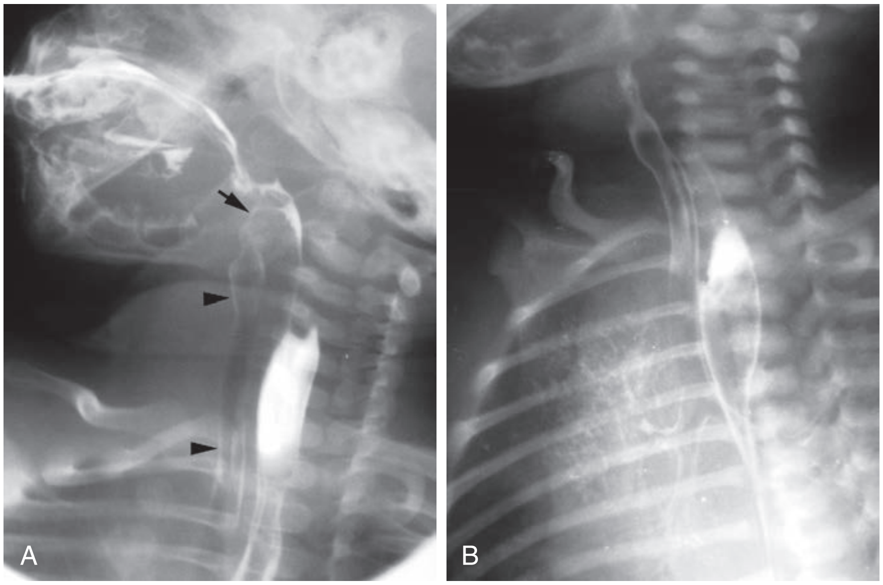

**Figure 97.5.** Aspiration. (A) Oblique image shows laryngeal penetration *(arrow)* and aspiration of contrast into the trachea *(arrowheads)*, secondary to lack of coordination during swallowing. (B) Oblique view reveals the extensive airway aspiration outlining bronchi and airspaces.

fusion of the palatal shelves between the 8th and 12th weeks of gestation.[24,27] Micrognathia may be seen alone or as part of a syndrome such as the Robin sequence[28] and is usually due to syndromic incomplete mandibular maturation or failure of normal mandibular development due to external causes.[29,30]

***Clinical Presentation.*** Symptoms correlate with the anatomic abnormality and therefore can vary widely, but all may present with choking, nasal regurgitation, pneumonia, or repeated pneumonitis. Cleft lip and cleft palate occur in varying degrees but usually are clinically apparent either externally or during the neonatal physical examination.

***Imaging.*** Conditions such as cleft lip/palate, micrognathia, and macroglossia are not routinely imaged postnatally beyond evaluation of the functional difficulties presented and may be identified prenatally with ultrasound or MRI.[24–26,28] On VFSS, one would note anterior loss in the oral phase in patients with cleft lip and pharyngonasal backflow potentially resulting in nasal regurgitation in the pharyngeal phase in patients with cleft palate. In the absence of other abnormalities, the pharyngeal phase of swallowing would be otherwise normal and aspiration is less likely. However, with more severe craniofacial anomalies, alteration in the muscles of deglutition increases the risk of significant swallowing dysfunction and aspiration.

***Treatment and Follow-up.*** Cleft lip and cleft palate are corrected surgically in infancy to allow for adequate feeding. Follow-up is usually endoscopic. Micrognathia treatment depends upon the severity. Mild micrognathia may be relieved with prone positioning and a nasopharyngeal airway until the patient grows. More severe mandibular hypoplasia may be treated by distraction osteotomy.[29] Macroglossia is treated clinically or surgically with partial anterior wedge lingual resection to allow for the return of normal swallow function.[31]

## Retropharyngeal Processes

***Overview.*** Retropharyngeal processes can be congenital or acquired. Cricopharyngeal spasm or achalasia is sometimes associated with an underlying neuromuscular disorder but often occurs as a primary abnormality.[22] Masses, both benign and malignant, are rare causes of dysphagia and range from congenital masses such as lymphatic malformation or cervical esophageal duplication, to acquired lesions such as foreign bodies, or traumatic or infectious abnormalities.

***Etiology.*** The swallowing abnormality in these patients is related to the mass effect of the lesion, which interferes with the coordinated peristaltic activity needed to effect proper swallowing. In patients with cricopharyngeal achalasia, the normal relaxation of the cricopharyngeus muscle in response to contraction of the middle and inferior pharyngeal constrictors does not occur, resulting in varying degree of obstruction to propulsion of the bolus into the esophagus.[22,23]

***Clinical Presentation.*** Symptoms of dysphagia will vary in presentation with the underlying abnormality. Cricopharyngeal achalasia presents with symptoms of aspiration, choking, and pharyngonasal regurgitation. Congenital masses may have been noted on prenatal imaging and in some cases may be visible externally on physical examination. Onset of dysphagia in conjunction with fever or other signs of infection suggest the presence of a retropharyngeal abscess or superinfection of a preexistent lesion. Prior trauma, such as insertion of orogastric tube or caustic or foreign body ingestion, represent other causes of dysphagia and disordered swallowing.

***Imaging.*** Radiographs of the neck are helpful in assessing whether there are pertinent abnormalities, such as narrowing or mass impression upon the airway, or evidence of foreign body. In patients with a retropharyngeal or prevertebral process, radiographs demonstrate increased density along the prevertebral space or posterior mediastinum, with mass effect bowing and/or narrowing the airway. Swallow study demonstrates similar findings upon the esophagus (Fig. 97.6).

Ultrasound, computed tomography, and MRI all have roles in the evaluation of neck masses. If present prenatally, imaging may guide any immediate intervention needed at birth.

In patients with cricopharyngeal spasm or achalasia, the VFSS study demonstrates a cricopharyngeal "bar", the posterior impression of the cricopharyngeus muscle that persists on multiple swallows and is associated with either partial or complete obstruction at the upper esophageal sphincter, often resulting in pharyngeal residue, aspiration, and pharyngonasal regurgitation (Fig. 97.7).

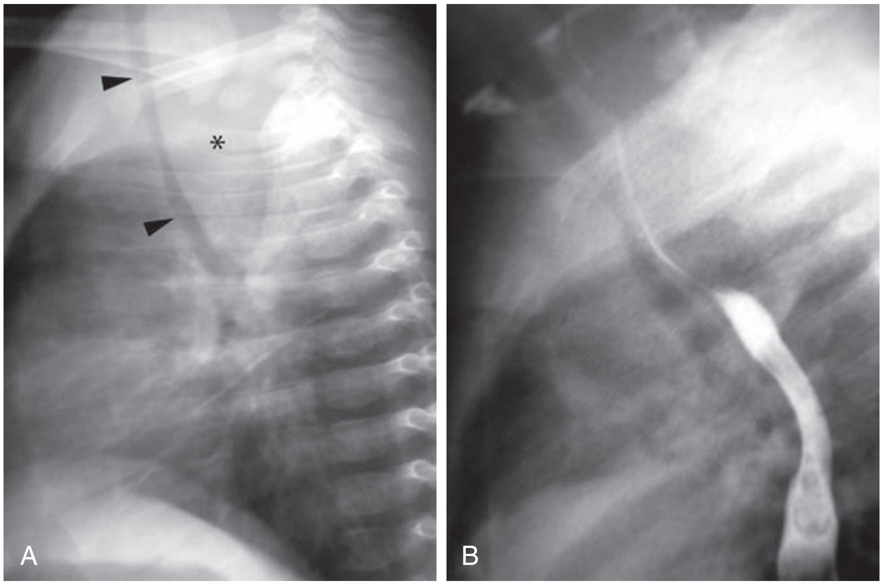

**Figure 97.6.** Prevertebral abscess. (A) Lateral chest radiograph shows a soft tissue density mass in the posterior mediastinum *(asterisk)* compressing and displacing the trachea anteriorly *(arrowheads)*. (B) Barium swallow demonstrates narrowing and anterior displacement of the esophagus and trachea.

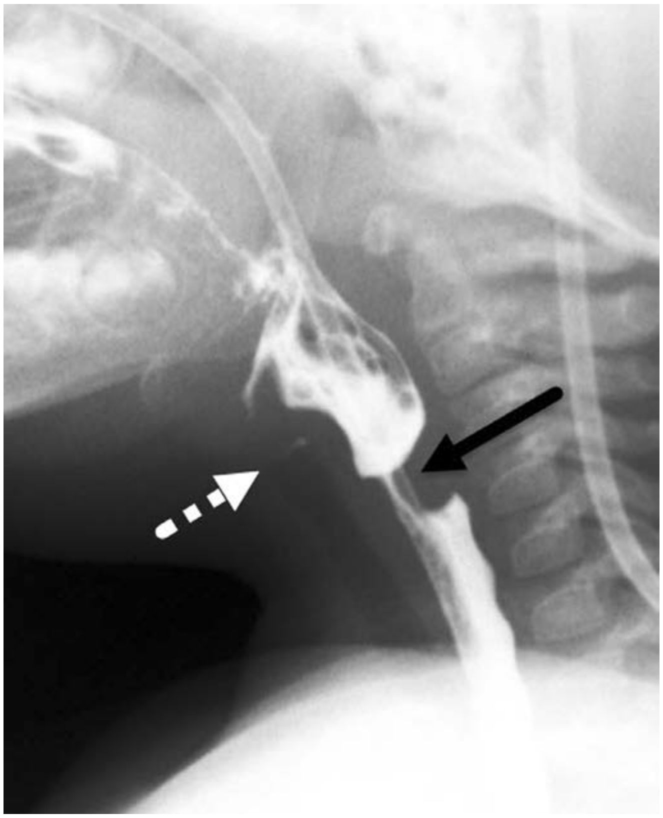

**Figure 97.7.** Cricopharyngeal achalasia and aspiration. Lateral image from a barium swallow shows a fixed filling defect in the posterior esophagus resulting from persistent contraction of the cricopharyngeus muscle *(black arrow)*. This has resulted in pharyngeal pooling of contrast, with resultant tracheal aspiration *(white dashed arrow)*.

***Treatment and Follow-up.*** The treatment depends upon the etiology of the lesion and ranges from medical, radiologic, oncologic, or surgical intervention. In patients with cricopharyngeal achalasia without significant obstruction, waiting may allow time for maturation, particularly when found in otherwise normal premature infants. In patients with primary cricopharyngeal achalasia, balloon dilatation has been advocated; surgical management remains controversial.[22,23]

## Connective Tissue Disorders

***Overview.*** Scleroderma and other connective tissue disorders are rare in childhood, most frequently occurring in adolescents and adults. While the esophagus is commonly involved, pharyngeal and upper esophageal function is usually normal. However, in adults with scleroderma, 26% may show swallowing dysfunction, and those with oropharyngeal abnormalities had more severe clinical disease and a higher incidence of pulmonary disease.[32,33] Gastroesophageal reflux (GER) that results in regurgitation or that reaches that pharynx and is swallowed has been associated with delay in swallowing initiation in children and can result in aspiration.[34] Anecdotally, GER is one of the most frequent associated abnormalities in otherwise normal infants with aspiration on VFSS performed for swallowing difficulties.

***Etiology.*** In patients with scleroderma, there is swelling of endothelial cells, with an adventitial periarterial fibrotic cuff.[35] Esophageal dysmotility typically begins at the level of the aortic arch. At this level, the esophageal muscle layer changes from striated to smooth muscle, which is affected more in patients with scleroderma.[33] Poor to absent primary peristalsis occurs in the distal two-thirds of the esophagus. Secondary gastroesophageal reflux, with or without esophagitis, may occur.

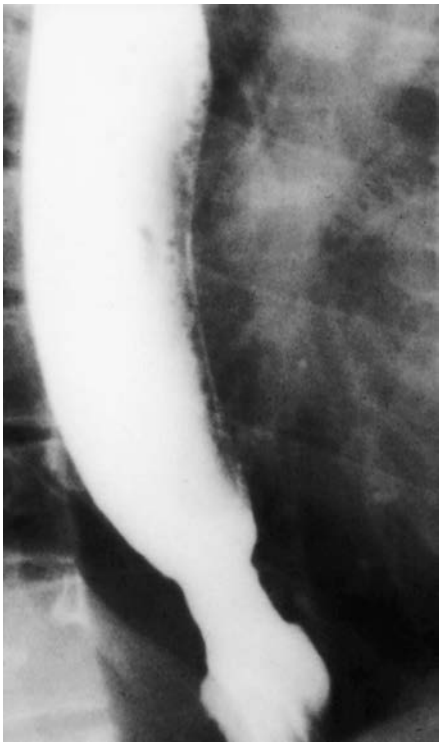

**Figure 97.8.** Scleroderma and distal esophageal stricture. Esophagram demonstrates narrowing of the distal esophagus with proximal dilatation. There was poor esophageal motility.

Dermatomyositis is an inflammatory myositis associated with a complement-mediated microangiopathy. In contrast to scleroderma, it primarily affects the striated muscle of the pharynx and upper esophagus. Dilation of these structures with disordered peristalsis frequently occurs, as does reflux of ingested material into the nasopharynx. The associated vasculitis may result in esophageal ulceration and perforation.[34]

***Clinical Manifestations.*** The esophagus is involved in nearly all patients with scleroderma, and approximately 50% to 90% have clinical symptoms of esophageal dysfunction, most commonly dysphagia and dyspepsia.[35] Those with moderate to severe esophageal manifestations have associated swallowing symptoms as well. Dermatomyositis involves the pharynx and upper esophageal sphincter, thus interfering with the appropriate direction of the bolus into the esophagus. In addition to dysphagia and inability to swallow without the aid of gravity if lying down, patients have hoarseness, nasal speech, and nasal regurgitation.

***Imaging.*** In older children and adolescents, a chest radiograph may aid with the initial workup. This may demonstrate a dilated esophagus with possibly an air-fluid level or interstitial lung disease.

VFSS in patients with mild scleroderma usually demonstrates a normal swallow mechanism but abnormal distal esophageal motility and dilation. Distal stricture formation is usually related to gastroesophageal reflux secondary to the incompetent lower esophageal sphincter (Fig. 97.8). In patients with moderate to severe disease, one may detect oral leakage, oropharyngeal residue, vestibular penetration, aspiration, and transient cricopharyngeal dysfunction.

Dermatomyositis can cause disordered swallowing of the pharynx and upper esophagus with similar findings, and pharyngeal-nasal reflux may also be detected.

***Treatment and Follow-up.*** Treatment of the underlying disease is the primary goal; findings and symptoms of reflux can be addressed medically.[35]

## KEY POINTS

- Swallowing is divided into oral, pharyngeal, and esophageal phases.
- Swallowing abnormalities can be due to a central neurologic disorder, anatomic disorders of the tongue, mouth, jaw, or esophagus, or an acquired condition.
- The primary purposes of the VFSS are to assess the structure and function of swallowing and the risk of aspiration, and to identify compensatory strategies and a management plan that enables the patient to feed functionally and safely.
- The assessment of swallow function in most departments is combined with speech therapy or occupational therapy.

# Acquired Esophageal Disorders

Alexander J. Towbin and Lincoln O. Diniz

## OVERVIEW

The esophagus is a muscular tube that transports food and oral secretions from the mouth to the stomach via coordinated peristalsis of striated and smooth muscle.[1] Acquired abnormalities of the esophagus can be separated into several broad categories: gastroesophageal reflux (GER), trauma including foreign bodies, inflammatory conditions, infections, motility disorders, postsurgical changes, neoplasms, and other conditions.

An esophagram or upper gastrointestinal (UGI) series is the most common method used to image the esophagus directly; the esophagram focuses on the esophagus, while the UGI is a more general examination of esophagus, stomach, and duodenum. See Chapter 84 for a description of the technique.

Computed tomography (CT) and magnatic resonance imaging (MRI) are rarely used as primary methods of imaging the esophagus; however, both CT and MRI have the advantage of allowing the radiologist to visualize the esophageal wall and lesions extrinsic to the esophagus.[2] There are several major limitations of cross-sectional imaging in evaluating the esophagus that prevent their use as a primary imaging modality: first, neither CT nor MRI provides functional information of esophageal motility; second, the esophagus is not able to be distended reliably to evaluate wall thickness accurately; third, neither study is able to provide mucosal detail; and finally, CT uses ionizing radiation.

## GASTROESOPHAGEAL REFLUX

***Overview and Etiology.*** Gastroesophageal reflux is defined as the retrograde passage of gastric contents into the esophagus.[3] When symptoms or lesions occur due to GER, it is referred to as gastroesophageal reflux disease (GERD).[4]

The primary mechanism of GER is transient relaxation of the lower esophageal sphincter. This relaxation can be triggered by a vasovagal reflex initiated by gastric distension or cardiopulmonary receptors, or a swallow that does not trigger esophageal peristalsis.[3] In children, severe GERD has several known underlying risk factors, including neurologic disorders such as spastic quadriplegia and cerebral palsy, esophageal atresia, chronic lung disease such as cystic fibrosis, and hiatal hernia.[5,6]

***Clinical Presentation.*** GER is ubiquitous in infants, occurring in 100% of 3-month-olds, 40% of 6-month-olds, and 5% to 20% of 1-year-olds.[4,6] In older children and adolescents, reported prevalence of weekly GERD symptoms increases with age, from 2% of 3- to 9-year-olds to 5% to 8.2% of children aged 10 to 17 years.[7]

The symptoms of GERD depend on age. In infants, symptoms include irritability, feeding difficulty, poor weight gain, and sleep disturbance. In older children, these include heartburn, abdominal pain, regurgitation or vomiting, and dysphagia.[3] Extraesophageal symptoms of GERD include chronic cough, asthma, apnea, bradycardia, sore throat, dental erosions, and recurrent otitis or sinusitis.[3] When compared with adults, children have fewer episodes of heartburn, dysphagia, and chest pain and more episodes of vomiting and regurgitation.[4]

GERD is often diagnosed based on symptoms and a trial of acid-reduction therapy. When symptoms are not specific or are atypical, confirmatory testing can be performed. Intraesophageal pH monitoring has traditionally been considered the gold standard due to its ability to measure the pH in the esophagus over a long period of time. The main limitation of this technique is that patients may have abnormal esophageal acid exposure without symptoms of GERD or retrograde bolus movement in the esophagus.[3,8] To evaluate for the retrograde passage of gastric contents as well as esophageal acidity, combined pH/impedance probes are used.[8]

***Imaging.*** According to the North American and European Pediatric Gastroesophageal Reflux Clinical Practice Guidelines, imaging studies are not required to make a diagnosis of GER.[9] UGI is often performed in the setting of GER to evaluate for an anatomic abnormality; however, it should not be used as the primary method of diagnosing GER or GERD. There are multiple limitations of UGI in diagnosing GER, including use of nonstandard techniques, lack of correlation with symptoms, and use of ionizing radiation. Methods used to provoke reflux such as Valsalva maneuver, positional changes, abdominal compression, or leg lifting may increase the sensitivity of detecting GER but lower the specificity.[3] Because there are more sensitive diagnostic tests and the radiologic findings do not correlate with symptoms, the collaborative practice parameter set forth by the American College of Radiology and the Society for Pediatric Radiology do not recommend provocative maneuvers or prolonged fluoroscopy for the detection of GER.[10]

Although UGI should not be prolonged to identify GER, it should be documented when present (Fig. 98.1). The percentage of patients who have GER on UGI decreases with age from 80% of infants less than 18 months to 30% of adolescents between 12 and 18 years old.[3] It should be noted that, although the height of reflux is often reported as a surrogate for its severity, there is no correlation with GERD symptoms.[3]

Technetium-99m (Tc-99m) sulphur colloid can also be used to diagnose GER. While scintigraphy is a sensitive method of detecting GER, it suffers many of the same limitations of UGI; mainly, the presence of GER does not correlate with symptoms of GERD and also requires ionizing radiation. A limitation of scintigraphy is its inability to diagnose some of the complications of GERD. Scintigraphy is thus reserved for cases where pH monitoring is not able to be performed or when evaluation of gastric motility is required.

Ultrasound benefits include its low cost, rapid performance, lack of ionizing radiation, and ability to perform a dynamic scan. While the North American and European Pediatric Gastroesophageal Reflux Clinical Practice Guidelines state that ultrasound is not recommended for routine evaluation of GER, some authors have described its use in evaluating the length of the abdominal esophagus, position of the lower esophageal sphincter relative to the diaphragm, and the presence of other potential causes of vomiting such as hiatal hernia.[9,11]

Esophageal complications of GERD include strictures and Barrett esophagitis. Esophageal strictures, also known as peptic strictures when caused by GERD, typically occur in the lower third of the esophagus and are a result of acidic injury. They are cited as being present in up to 15% of children with GERD and can occur at any age.[12] Many of the patients who develop strictures have an associated comorbidity, with 25% having a neurologic impairment.[12]

## Abstract:

The esophagus is a muscular tube that transports food and oral secretions from the mouth to the stomach via coordinated peristalsis of striated and smooth muscle. Acquired abnormalities of the esophagus can be separated into several broad categories: gastroesophageal reflux (GER), trauma including foreign bodies, inflammatory conditions, infections, motility disorders, postsurgical changes, neoplasms, and other conditions. This chapter will review the common abnormalities that affect the esophagus focusing on the unique imaging findings of each entity.

## Keywords:

gastroesophageal reflux (GER)
inflammatory conditions
motility disorders
postsurgical changes
neoplasms

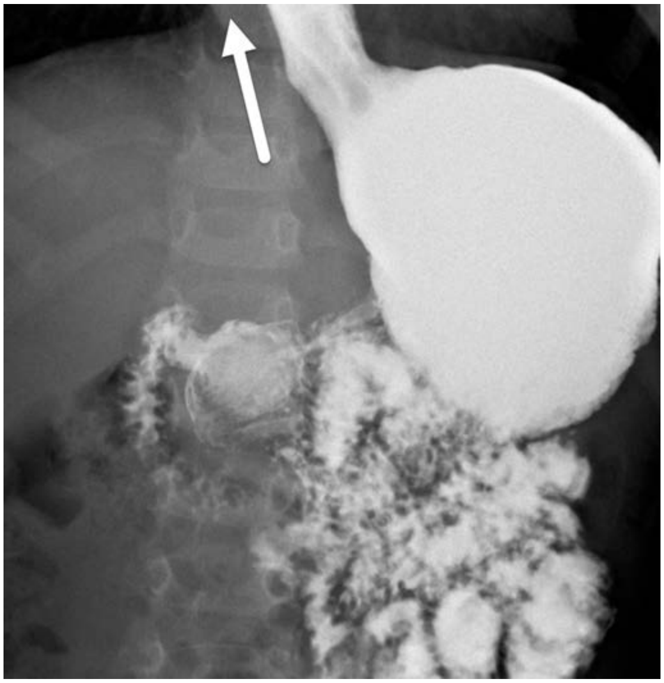

**Figure 98.1. Gastroesophageal reflux.** Image from an upper gastrointestinal examination shows retrograde flow of contrast from the stomach into the esophagus. The *arrow* shows the direction of contrast passage.

Barrett esophagus is defined as metaplasia of cells in the distal esophagus from squamous to columnar epithelium. Its prevalence in children with GERD ranges from 0.25% to 4.8%.[6,13] Risk factors for developing Barrett esophagus in children include severe chronic GERD, congenital abnormalities, neurologic impairment, hiatal hernia, and family history.[6] While it is associated with a 30-fold increase in esophageal adenocarcinoma in adults, the risk of developing adenocarcinoma is not defined in children.[6]

***Treatment.*** There are multiple options for treating GERD depending on the patient's age, comorbidities, and severity of symptoms. Generally, lifestyle changes and pharmacotherapy are first-line options. Lifestyle changes include avoidance of overfeeding, thickening feeds, upright positioning during sleep, and avoidance of second-hand smoke.[3] A goal of medical therapy is to decrease the acidity of the refluxed gastric contents. This is generally performed by using proton pump inhibitors and histamine receptor antagonists.[3] In patients with continued severe GERD after pharmacotherapy or who have other comorbidities such as neurologic impairment, antireflux surgery such as Nissen fundoplication is performed. Strictures are treated with esophageal dilation and fundoplication. In a small percentage of patients, severe and recurrent strictures will require extensive and repeated dilatations, and may come to surgical resection or esophageal replacement.[12]

## TRAUMA

Esophageal injury can occur through ingestion of foreign bodies or caustic substances, blunt injury, or forceful vomiting.

### Foreign Bodies

Ingested foreign bodies are common in children with the majority occurring in those younger than 3 years of age.[14] There were 86,261 pediatric foreign body ingestions in 2014 reported to the American Association of Poison Control Centers,[15] representing a fraction of the actual number of foreign bodies ingested.

#### Coins

***Overview and Etiology.*** In the United States and Europe, coins are the most commonly ingested foreign body.[16] It is estimated that there are more than 250,000 coin ingestions per decade.[16] While most coins spontaneously pass through the gastrointestinal tract, they can lodge in the esophagus. Coins typically lodge in one of three locations: the thoracic inlet (60%–70%), midesophagus at the level of the aortic arch (10%–20%), and just above the lower esophageal sphincter (20%).[14] When not witnessed, the patient may present beyond the acute stage.

***Clinical Presentation.*** Symptoms of chronic foreign body impaction include respiratory distress, asthma-like symptoms, cough, nausea, vomiting, and dysphagia. Respiratory symptoms are due to local inflammation surrounding the foreign body.[17] Patients with chronic foreign body impaction are at risk of esophageal perforation.

***Imaging.*** Radiographs are useful to identify the location of the coin and to look for signs of chronic impaction (e-Fig. 98.2). Coins are generally described as oriented in the coronal plane when located in the esophagus on the frontal radiograph, although there have been reports of sagitally oriented esophageal coins.[18] Inflammatory changes that develop in patients with chronic foreign body impaction cause thickening of the space between the esophagus and trachea on lateral chest radiographs, and often tracheal narrowing (e-Fig. 98.2B); lateral radiographs are therefore useful in patients in whom the episode was not witnessed and the time course is not known. Esophagram may be performed in patients with a chronic foreign body impaction after removal to evaluate for perforation or development of a tracheoesophageal fistula.

***Treatment.*** Coins, like other esophageal foreign bodies, can be removed via Foley catheter balloon extraction or endoscopy. Foley catheter extraction has been used as a safe and effective method of coin removal in children older than 1.5 years with acute ingestion, before the development of esophageal edema.[19] Despite its history of safe extractions and lower cost, Foley balloon extraction has fallen from favor due to concerns for patient safety related to airway compromise or esophageal injury.[20] Endoscopy is now the preferred method for extraction at most centers.

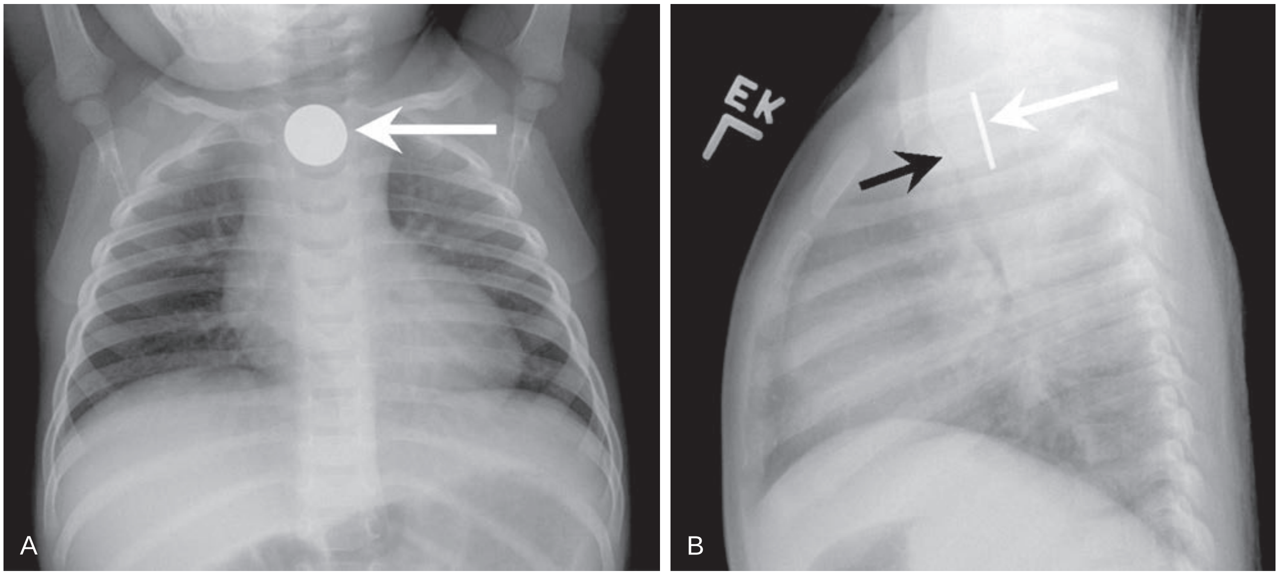
#### Batteries

***Overview and Etiology.*** Esophageal injury in children caused by button battery ingestion is increasing in frequency.[20,21] This increase in injury is thought to be due to an increase in size of the batteries coupled with the shift to a lithium cell.[16,22] Button batteries are often found in objects such as watches, calculators, toys, and hearing aids. Management of battery ingestion is different than that of coins because batteries lodged in the esophagus can cause severe damage in as little as 15 minutes.[16] Tissue damage is caused primarily by the generation of hydroxy ion radicals in the mucosa. This results in a caustic injury from high pH.[16]

***Clinical Presentation.*** If ingestion is witnessed, extraction should occur before the development of symptoms. If these develop, they include drooling, chest discomfort, choking, gagging, and airway obstruction. Damage can include esophageal perforation, or fistula to the trachea or to the aorta leading to exsanguination.[21] Children at greatest risk for developing aortoesophageal fistula are those younger than 5 years of age and those who have ingested batteries larger than 20 mm.[16]

***Imaging.*** Imaging is crucial in the diagnosis and management of button battery ingestion. Batteries can be distinguished on radiographs by their characteristic halo appearance with a circle of lucency just within the outer border (Fig. 98.3A and B).

Progression of injury, even days to weeks after the battery ingestion, is a hallmark of this disease entity. Therefore imaging



**e-Figure 98.2. Coin in esophagus.** (A) Frontal chest radiograph shows a coin lodged in the proximal esophagus *(arrow)* at the level of the thoracic inlet. (B) Lateral view of the chest shows the coin *(white arrow)* lodged in the proximal esophagus. The trachea *(black arrow)* is located anterior to the esophagus. The trachea is narrowed at the level of the foreign body. There is thickening of the space between the esophagus and trachea.

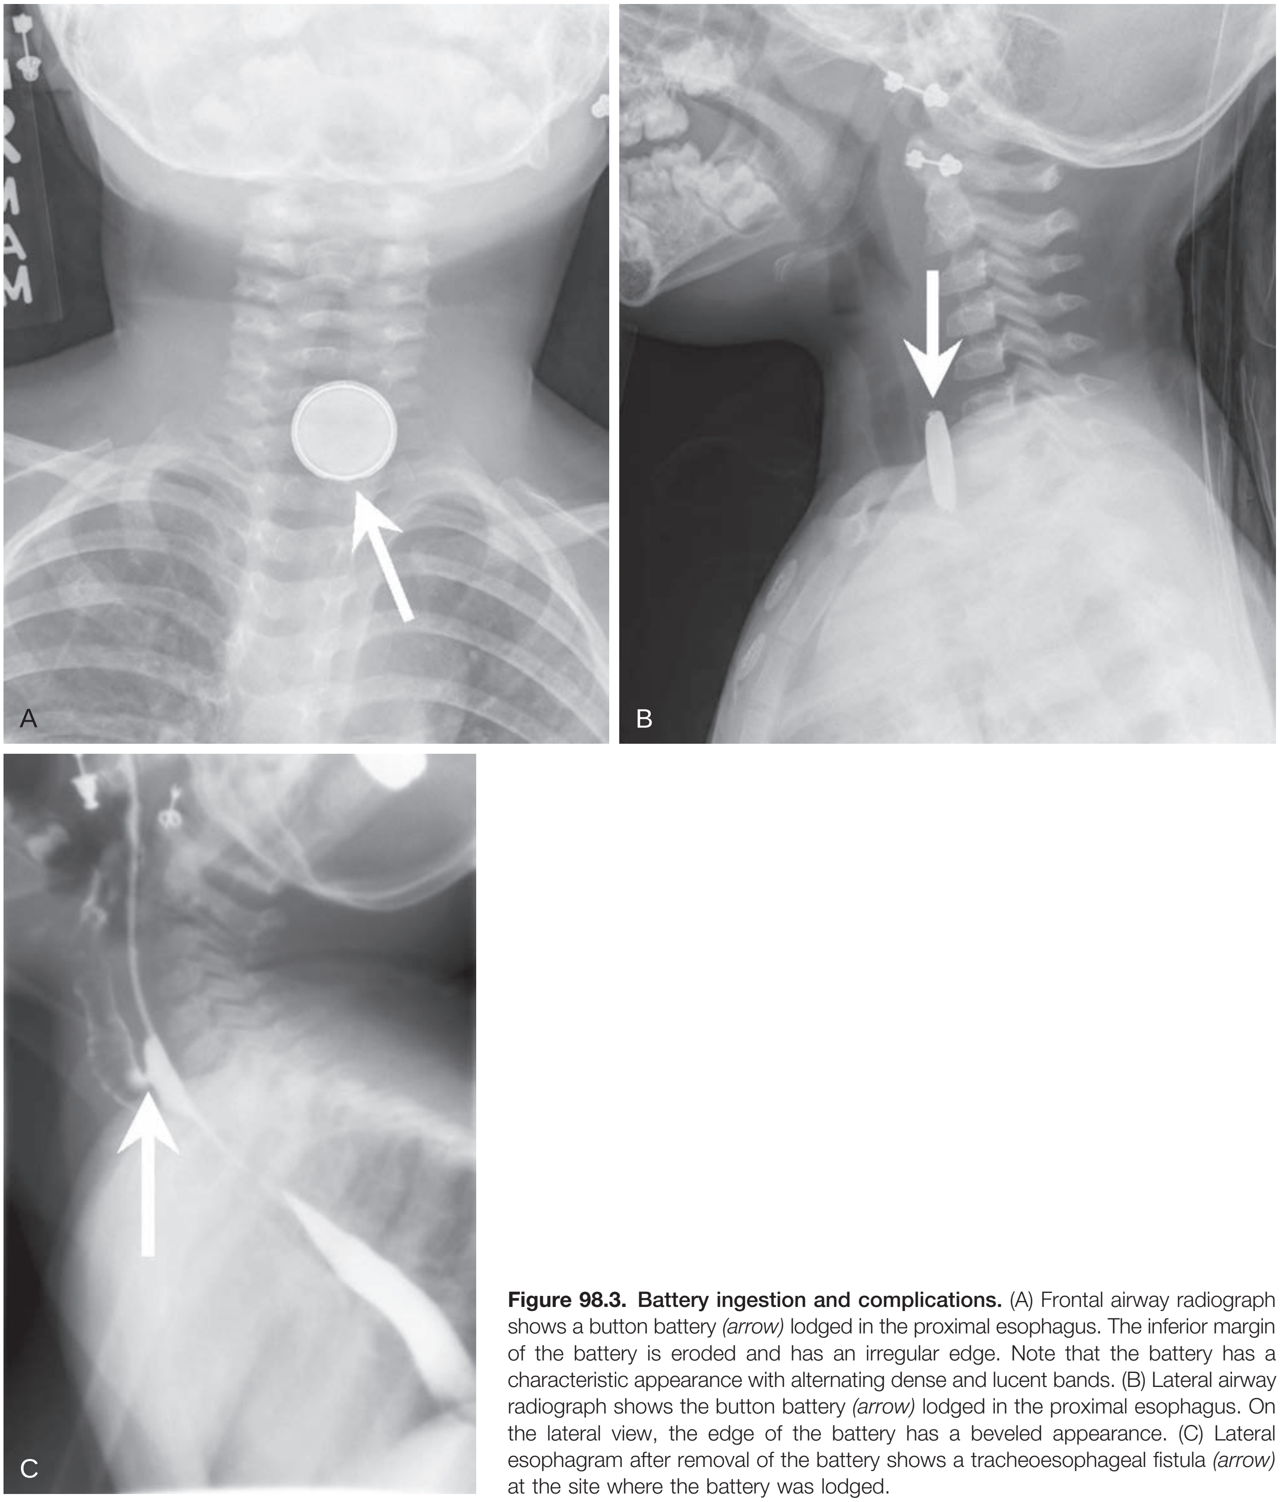


**Figure 98.3. Battery ingestion and complications.** (A) Frontal airway radiograph shows a button battery *(arrow)* lodged in the proximal esophagus. The inferior margin of the battery is eroded and has an irregular edge. Note that the battery has a characteristic appearance with alternating dense and lucent bands. (B) Lateral airway radiograph shows the button battery *(arrow)* lodged in the proximal esophagus. On the lateral view, the edge of the battery has a beveled appearance. (C) Lateral esophagram after removal of the battery shows a tracheoesophageal fistula *(arrow)* at the site where the battery was lodged.

plays a role in the continued management of these patients.[23] Esophagram with water-soluble iso-osmolal contrast can be performed after removal to evaluate for the presence of complications, such as esophageal perforation or tracheoesophageal fistula. (Fig. 98.3C and eD). Long-term complications, such as esophageal stricture, can also be diagnosed.[23]

Recently, the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) has advocated for CT or MR angiography in the setting of a button battery ingestion when an esophageal injury is identified at the level of the aorta on endoscopy.[16] This recommendation was echoed by the Button Battery Task Force which further recommended using CT or MRI to evaluate for signs of mediastinitis and inflammation surrounding the aorta.[24]

***Treatment.*** If a battery is lodged in the esophagus, the requesting clinician should be contacted immediately to arrange emergent extraction. Follow-up imaging may be indicated, as previously discussed. There is no consensus recommendation for follow-up in the setting of esophageal inflammation, mediastinitis, or inflammation surrounding the aorta.

## Food Bolus Impaction

***Overview and Etiology.*** Impacted food boluses are relatively infrequent in children but may represent the initial presenting symptom of eosinophilic esophagitis, peptic stricture, achalasia, vascular rings, or an extrinsic mass.[25,26] Eosinophilic esophagitis is the major cause of food bolus impaction in children accounting for more than 50% of all cases. The second most common cause is an area of narrowing in a patient with prior esophageal atresia repair or Nissen fundoplication surgery.[27]

***Clinical Presentation.*** Acute impaction of food typically leads to symptoms of dysphagia and drooling; difficulty swallowing may lead to aspiration.

***Imaging.*** On esophagram, an impacted food bolus appears as a persistent filling defect in the esophagus (e-Fig. 98.4). The impacted food can completely obstruct the esophagus. This is seen on esophagram as a standing column of contrast that does not pass beyond the food bolus.

***Treatment.*** When identified, the food bolus is removed endoscopically. Esophagram can be performed after extraction or passage of the food bolus, to evaluate for the underlying cause, if not already known. Esophageal biopsy is recommended in patients diagnosed with food bolus impaction to assess for eosinophilic esophagitis, particularly in those who do not have a history of prior esophageal surgery.[27]

## Caustic Ingestion

***Overview and Etiology.*** Ingestion of caustic materials in childhood is relatively common and typically accidental. In 2014, there were 198,018 ingestions of household cleansers reported to the American Poison Control Centers, more than 65% of which occurred in children.[15] The age group at highest risk for caustic ingestion is children under 5 years of age,[15] with a peak around 2 years when children are learning to explore but not yet able to distinguish between harmless and harmful substances.[28]

The extent and severity of injury depends on several factors: the corrosiveness of the ingested substance, the quantity ingested, the physical state of the substance, the duration of the contact time of the substance with the esophagus, and subsequent secondary infection.[28,29]

A variety of substances can cause a caustic injury, including alkalis (pH up to 12), acids (pH as low as 2), and bleaches (pH near 7). In contrast to acidic substances that are sour, alkalis have a relatively innocuous taste, leading to a greater volume ingested.[28] Further, alkaline agents produce liquefaction necrosis and rapid penetration leading to more severe injury.[29]

***Clinical Presentation.*** After caustic ingestion, patients with severe injury typically present with pain, drooling, and airway symptoms; more visible signs of tissue damage include lip swelling, mouth ulcers, and erythema of the tongue.[28] Esophageal stricture is an important late complication with a reported frequency between 2% and 63% of patients.[29] A stricture can form in as little as 3 weeks after injury.[30]

***Imaging.*** Initial management of patients with caustic ingestion includes a radiograph of the chest and lateral neck to evaluate for pneumomediastinum. Esophagram is not indicated in the acute phase because it delays endoscopy and does not detail mucosal injuries.[28]

When strictures develop, they can be diagnosed based on symptoms, and confirmed with esophagram (Fig. 98.5). Caustic strictures can be focal or occupy a long segment of the esophagus depending on the substance ingested; acid ingestion typically causes a focal or short segment stricture while alkali substances cause a long segment stricture.[30] Strictures most commonly occur in the upper or midesophagus. Multiple strictures can also occur.

***Treatment.*** Acutely patients are treated with steroids, proton pump inhibitors, and antibiotics; endoscopic evaluation is performed to assess the extent of damage and to grade the injury. Strictures are first treated with balloon dilation under fluoroscopy. The advantage of balloon dilation over dilation using a bougie is that balloons dilate strictures in a radial direction rather than a longitudinal direction. This is thought to be less likely to cause an esophageal perforation.[28] After the balloon is inflated and the waist is seen to disappear, an esophagram is performed to evaluate for a leak that occurs in 4% to 30% of patients.[30] If balloon dilation fails, operative treatment with stricture resection is performed; esophageal replacement may be necessary.

Patients with a history of caustic ingestion are at risk of developing squamous cell carcinoma of the esophagus. These patients should undergo endoscopic surveillance as adults.[28]

## Pill Esophagitis

***Overview and Etiology.*** Pill esophagitis is an injury caused by medications; the drugs most frequently implicated are doxycycline and alendronate.[31] Other drugs reported to cause esophageal injury include nonsteroidal antiinflammatory drugs, potassium chloride, ferrous sulfate, phenytoin, and quinidine.[31] Characteristics of medications that are more likely to cause esophageal injury include the acidity of the medication and a capsule formulation that renders it more likely to stick in the esophagus.[32] Pill esophagitis is also more likely to occur in patients with delayed esophageal transit time including taking a pill with little or no water immediately before going to bed, decreased saliva production, and anatomic areas of narrowing.[32]

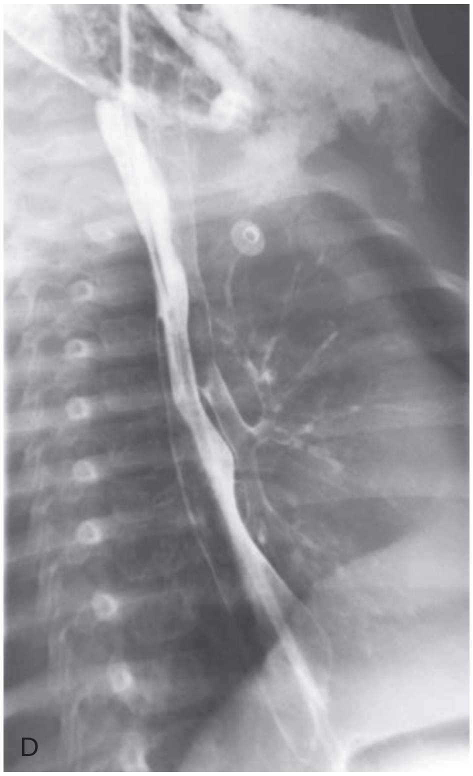
***Clinical Presesentation.*** Patients with pill esophagitis typically present with dysphagia, odynophagia, and chest pain. Pill esophagitis can often be diagnosed by history alone.

***Imaging.*** Esophagram is not commonly performed due to the classic history but can show a circular area of ulceration. If endoscopy is performed, a circular ulceration is identified with normal surrounding mucosa. The ulceration typically occurs at an anatomic area of narrowing such as at the level of the aortic arch, left mainstem bronchus, or gastroesophageal junction.[32]

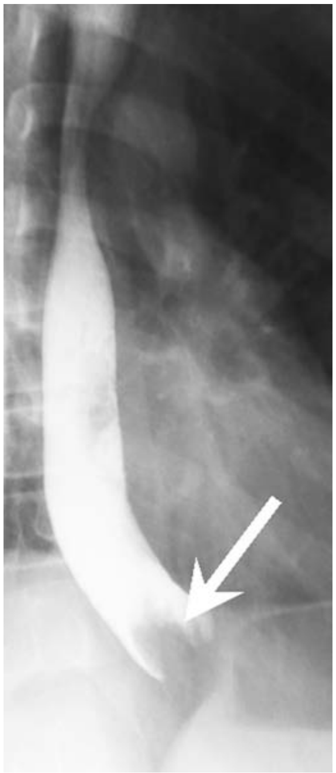
***Treatment.*** Pill esophagitis is treated and prevented with changing pill-taking habits (taking pills with more water, taking pills long before going to bed), crushing pills, taking a liquid suspension, or switching medications.

## Iatrogenic Trauma

***Overview and Etiology.*** Iatrogenic trauma is the most common cause of esophageal perforation in children, representing 75% to 85% of all cases.[33] Esophageal perforation can be life-threatening



**e-Figure 98.3.** (D) Oblique view from an esophagram shows contrast in both the esophagus and the tracheobronchial tree due to the tracheoesophageal fistula.



**e-Figure 98.4.** Esophagram shows a persistent filling defect *(arrow)* in the distal esophagus. The patient underwent endoscopy to remove the food bolus. The biopsy obtained during endoscopy confirmed a diagnosis of eosinophilic esophagitis.

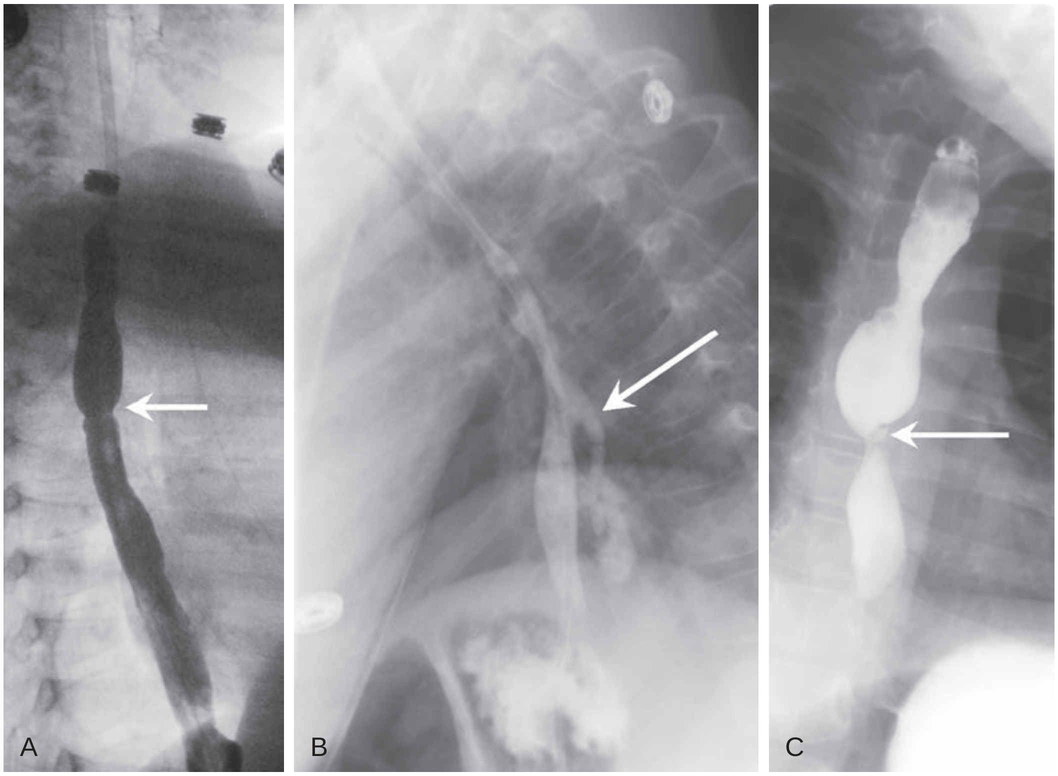


**Figure 98.5. Stricture and other complications of caustic ingestion.** (A) Esophagram in a patient with a recent history of lye ingestion shows an irregular contour of the esophagus and a focal area of narrowing *(arrow)*. (B) Esophagram in the same patient 3 months later and immediately after dilation of an esophageal stricture shows an esophageal perforation with a contrast leak *(arrow)*. (C) Esophagram in the same patient after the esophageal perforation had healed shows a stricture *(arrow)* in the midesophagus. The esophagus proximal to the stricture is dilated.

as the esophagus lacks a serosa, and the surrounding loose areolar connective tissue is unable to prevent the spread of infection; thus oral flora and digestive enzymes are able to spread to the mediastinum.[33]

The most common cause of iatrogenic perforation in children is from stricture dilation (see Fig. 98.5B). Other causes include complications of nasogastric tube placement, endotracheal intubation, endoscopy, pedicle screw placement, and sclerotherapy of esophageal varices.[34–36] The typical location of perforation depends on the age of the patient. In neonates, perforation typically occurs in the cervical esophagus at the pharyngeal/esophageal junction.[33] (See Chapter 96.)

***Clinical Presentation.*** Neonates often present after a difficult intubation with nonspecific symptoms, including drooling, choking, or coughing with feeds. In older children, perforation is more common in the thoracic esophagus. They typically present with respiratory distress, chest pain, or subcutaneous emphysema.[33]

***Imaging.*** The initial diagnostic examination is often frontal and lateral radiographs of the chest. Findings on the chest x-ray include pneumothorax, pneumomediastinum, pleural effusion, and, if the event was caused by nasogastric tube placement, an abnormal course of the tube may be seen (Fig. 98.6).[33] The location of the perforation can often be determined from the radiograph. Left-sided pneumothorax and effusion are more likely to occur in the setting of an upper thoracic perforation while right-sided findings are more likely to occur with perforations in the distal esophagus.[33]

Esophagram can be useful in diagnosing and locating a perforation. Water-soluble iso-osmolal contrast should be used first. If no contrast extravasation is noted, barium may then be used, as it is more sensitive in the detection of an esophageal leak.[33] Three patterns of perforation have been described on esophagram: a local cervical leak is identified if there is a retropharyngeal pocket of contrast; a submucosal leak appears as a linear tract posterior and lateral to the esophagus; finally, free perforation appears as contrast flowing into the pleural space.[33]

CT is not generally used to diagnose an esophageal perforation; however, in a complex, acutely ill patient, this may be the first study performed. Signs of esophageal perforation on CT include pneumomediastinum, mediastinal fluid, esophageal wall thickening, and a catheter extending beyond the esophagus.

***Treatment.*** Treatment usually consists of expectant medical management, with broad spectrum antibiotics, pleural drainage via chest tube and nutritional support with total parenteral nutrition or gastrostomy; a nasogastric (NG) tube may be placed beyond the perforation under direct visualization. Operative exploration is considered in patients in whom the above more conservative management fails.[33]

## Blunt Esophageal Trauma

***Overview and Etiology.*** The esophagus is rarely injured after chest trauma due to its flexibility and ability to decompress via the mouth and stomach.[37] Reported causes of esophageal injury include handlebar injury, crush injury, opening a bottle of carbonated drinks in the mouth, and child abuse.[38–41] Tracheoesophageal fistula is an even rarer complication of trauma.

***Clinical Presentation.*** Patients usually present with coughing induced by swallowing. Other findings include subcutaneous emphysema, pneumothorax, dysphagia, dyspnea, and hoarseness.

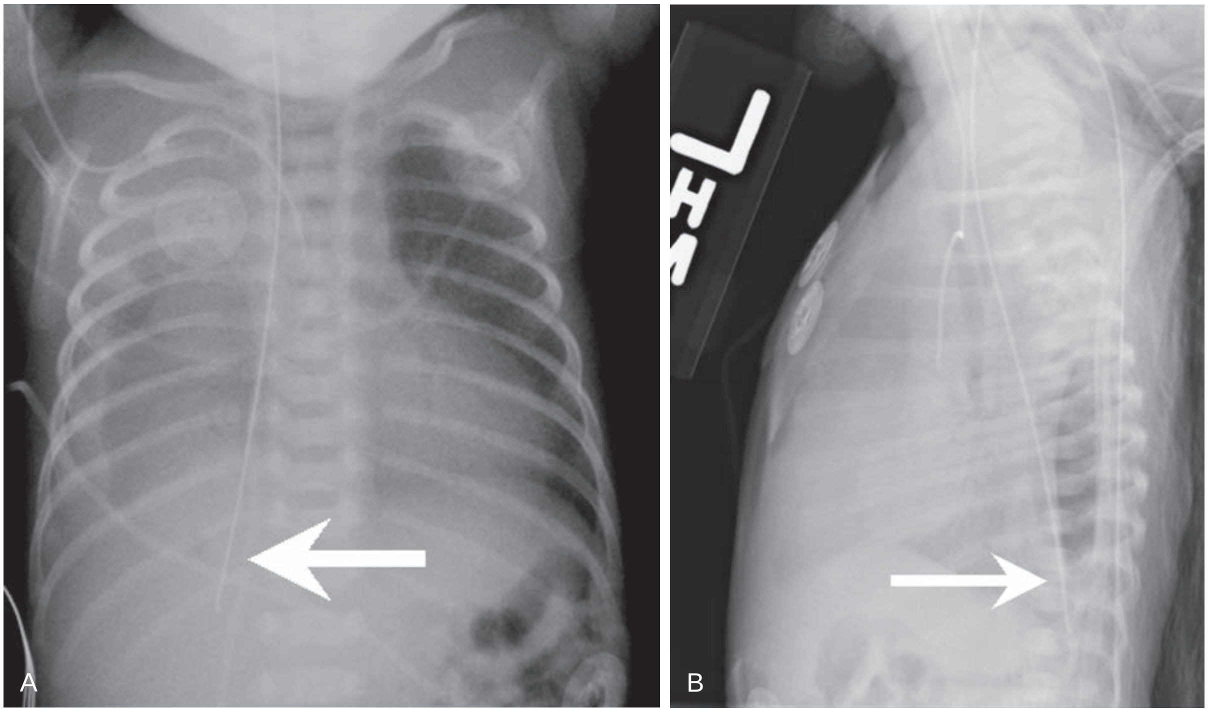

**Figure 98.6. Esophageal perforation.** (A) Frontal chest radiograph in a premature infant shows an abnormal course of the nasogastric tube *(arrow);* the tip of the tube overlies the right upper quadrant. There is a right pleural effusion. (B) Lateral chest radiograph also shows the abnormal course of the nasogastric tube *(arrow);* the tip of the tube projects in the pleural space over the posterior costophrenic sulcus.

***Imaging.*** Chest radiograph or CT may show pneumomediastinum and pleural effusion in a child presenting with blunt trauma. Esophagram can be performed for confirmation and to diagnose a tracheoesophageal fistula.[42] Water-soluble iso-osmolal contrast material should be used in these cases, as noted in previous section.

## Boerhaave Syndrome

***Overview and Etiology.*** Boerhaave syndrome is defined as spontaneous rupture of the esophagus, often related to vomiting. The rupture typically involves the distal portion of the thoracic esophagus. Boerhaave syndrome is rare in children, but nearly 50% of cases occur in neonates.[43]

***Clinical Presentation.*** Patients typically present with vomiting, lower thoracic pain, and subcutaneous emphysema.

***Imaging.*** In most children, the rupture occurs on the right side in contrast to adults in whom rupture is usually left-sided[43] and therefore chest radiograph will demonstrate right sided pneumothorax and pleural effusion. Diagnosis is confirmed with esophagram and/or endoscopy; however, insufflation may lead to life-threatening pneumothorax.

***Treatment.*** While children and neonates are more likely to have a better prognosis than adults, surgery remains the treatment of choice of Boerhaave syndrome. Conservative approach can be used in patients with small tears and is used in patients with presentation or diagnosis greater than 24 hours.[43]

# INFLAMMATORY CONDITIONS

## Eosinophilic Esophagitis

***Overview and Etiology.*** Eosinophilic esophagitis is a chronic inflammatory disease characterized by dense esophageal eosinophilia. Over the past decade, there has been an increase in awareness of the disease as well as an increase in the number of cases diagnosed. Currently it is thought that eosinophilic esophagitis occurs with an incidence of up to 1:10,000 children per year.[44] Eosinophilic esophagitis is three to four times more common in males and can occur at any age.[45] To be diagnosed with eosinophilic esophagitis, patients must have both the histologic and clinical features of the disease. Histologically, eosinophilic esophagitis is characterized by an esophageal mucosal biopsy with more than 15 eosinophils per high-power field.

***Clinical Presentation.*** Patients present with esophageal symptoms mimicking GERD. Older children tend to present with vomiting and abdominal pain, although in infants the presentation is more likely feeding difficulties; diagnosis at age less than 6 months is rare. Patients often have other signs of atopy, including dermatitis, food allergies, and asthma.[45]

***Imaging.*** Because the symptoms of eosinophilic esophagitis are protean and simulate those of GERD, diagnosis is often delayed. UGI is frequently performed as part of the diagnostic work of patients due to their esophageal symptoms. On UGI, the most common finding is a normal esophagus.[46] The most common positive findings are GER, irregular contractions, esophageal dysmotility, esophageal strictures, esophageal rings, small caliber esophagus, and food bolus impaction (Fig. 98.7).[46]

***Treatment.*** Eosinophilic esophagitis is thought to represent an allergic response to food and is usually treated with attempts to identify and eliminate the offending agent(s), or with an elemental diet. Steroids may also be used alone or in combination with diet therapy.[45]

## Epidermolysis Bullosa

***Overview and Etiology.*** Epidermolysis bullosa is a rare group of hereditary blistering disorders caused by mutations in genes

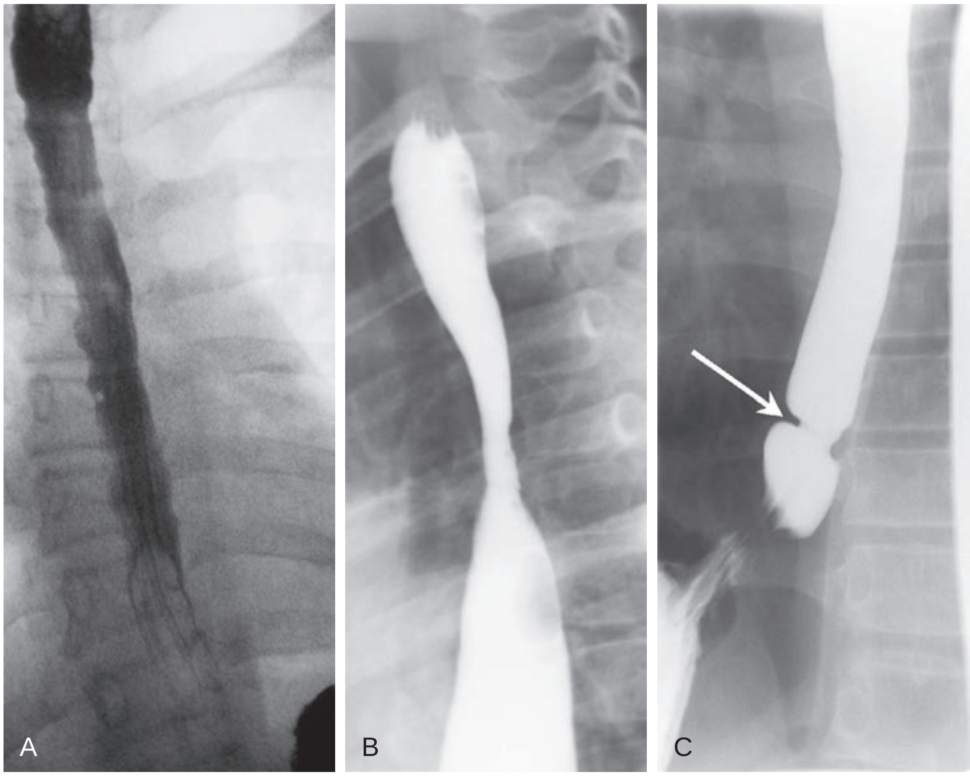

**Figure 98.7. Eosinophilic esophagitis.** (A) Esophagram shows diffuse irregular esophageal contractions. (B) Esophagram shows a stricture *(arrow)* of the mid esophagus. (C) Esophagram shows a Schatzki ring *(arrow)* of the distal esophagus.

expressed at the dermal-epidermal junction. More than 100 distinct genotypes and 20 phenotypes of disease of varying severity have been described.[47]

***Clinical Presentation.*** Patients often develop skin blistering and erosions with minor mechanical trauma. Repeated blistering leads to scar formation and causes symptoms such as contractures. Extracutaneous sites can also be affected and include the esophagus, bowel, rectum, anus, bladder, urethra, and trachea.[47]

***Imaging.*** In the esophagus and oropharynx, scar formation leads to dysphagia and esophageal strictures. Any segment of the esophagus may be involved, although approximately half of strictures occur in the cervical esophagus.[48]

***Treatment.*** The initial treatment of choice for esophageal strictures in children is balloon dilation under fluoroscopic or endoscopic visualization (Fig. 98.8).[47,48] Patients often require multiple dilations to treat recurrent or persistent strictures.[48]

## Crohn Disease

***Overview and Etiology.*** Crohn disease is a chronic inflammatory disease of the gastrointestinal tract characterized by waxing and waning symptoms, transmural inflammation of the bowel wall, and skip lesions. It can affect any portion of the gastrointestinal tract from the mouth to the anus, but it most commonly affects the small bowel and colon in children. Esophageal symptoms of Crohn disease are uncommon; however, endoscopic and histologic findings are more frequent and occur in 7.6% and 17.6%, respectively.[49]

***Clinical Presentation.*** Dysphagia is the most common symptom of esophageal Crohn disease followed by odynophagia, chest pain, nausea, and vomiting.[50]

***Imaging.*** While the esophagram is often normal, esophageal Crohn disease can manifest with mucosal irregularity, aphthous ulcers, or stricture.[49]

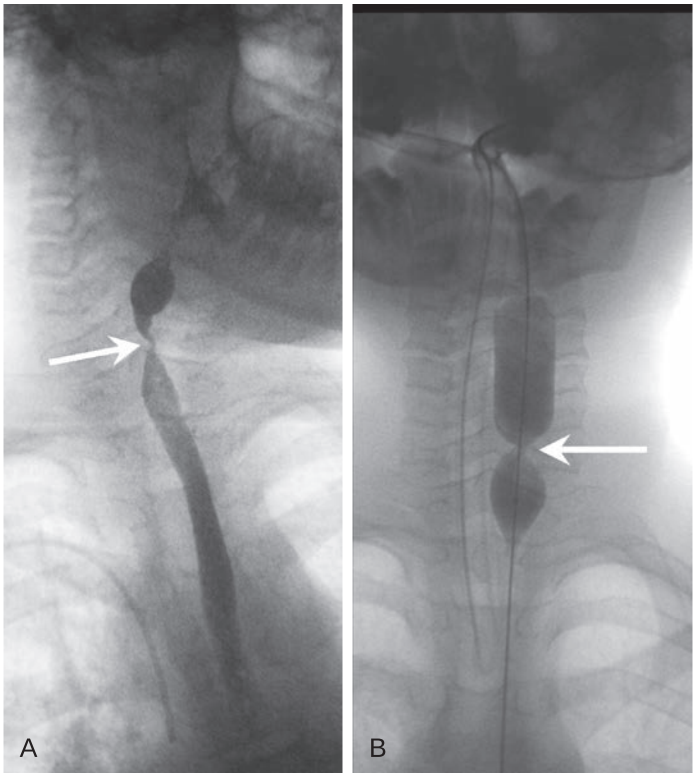

**Figure 98.8. Epidermolysis bullosa.** (A) Esophagram shows a tight stricture *(arrow)* in the cervical esophagus. (B) Image from esophageal dilation shows a balloon dilated in the cervical esophagus. There is a focal area of narrowing *(arrow)* at the site of stricture.

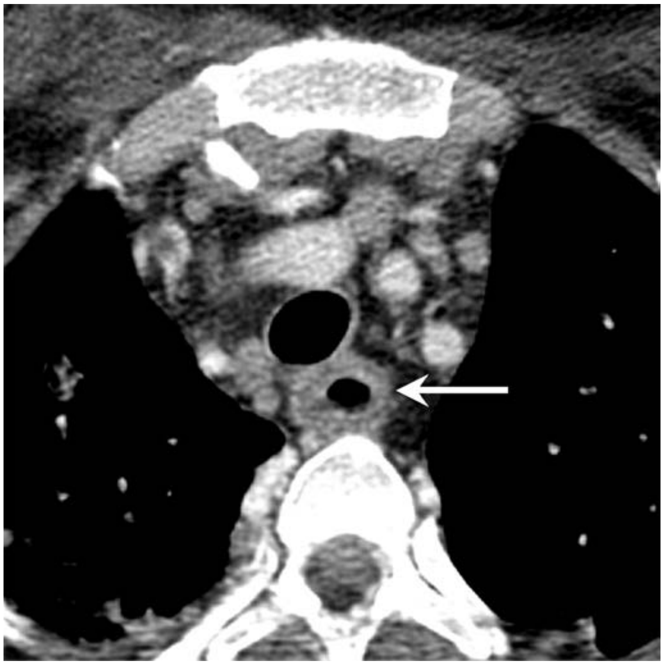

**Figure 98.9. Chronic granulomatous disease.** Axial contrast-enhanced CT in a patient with chronic granulomatous disease shows thickening of the wall of the proximal esophagus *(arrow)*.

## Chronic Granulomatous Disease

***Overview and Etiology.*** Chronic granulomatous disease is an uncommon primary immunodeficiency characterized by recurrent bacterial and fungal infections occurring at epithelial surfaces. Gastrointestinal manifestations are present in most patients with chronic granulomatous disease. Any portion of the gastroesophageal tract may be involved from the mouth to the anus. Esophageal involvement is uncommon.

***Clinical Manifestations.*** The symptoms overlap those of other entities affecting the esophagus, and include vomiting, dysphagia, heartburn, and odynophagia.[49]

***Imaging.*** In the esophagus, dysmotility and strictures have been seen on esophagram. CT of the chest can demonstrate esophageal wall thickening (Fig. 98.9).[51]

***Treatment.*** Treatment is with pharmacologic agents targeted at the infection and esophageal dilatation when necessary.[52]

## Behçet Syndrome

***Overview and Etiology.*** Behçet disease is an immune-mediated systemic vasculitis which affects multiple systems, likely representing an exaggerated inflammatory endothelial response. The entity is more prevalent in Mediterranean and Middle Eastern countries, Japan, and Southeast Asia.

***Clinical Manifestations.*** Behçet syndrome is characterized by pyoderma, gastrointestinal and genital mucous membrane ulceration, uveitis, and central nervous system vasculitis.[53] Oral ulcerations are often the first manifestation of disease. Because these ulcerations are nonspecific, diagnosis is often delayed until abnormalities of the genitals, gastrointestinal system, or central nervous system develop. Patients are also at risk of developing venous thrombosis and arterial aneurysms which can be life-threatening.

***Imaging.*** In the esophagus, dysmotility, ulceration, and stricture have been described on UGI.[53] These findings are often difficult to distinguish from Crohn disease. Diagnosis is made by the presence of mouth ulcers in association with two other major criteria, including skin lesions, recurrent genital ulcerations, or the presence of an excessive dermal inflammatory response termed pathergy.

***Treatment.*** Treatment is geared at reducing the overactive inflammatory response, and includes corticosteroids, azathioprine, and interferon.[10,54]

## INFECTIOUS ESOPHAGITIS

Infectious esophagitis is typically seen in children with congenital or acquired immunodeficiency such as chemotherapy or post-transplant immunosuppression. Endoscopy has replaced esophagram as the method of diagnosing infective esophagitis due to its ability to visualize the abnormality directly and to obtain a tissue sample for culture. If esophagram is performed for infectious esophagitis, the double-contrast technique is preferred, if possible, to better define mucosal detail.

### Candida Esophagitis

***Overview and Etiology.*** *Candida albicans* is the most common infective agent to cause esophagitis.[55] Oropharyngeal candidiasis is the strongest risk factor for the development of esophagitis in patients with neutropenia or human immunodeficiency virus (HIV) infection. On endoscopy, the appearance of esophageal Candidiasis varies from a few small, raised white plaques to confluent plaques with hyperemia and ulceration.[55]

***Clinical Manifestations.*** Patients typically present with odynophagia, dysphagia, and chest pain.

***Imaging.*** Esophagram is less sensitive than endoscopy in making the diagnosis.[55] On esophagram, severe infection is characterized by a shaggy appearance of the esophagus due to multiple ulcers and nodular plaques.

***Treatment.*** Treatment is with antifungal medications including fluconazole and nystatin; caspofungin and amphotericin are reserved for systemic cases and cases resistant to therapy. Prophylactic therapy is employed in immunocompromised patients.

### Cytomegalovirus Esophagitis

***Overview and Etiology.*** Cytomegalovirus (CMV) is common in the population at large and is one of the more common opportunistic infections in immunocompromised patients. When affecting the gastrointestinal tract, CMV most commonly involves the esophagus and the colon.

***Clinical Manifestations.*** Patients with CMV involving the gastrointestinal tract present with chronic diarrhea, abdominal pain, bleeding, perforation, odynophagia, peritonitis, and bowel obstruction.[56]

***Imaging.*** Esophagitis is the second most common gastrointestinal manifestation of CMV infection after colitis.[56] Endoscopy is the diagnostic method of choice; however, esophagram can demonstrate the large, shallow ulcers characteristic of CMV infection.

***Treatment.*** The most effective treatment for CMV infection in immunocompromised patients is restoration of immunocompetence, such as the use of antiretrovirals in patients with HIV.[56]

### Human Immunodeficiency Virus Esophagitis

***Overview and Etiology.*** Giant esophageal ulcers can occur in patients with HIV infection. There are several different causes of ulcers in immunocompromised patients including those with HIV infection, and these include CMV, *Candida albicans*, mycobacteria, and herpes simplex virus.[57] The ulcer is called an HIV-related or idiopathic giant ulcer when the cause of the ulcer cannot be attributed to other known pathogens, such as those previously described.

***Clinical Presentation.*** Patients present with esophageal symptoms of odynophagia, dysphagia, and retrosternal chest pain and may experience hematemesis. Complications include bleeding, strictures, and fistulas into the tracheobronchial tree.[58]

***Imaging.*** Idiopathic giant ulcers typically occur in the middle to distal third of the esophagus. Smaller satellite ulcers may also be present.[57] Idiopathic giant ulcers are difficult to distinguish from ulcers caused by CMV infection, although idiopathic giant ulcers are said to be larger and have overhanging edges.[57]

***Treatment.*** Treatment is geared to the infectious agent identified; if the ulcer is idiopathic, treatment is with steroids; thalidomide may also be added.[58]

## Tuberculosis

***Overview and Etiology.*** Involvement of the esophagus by tuberculosis is rare. There have been several reports of esophageal erosion with formation of a tracheoesophageal fistula in patients with tuberculosis.[59,60] Esophageal perforation is thought to occur by one of three methods: rupture of a mediastinal abscess into the esophagus, formation of a traction diverticulum due to tuberculous mediastinitis, or erosion due to pressure necrosis of adjacent lymph nodes.[59]

***Clinical Presentation.*** Symptoms depend on the complications; patients with esophagotracheal or esophagobronchial fistulas may experience extensive coughing after ingestion of fluids, and hematemesis.[61]

***Imaging.*** When perforation occurs, esophagram shows extraluminal extension into the mediastinum or into the fistula. On CT, there are large, low-density mediastinal lymph nodes in addition to pneumomediastinum.

***Treatment.*** Treatment is geared to addressing the complications in addition to antituberculous medications.Esophageal Motility Disorders

Primary esophageal motility disorders are uncommon in children. Esophageal dysmotility is most commonly seen in patients with esophageal atresia, due to an underlying inflammatory condition such as GERD, or rarely to a primary motor disorder such as achalasia.

## Esophageal Atresia

***Overview and Etiology.*** Esophageal atresia (see Chapter 96) is corrected via surgical repair in the early neonatal period. There are several potential complications of the repair: recurrent tracheoesophageal fistula, esophageal strictures at the site of anastomosis, and food bolus impaction (e-Fig. 98.10 and Fig. 98.11).

Esophageal dysmotility is near ubiquitous in patients with a history of esophageal atresia. There are two potential theories for the etiology of esophageal dysmotility: primary dysgenesis or postoperative sequela to the esophageal nerve supply.[62]

## Achalasia

***Overview and Etiology.*** Achalasia is a primary motor disorder characterized by failure of the lower esophageal sphincter to relax with swallowing.[63] Diagnosis can be made via manometry, upper endoscopy, or esophagram. Manometry is the gold standard for diagnosis and shows aperistalsis of the smooth muscle of the esophagus, and incomplete relaxation and elevated resting pressure in the lower esophageal sphincter.[64] Biopsy confirms the diagnosis of achalasia with hypertrophy of the muscularis and absent ganglion cells.

***Clinical Presentation.*** Patients present with progressive dysphagia, regurgitation, chest pain, nocturnal cough, and heartburn.[64]

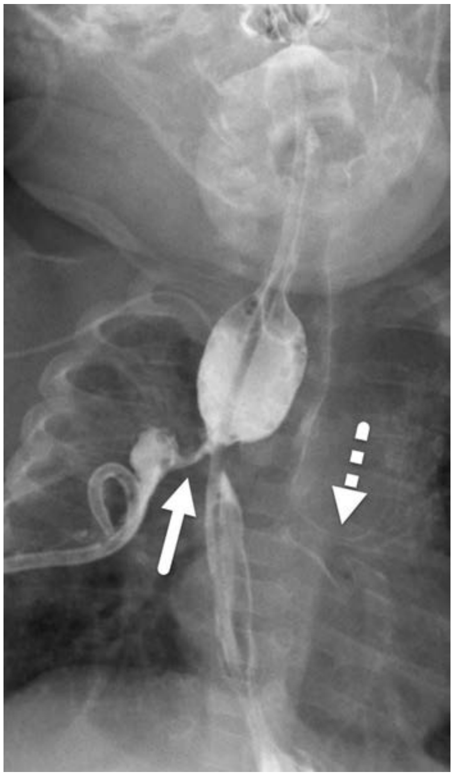

**Figure 98.11. Esophageal leak at anastomosis, and aspiration status postesophageal atresia repair.** Frontal image from an esophagram in a neonate with esophageal atresia status post repair shows a leak *(solid arrow)* at the esophageal anastomosis. Note that aspiration also occurred and contrast is visible in the left bronchial tree *(dashed arrow)*.

***Imaging.*** On chest x-ray, the esophagus can appear dilated and air-filled (Fig. 98.12). This appearance is often unusual and can mimic a medial pneumothorax. Esophagram shows dilation of the proximal esophagus, lack of peristalsis, and smooth tapering of the distal esophagus with a bird's beak appearance near the gastroesophageal junction.[64] This appearance of the distal esophagus can also be seen on sonography[64] and should be recognized if captured incidentally during abdominal ultrasound.

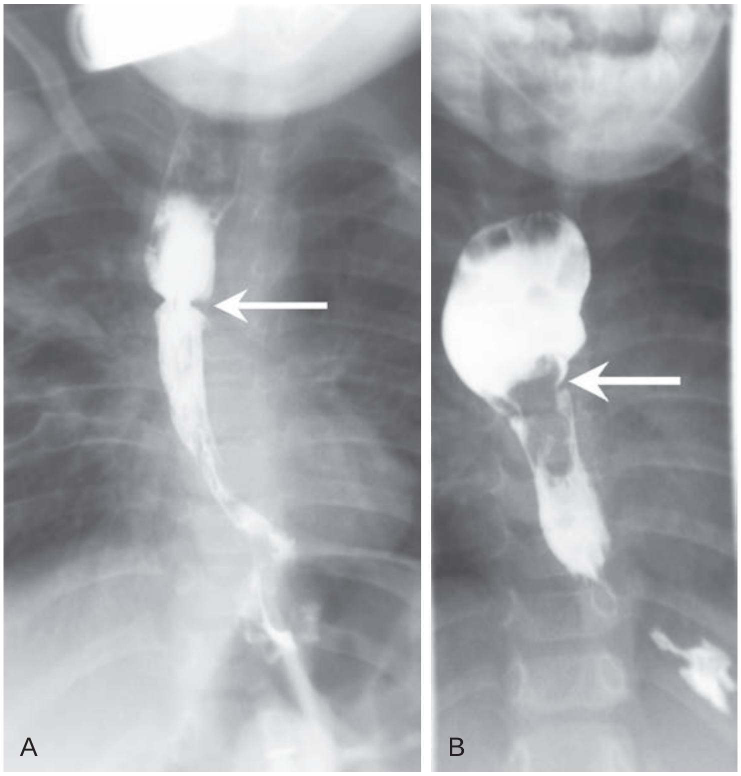
***Treatment.*** Achalasia can be treated with balloon dilation or Heller myotomy. Patients with untreated achalasia can develop aspiration pneumonia and esophageal perforation, and are at higher risk to develop esophageal cancer.[64,65]

# ESOPHAGEAL MASSES

## Leiomyomas

***Overview and Etiology.*** Although rare, leiomyomas are the most common esophageal tumor in children. In contrast to adults, the lesions in children are more likely to be multiple or diffuse.[66] Diffuse esophageal leiomyomatosis is a rare hamartomatous condition in which there is proliferation of the smooth muscle of the esophagus. Esophageal leiomyomatosis can be associated with leiomyomas at other sites or with Alport syndrome (nephropathy, astigmatism, and myopia).[67]

***Clinical Presentation.*** Isolated leiomyomas may be an incidental finding; leiomyomatosis presents with progressive symptoms of dysphagia, vomiting, regurgitation, weight loss, and retrosternal pain.[67]



**e-Figure 98.10. Esophageal stricture after esophageal atresia repair.** (A) Esophagram in a patient with a history of previously repaired esophageal atresia and tracheoesophageal fistula shows a persistent filling defect at the site of the esophageal anastomosis *(arrow)*. Obstruction is denoted by dilatation of the proximal esophagus. (B) Esophagram in a different patient with a history of esophageal atresia repair shows a lobulated filling defect *(arrow)* at the site of anastomosis. The filling defect represented an impacted food bolus.

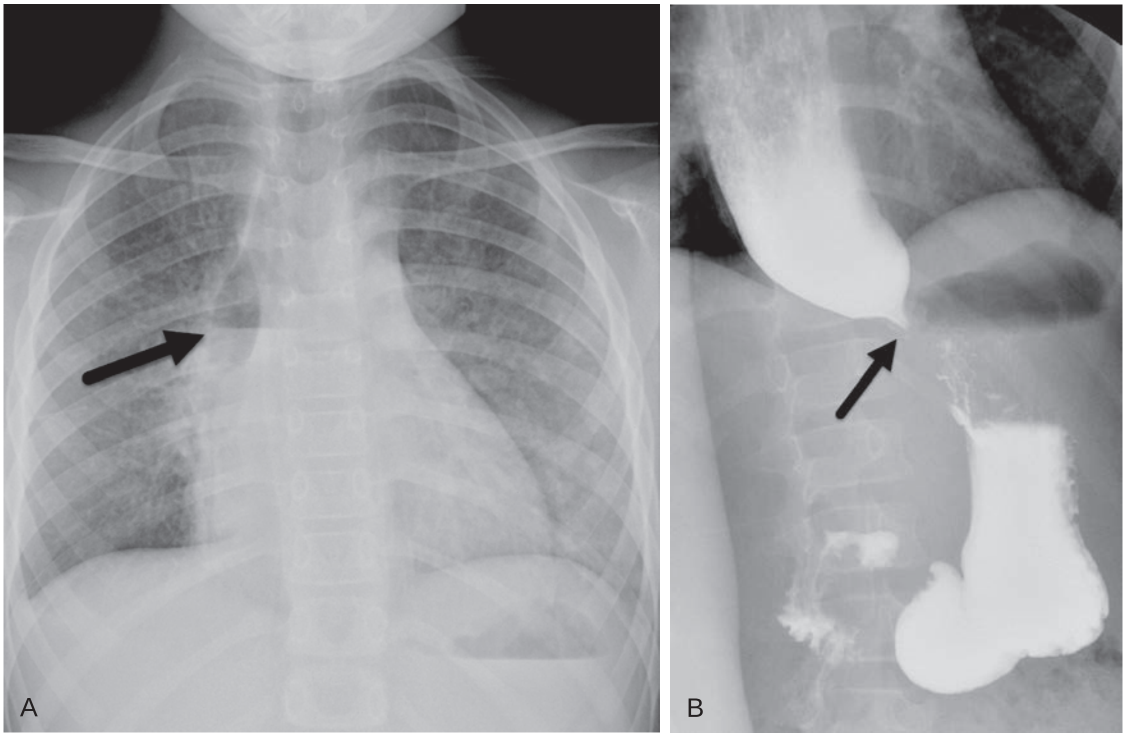


**Figure 98.12. Achalasia.** (A) Frontal chest radiograph in a patient with achalasia shows an oblong lucency of the dilated air-filled esophagus with an air-fluid level *(arrow)* in the right paraspinal region. (B) Spot image from esophagram shows the dilated distal esophagus coming to a point at the gastroesophageal junction. The distal narrowing gives the characteristic "bird's beak" appearance of achalasia *(arrow)*.

***Imaging.*** There are two potential findings on chest x-ray, including a tubular posterior mediastinal mass and rightward deviation of the azygoesophageal stripe.[66,67] Findings on esophagram can mimic achalasia and demonstrate a dilated tortuous esophagus with decreased peristalsis, tapered narrowing, and deviation from midline caused by the intramural masses.[67] If performed, cross-sectional imaging can show diffuse circumferential wall thickening of the esophagus; a discrete soft tissue mass protruding from the esophagus may also be present.[67]

***Treatment.*** Esophageal leiomyomatosis is generally treated with esophagectomy and gastric pull through.

### Malignancies

***Overview and Etiology.*** Esophageal malignancies are very rare in children. There are several conditions that place patients at a higher risk for malignancy including GERD with Barrett esophagitis, caustic ingestion, and achalasia. Esophageal carcinoma is more common in certain regions of the world due to nutrient deficiency of trace elements, consumption of pickled moldy foods, nitrosamines, and thermal injury. Areas with endemic human papilloma virus infection also have a higher incidence of esophageal carcinoma.[68]

### Extraesophgeal Tumors Affecting the Esophagus

***Overview and Etiology.*** The most common thoracic tumors to affect the esophagus are thoracic neuroblastomas and plexiform neurofibromas (Fig. 98.13),[69] with other tumors such as lipoblastoma being much less common (Fig. 98.14). These tumors can cause displacement or mass effect on the esophagus but rarely invade it. Depending on the degree of mass effect, the patient may present with dysphagia.

## OTHER ESOPHAGEL LESIONS

### Esophageal Varices

***Overview and Etiology.*** Esophageal varices are seen in the setting of portal hypertension. They occur primarily around the esophagus, stomach, spleen, and retroperitoneum. When portal hypertension is suspected, endoscopy is the best method to screen for varices.

***Clinical Presentation.*** The symptoms are those associated with portal hypertension; varices themselves are clinically silent until an episode of bleeding ensues. Variceal bleeding is the most serious complication of portal hypertension, and is associated with a mortality of up to 30%.[70]

***Imaging.*** Varices can be identified on contrast-enhanced CT as dilated serpiginous vessels and when very large can be seen on chest radiographs (Fig. 98.15). On esophagram, they appear as lobulated filling defects in the distal esophagus.

***Treatment.*** Varices are typically treated with sclerotherapy, banding, or placement of a portosystemic shunt.

### Esophageal Diverticula

***Overview and Etiology.*** Esophageal diverticula are uncommon in children. They can be associated with stricture, prior esophageal atresia repair, prior injury such as with a chronic foreign body, and connective tissue disorders such as Ehlers–Danlos syndrome.[71–73]

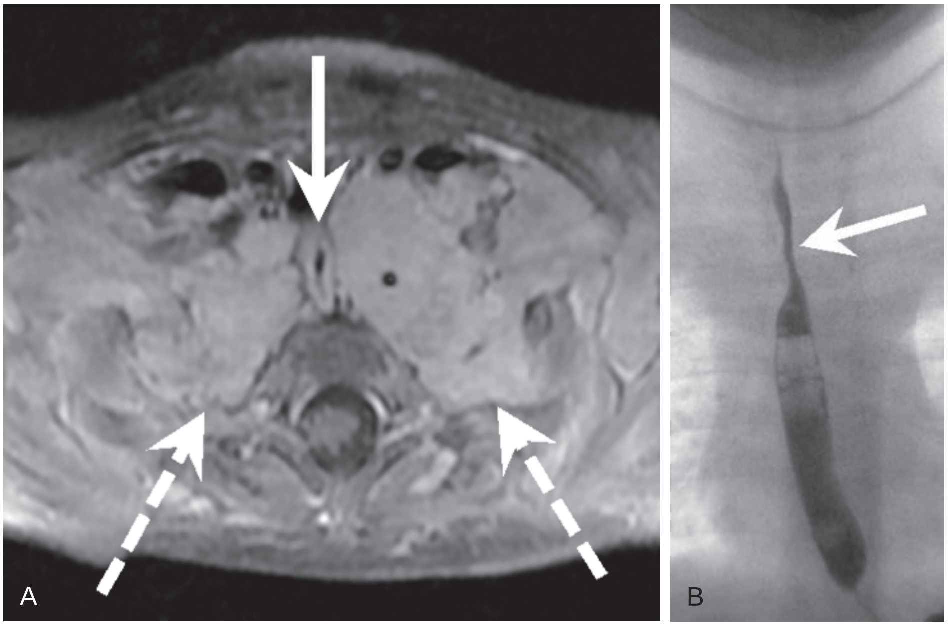

**Figure 98.13. Plexiform neurofibromas in neurofibromatosis type 1.** (A) Axial T1-weighted fat-saturated postcontrast image of the upper chest in a patient with neurofibromatosis, type 1 shows bilateral plexiform neurofibromas *(dashed arrows)* occupying the lung apices and extending to the axillae. The bilateral masses are compressing the esophagus *(arrow)*. (B) Esophagram in the same patient shows narrowing of the proximal esophagus *(arrow)* as it passes between the plexiform neurofibromas; the density from the masses can also be appreciated extending to the thoracic apices.

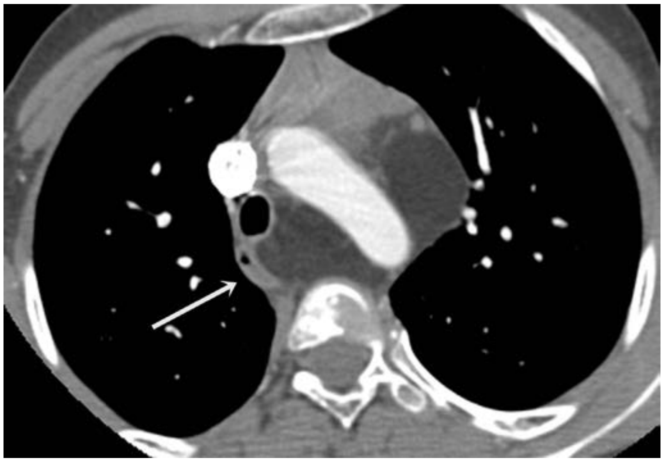

**Figure 98.14. Thoracic lipoblastoma.** Axial contrast-enhanced CT shows a large lipoblastoma displacing the trachea and the esophagus *(arrow)* leftward. *(Courtesy of Marta Hernanz-Schulman, Nashville, TN.)*

## KEY POINTS

- The symptoms of GERD depend on age.
- When compared with adults, children with GERD report fewer episodes of heartburn, dysphagia, and chest pain and more episodes of vomiting and regurgitation.
- Provocative maneuvers or prolonged fluoroscopy is not recommended for the detection of GER.
- Coins are the most common ingested foreign body.
- Button batteries lodged in the esophagus should be removed emergently.
- Food bolus impaction is commonly associated with eosinophilic esophagitis.
- Iatrogenic trauma is the most common cause of esophageal perforation in children.
- Infectious esophagitis is typically seen in immunocompromised children.

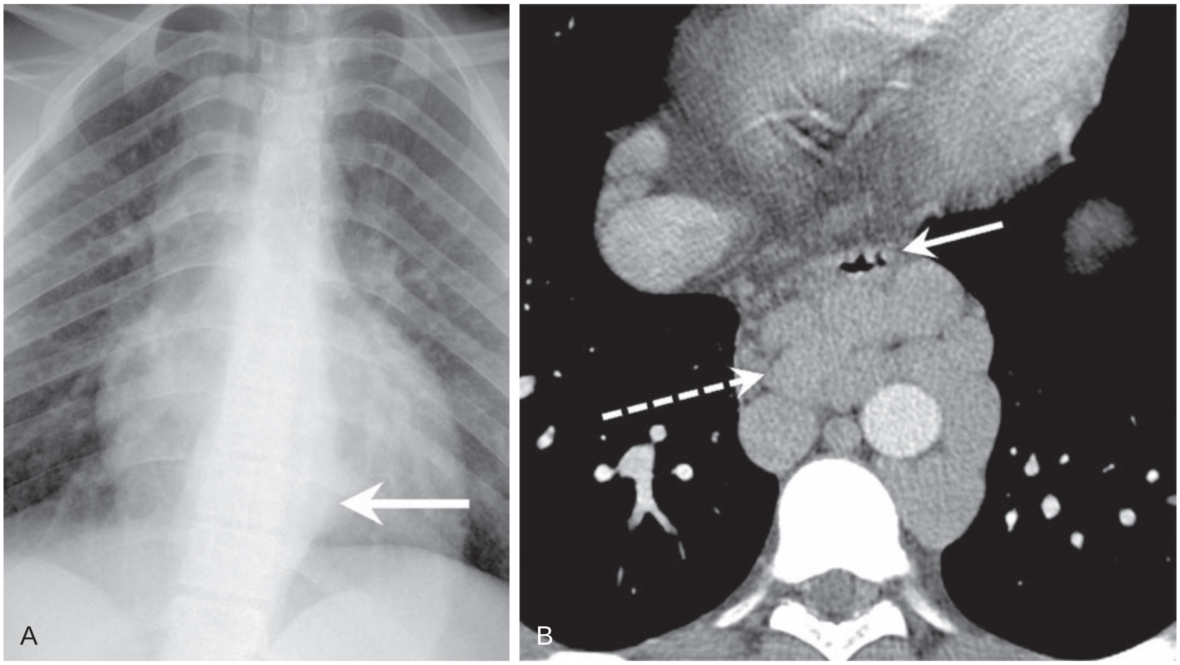

**Figure 98.15. Esophageal varices.** (A) Frontal chest radiograph in a patient with portal hypertension shows a soft tissue mass *(arrow)* in the left paraspinal region. (B) Axial contrast-enhanced CT in the same patient shows multiple dilated esophageal varices *(dashed arrow)* responsible for the paraspinal soft tissue mass on the chest radiograph, and displacing the esophagus *(arrow)* anteriorly, away from the aorta.

# PART 6 Stomach

## 99

## Congenital and Neonatal Abnormalities of the Stomach

*Nancy R. Fefferman, Sudha P. Singh, and Marta Hernanz-Schulman*

Congenital abnormalities of the stomach, and those manifested in the neonatal period, are uncommon and include such entities as duplication cysts, diverticula, microgastria, and anomalies involving the antropyloric region.

### GASTRIC DUPLICATION CYST

***Overview.*** Duplication cysts may occur anywhere along the gastrointestinal tract, from the mouth to the rectum (see Chapters 96, 102, and 105). Gastric duplication cysts are rare and comprise approximately 4% to 7% of intestinal duplications.[1,2]

The cysts are most commonly located along the greater curvature of the stomach, share blood supply with the stomach, are invested in an outer smooth muscle layer, and typically contain gastric epithelial lining, although they may also contain pancreatic tissue or even small intestinal or colonic mucosa.[1,2] More than 80% of gastric duplications are spherical rather than tubular and do not communicate with the gastric lumen.[3] Complete duplications of the pylorus have also been described.[4] Rarely, communication with the pancreatic ductal system has been reported.[1,5]

***Etiology.*** The etiology remains controversial with several hypotheses postulated to explain the embryology of gastrointestinal tract duplications, as no single theory is sufficient to explain the characteristics of all types of duplication cysts; these theories include abortive twinning, split notochord, and persistence of an embryologic diverticulum (see Chapter 102).[6]

***Clinical Presentation.*** Gastric duplication cysts occur more frequently in females at a ratio of 2 : 1.[7] If not discovered prenatally,[8,9] postnatal clinical presentation of gastric duplication cysts usually occurs during the first year of life with symptoms including intestinal obstruction, abdominal pain, palpable mass, gastrointestinal bleeding, and hematemesis[10,11] or melena. Uncommon complications of gastric duplication cysts include pancreatitis[1,12] and gastric outlet obstruction simulating hypertrophic pyloric stenosis when abutting the distal antrum.[3,13] Malignancy has developed within the duplication cyst in some cases.[14,15]

***Imaging.*** Although gastric duplication cysts may be evident on plain radiography as a masslike density in the upper abdomen,[10] the low sensitivity and specificity limits the utility of plain radiography in the evaluation of gastric duplication cysts. Upper gastrointestinal (UGI) contrast examination may demonstrate mass effect by the cyst (Fig. 99.1A and B). Ultrasonography is an excellent imaging modality for characterization of these cystic masses, which often demonstrate the typical “gut signature” or “double-wall” sign representing the inner hyperechoic mucosal layer and peripheral hypoechoic muscle layers (Figs. 99.1C and 99.2); free fluid may be found in cases of perforation (e-Fig. 99.3). Cysts may be completely anechoic, or may contain septations and internal echoes representing proteinaceous material, blood products, or debris related to infection. Computed tomography (CT) demonstrates a well-circumscribed homogeneously low attenuating mass in the left upper quadrant. Peripheral enhancement, wall thickening, and heterogeneous attenuation of the cyst wall may be present if complicated by inflammation. On magnetic resonance imaging (MRI), the cysts exhibit fluid characteristics at T1 and T2 weighting, but the signal may increase on T1-weighted sequences in the presence of hemorrhage or other proteinaceous material.[3] Imaging with technetium 99m-pertechnate is helpful when there is gastric mucosa lining the cysts.[16,17] Meticulous technique is necessary to differentiate the duplication cyst from the adjacent stomach; multiple views may be required, and SPECT CT may be useful in defining the abnormality.[17]

***Treatment.*** Treatment of both symptomatic and asymptomatic gastric duplication cysts entails surgical resection with complete excision of the cyst.[18,19] If the cyst cannot be resected without violating the adjacent gastric lumen, a partial gastric resection with mucosal stripping may be necessary.[5] Laparoscopic resection of gastric duplication cysts has also been described.[19–23]

### GASTRIC DIVERTICULA

***Overview.*** Gastric diverticula are rare in the general population, with a reported prevalence of 0.02% in autopsy studies and 0.04% in contrast studies. They are most commonly diagnosed in the sixth and seventh decades but are even more uncommon in children, with only 4% of gastric diverticula occurring in patients less than 20 years of age.[24–27]

Approximately 70% of gastric diverticula are congenital, consist of all three layers of the gastric wall, with approximately 75% of them located in the posterior wall of the fundus 2 to 3 cm from the gastroesophageal junction. Acquired diverticula are more likely to be located near the antrum and represent false diverticula secondary to inflammatory comorbidity.[24–27]

***Etiology.*** The cause of congenital gastric diverticula is thought to be related to the division of the longitudinal fibers of the wall of the stomach resulting in a defect in the musculature of the gastric wall, impacted by arterial perforators and focal absence of peritoneal investment contributing to mural weakness.[24] Alternatively a diverticulum could result from faulty fusion of the dorsal mesentery of the stomach with the left posterior body wall.[26] Acquired diverticula as previously noted are usually related to peptic ulcer disease or pancreatitis.[24,28]

***Clinical Presentation.*** Although most gastric diverticula are clinically asymptomatic, symptomatic lesions in children tend to present in late childhood and adolescence. The symptoms can range from nonspecific complaints, such as recurrent abdominal pain, nausea, and vomiting, to massive hemorrhage and perforation; such symptoms may relate to the presence of ectopic pancreatic tissue within the diverticula causing erosions and ulceration.[24,28,29]

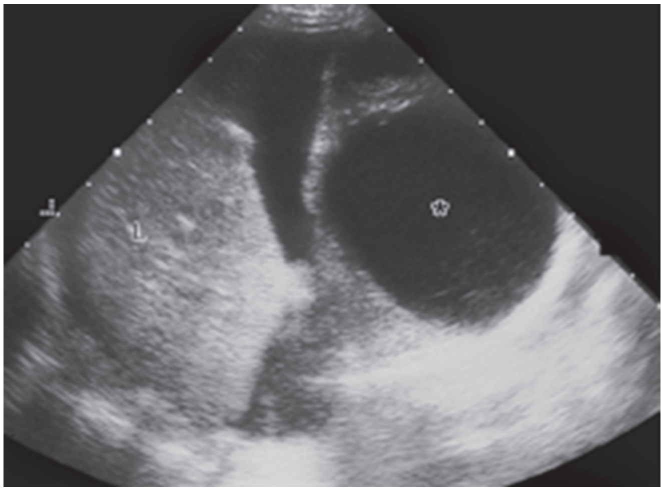
***Imaging.*** Imaging evaluation of suspected gastric diverticula includes UGI, which demonstrates an outpouching of the gastric wall that communicates with the gastric lumen. Right anterior oblique positioning optimizes the sensitivity of this imaging study due to the posterior wall location of most congenital gastric diverticula. Antral diverticula are similarly identified (Fig. 99.4). On CT and ultrasound, the diverticulum can be confused with other cystic lesions; positive oral contrast material is very helpful in establishing the correct diagnosis.[27,30,31]

## Abstract:

To detail the etiologies, clinical presentation, imaging appearances, and treatment plan of congenital and neonatal abnormalities of the stomach. Gastric duplication cyst, gastric diverticula, congenital microgastria are reviewed. Antropyloric obstructions including pyloric web, diaphragm and atresia are reviewed. Ectopic pancreas is also reviewed.

## Keywords:

Stomach, congenital anomalies
Gastric duplication cyst
Congenital gastric diverticula
Congenital microgastria and associations
Pyloric web
Pyloric atresia, multiple atresias (MIA), Epidermolysis bullosa
Ectopic pancreas



**e-Figure 99.3. Ruptured gastric duplication cyst.** Sagittal sonogram through the medial portion of the right lobe of the liver (L) demonstrates a thin-walled, approximately 4-cm cyst *(asterisk)*. Free fluid, complex in its dependent portion, was confirmed at surgery to represent hemorrhage secondary to perforation of the cyst. *(Courtesy of Dr. C. Mitchell, Peoria, IL.)*

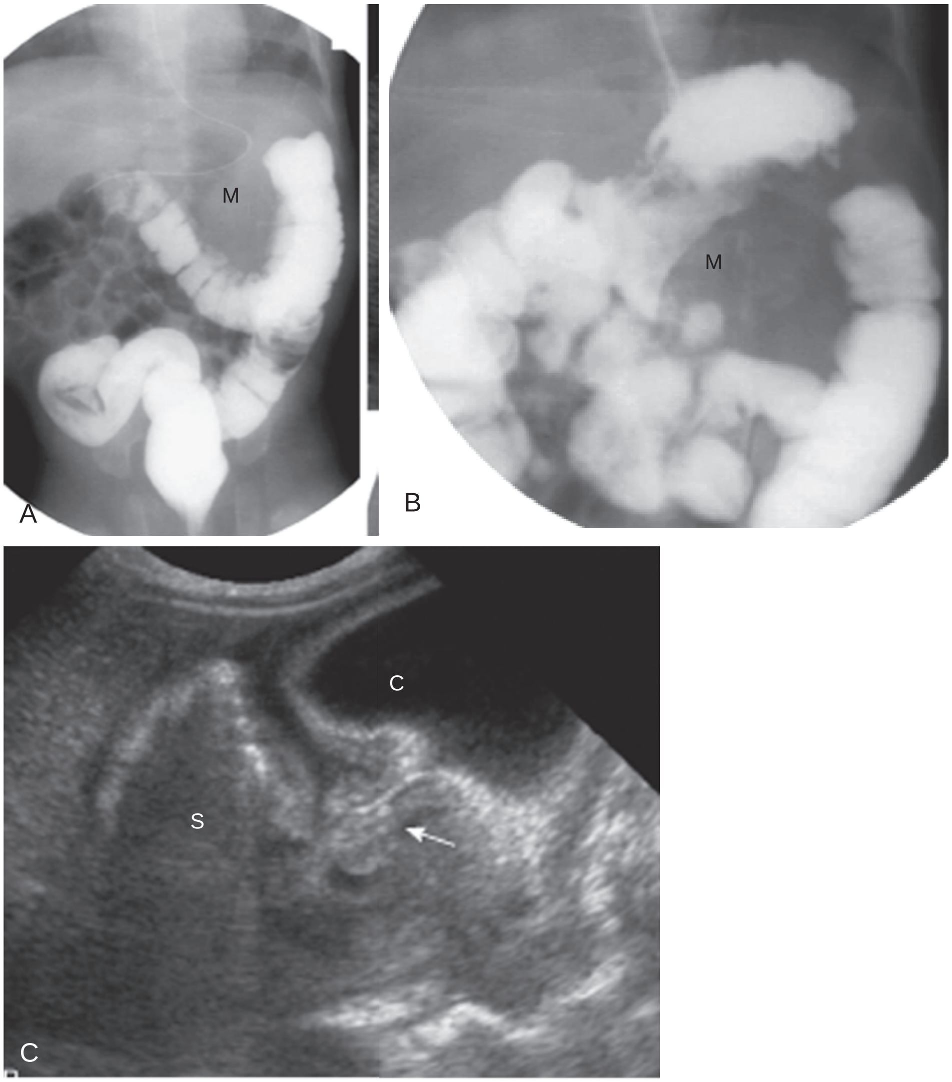


**Figure 99.1. Gastric duplication cyst.** (A) Contrast enema study in a 6-week-old infant demonstrates a mass (*M*) between the greater curvature of the stomach and the contrast-filled transverse colon. (B) UGI performed after the enema demonstrates mass effect (*M*) on the greater curvature of the stomach. (C) Ultrasound study demonstrates a fluid-filled cyst (C) with a hypo-hyperechoic bilayered outline typical of duplication cyst. The stomach (S) contains shadowing gas. The connection of the cyst with the gas-filled stomach is seen *(arrow)*. *(Courtesy of Dr. D. Barlev, New York, NY.)*

***Treatment.*** Symptomatic gastric diverticula may be treated pharmacologically with histamine-2 blockade. Surgical resection is reserved for patients whose symptoms are unresponsive to pharmacotherapy and can be performed with either laparotomy or laparoscopic excision.[29,32,33]

## CONGENITAL MICROGASTRIA

***Overview.*** Congenital microgastria is a rare anomaly characterized by a small, tubular stomach, located in the midline and typically associated with a distended esophagus. In persons with microgastria, the stomach is lined by normal gastric mucosa, but the total cell mass is significantly reduced.[34,35] Agastria, or complete absence of the stomach, is the most extreme form of microgastria.

Isolated congenital microgastria is extremely rare,[36] and this condition is nearly always accompanied by other congenital anomalies such as heterotaxy with splenic anomalies;[37,38] congenital diaphragmatic hernia;[39] trachea-esophageal clefts; hiatal hernia;[35] jaw and palate abnormalities;[40] DiGeorge syndrome; central nervous system abnormalities; and vertebral, cardiac, renal, and limb reduction anomalies (VACTERL association). The combination of microgastria in association with limb reduction defects and central nervous system anomalies may have an autosomal recessive mode of inheritance.[41,42]

***Etiology.*** Microgastria is thought to result from impaired foregut development (see also Chapter 83). The embryonic foregut elongates to form the primordial stomach during the fourth week of gestation. Dilatation of the region of the future stomach occurs in the fifth week. Lateral flattening of the stomach and a 90-degree rotation occur during the sixth week, and the lesser and greater curvatures become established during the sixth and seventh weeks. The growth of the fundus appears during the eighth or ninth week.[34] Early arrest of the process leads to microgastria; the size and the shape of the stomach therefore depend on when the arrest of development occurs.[35] During the fifth week of gestation, the spleen begins to form along the dorsal mesogastrium of the stomach; this association in development of the stomach and the spleen serves to explain the association of microgastria with splenic

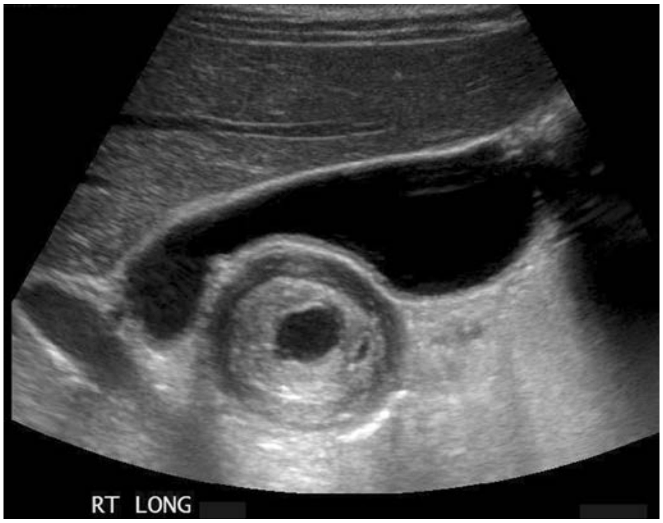

**Figure 99.2. Gastric duplication cyst.** Ultrasound image of the upper abdomen demonstrates a mass contiguous with the greater curvature of the stomach, with a bilayered hyper/hypoechoic wall suggesting the muscular and mucosal layers of gut signature. The wall and mucosa appear thickened suggesting inflammatory changes.

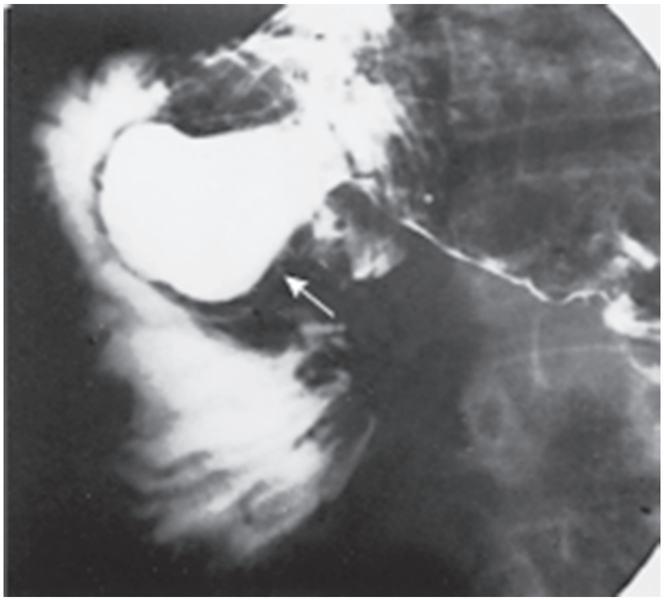

**Figure 99.4. Gastric diverticulum.** The barium-filled diverticulum is seen to be featureless with air-filled antrum *(arrow)* proximal and barium-filled duodenal sweep distal to it. The diverticulum originated at the gastroduodenal junction and was lined with gastric mucosa.

anomalies as in the heterotaxy syndromes. Association of microgastria with limb reduction anomalies is attributed to impairment of early mesodermal development.[42]

***Clinical Presentation.*** The infant may present with feeding intolerance, severe gastroesophageal reflux, and associated anomalies, which will modulate the clinical presentation and determine overall prognosis and mortality. Rare infants with isolated microgastria may present with failure to thrive, stridor or cyanosis during feeding,[43] feeding intolerance, recurrent aspiration pneumonia, and malnutrition as a result of severe gastroesophageal reflux.[36] Pernicious anemia may be present as a result of decreased intrinsic factor production because of the decreased gastric cell mass.[44]

***Imaging.*** Prenatally, failure of visualization of the fetal stomach with normal amniotic fluid volume raises concern for microgastria.[45] Chest and abdominal radiographs may show absence of the normal stomach bubble and, in some cases, the outline of a very dilated or megaesophagus might be visualized in the lower chest. UGI shows a small tubular stomach (less than 25% of the normal size) located in the midline, and associated with severe gastroesophageal reflux and a megaesophagus as a result of the overflow from the small capacity stomach (Fig. 99.5). Esophageal motility is ineffectual as a result of the gross dilatation, although after treatment the esophagus has been described as able to return to normal.[44] Additional imaging studies including spine radiographs, cardiac echo, ultrasound, CT, and MRI can be done as indicated to identify associated anomalies.

***Treatment.*** The treatment for microgastria is individualized, dependent on the severity of the microgastria and associated anomalies. Conservative or medical treatment may be tried initially but usually is not effective in severe cases because the stomach does not enlarge with time. Recent literature suggests that an early operation may be indicated for better growth and development and an improved quality of life overall. Most of the patients are treated with a Hunt–Lawrence pouch (a double lumen roux-en-Y jejunal pouch) for increasing the size of the gastric reservoir with improved growth patterns after surgery.[36,44]

## PYLORIC WEB, DIAPHRAGM, AND ATRESIA

***Overview.*** Pyloric atresia is a rare congenital anomaly which comprises less than 1% of intestinal atresias with a reported frequency of approximately 1 : 100,000 live births.[46] Although it can occur in isolation, in approximately 30% of cases, it has two major systemic associations: multiple intestinal atresias (MIA) and dermatologic abnormalities: epidermolysis bullosa (EB) and aplasia cutis congenita.[47,48] According to the Third International Consensus Meeting on Diagnosis and Classification of EB, pyloric atresia is associated with the simplex (EBS) and junctional (JEB) forms of EB.[49] Pyloric atresia is seen in three distinct anatomic types which somewhat mirror those of other intestinal atresias: (1) membranous, (2) atresia without a gap, and (3) atresia with an intervening gap. Membranous atresia is reported to be the most common, seen in approximately 60% of affected infants.[47,50]

Incomplete obstructions due to antral webs or diaphragms are reported to be the more commonly encountered form of this rare abnormality.[51] The webs are thin circumferential membranes measuring between 2 and 4 mm that span the lumen of the stomach, perpendicular to its long axis[52] typically located 1 to 2 cm from the pylorus, and composed of mucosal layers without a muscular component.[53,54]

***Etiology.*** The exact etiology remains controversial with a number of theories postulated including incomplete or abnormal canalization of the foregut during embryologic development or intrauterine mechanical or chemical injury.[46,55] When associated with EB, this has been thought to represent a specific clinical entity related to an abnormality in the cell surface signaling protein alpha 6 integrin or its ligands.[47]

***Clinical Presentation.*** Pyloric atresia presents in the neonate with nonbilious vomiting. Neonatal gastric perforation has been reported.[47] There is polyhydramnios in approximately 50% of cases, and the patients may be born prematurely.[48,56] When associated with EB, the skin changes are self-explanatory. In addition to multiple atresias, immunodeficiency has also been reported in some patients with pyloric atresia.[57]

Incomplete gastric outlet obstruction due to the presence of antropyloric webs or diaphragms has a variable clinical presentation depending on the size of the orifice, which can range from 2 to 30 mm. Clinical manifestations include vomiting, failure to thrive, and intermittent abdominal pain.[58]

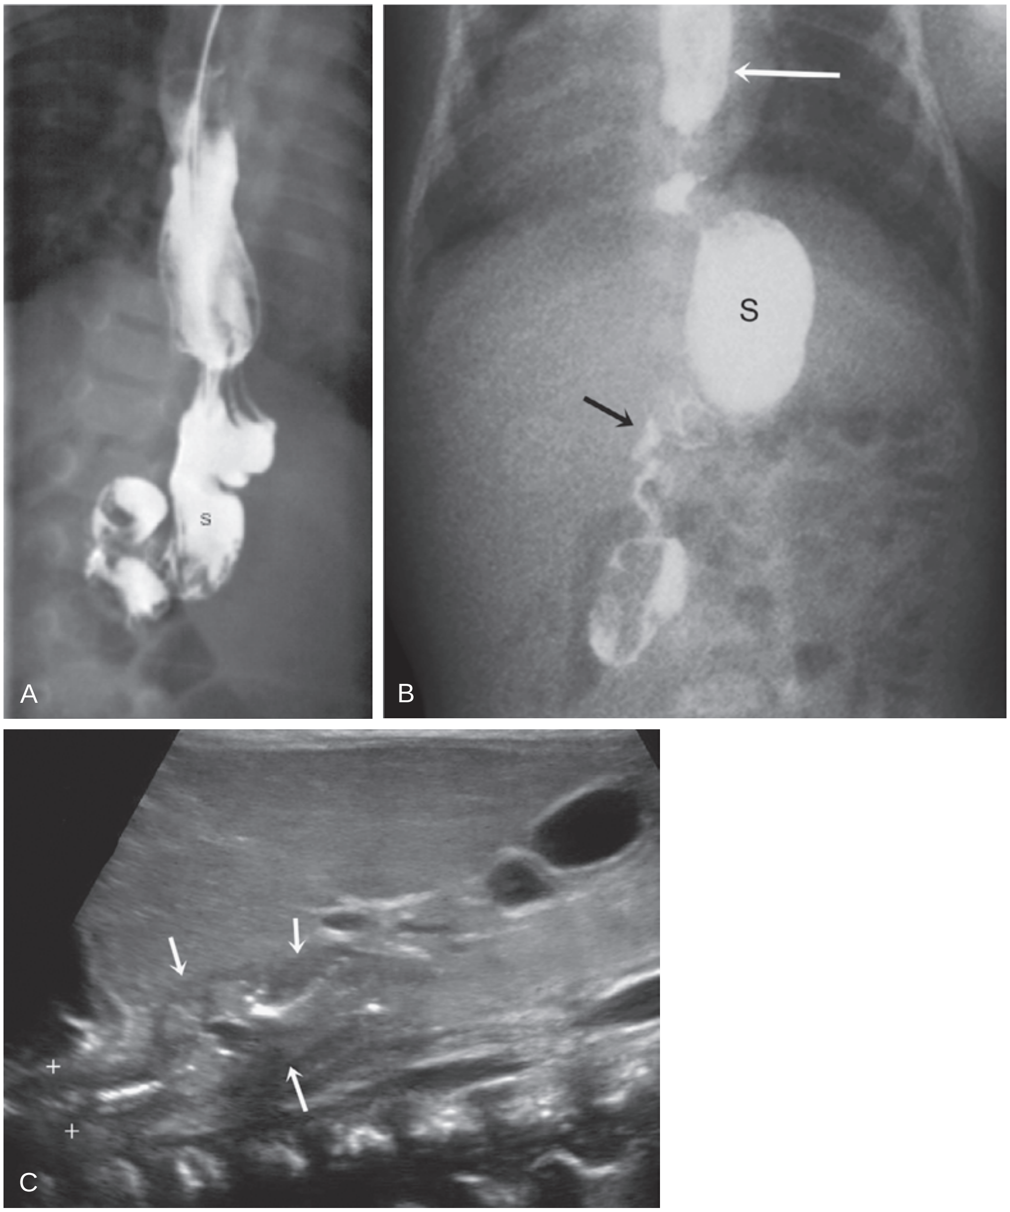

**Figure 99.5. Microgastria.** (A) Frontal image from an UGI performed with a nasogastric tube demonstrates a small midline stomach *(S)* with grossly patent gastroesophageal junction and megaesophagus. The patient also has malrotation of the bowel. (B) Frontal image from UGI in neonate with heterotaxy, asplenia and microgastria. Note the small, poorly differentiated midline stomach *(S),* large esophagus *(white arrow),* and malrotated duodenum *(black arrow)*. The heart is on the right, and the bulk of the liver mass is also on the right. (C) Midline sagittal sonogram in a neonate with heterotaxy and asplenia. The image shows a small midline stomach *(arrows)* and a large distal thoracic esophagus *(between calipers)*.

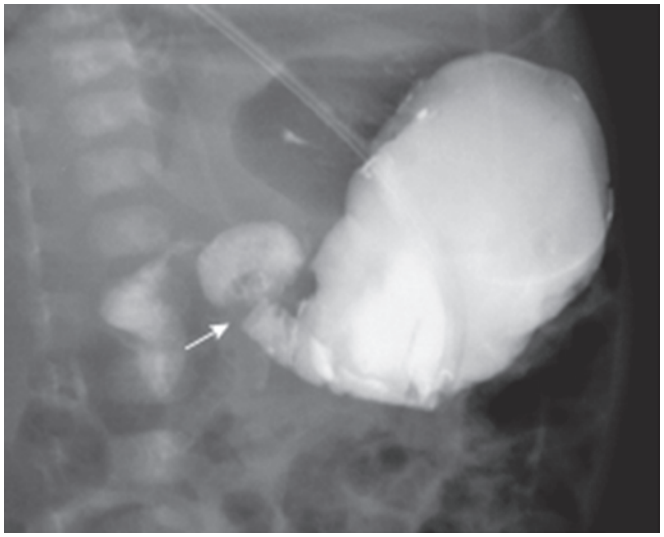
***Imaging.*** Prenatally, polyhydramnios, a dilated stomach and esophagus with collapsed distal bowel may be seen. “Snow flake” appearance of the amniotic fluid may be seen in cases associated with EB.[56] In patients with pyloric atresia, postnatal abdominal radiographs demonstrate a single bubble, representing the distended stomach, with absence of distal bowel gas.[59] Fluoroscopic contrast examination, if performed, will confirm gastric outlet obstruction. Ultrasound will reveal a blind-ending gastric antrum with no gas distally (Fig. 99.6).

In patients with antral web or diaphragm, fluoroscopic imaging evaluation of the stomach may demonstrate a double bulb appearance representing the distended antral segment interposed between the web and the true duodenal bulb, and/or linear filling defect in the distal stomach outlining the antral membrane (e-Fig. 99.7 and Fig. 99.8). Early filling images of the stomach are recommended as visualization of the filling defect may be obscured by dense contrast. Failure to achieve maximal distal antral distension may be associated with presence of a diaphragm or web that may not be visualized.[55] Sonographic demonstration of antropyloric webs has also been described in the literature.[60] Sonography needs meticulous technique and a fluid-filled stomach; sonographic findings include gastric distension, the presence of persistent linear echogenic structure projecting into the distal gastric lumen, and delayed gastric emptying. Recently, intramuscular fibrous bands



**e-Figure 99.7. Pyloric web in an infant with vomiting since birth.** Contrast demonstrates a circular band or indentation in the distal antrum *(arrow)*. Endoscopy demonstrated a pyloric web. *(Courtesy of Dr. Stuart C. Morrison, Cleveland, OH.)*

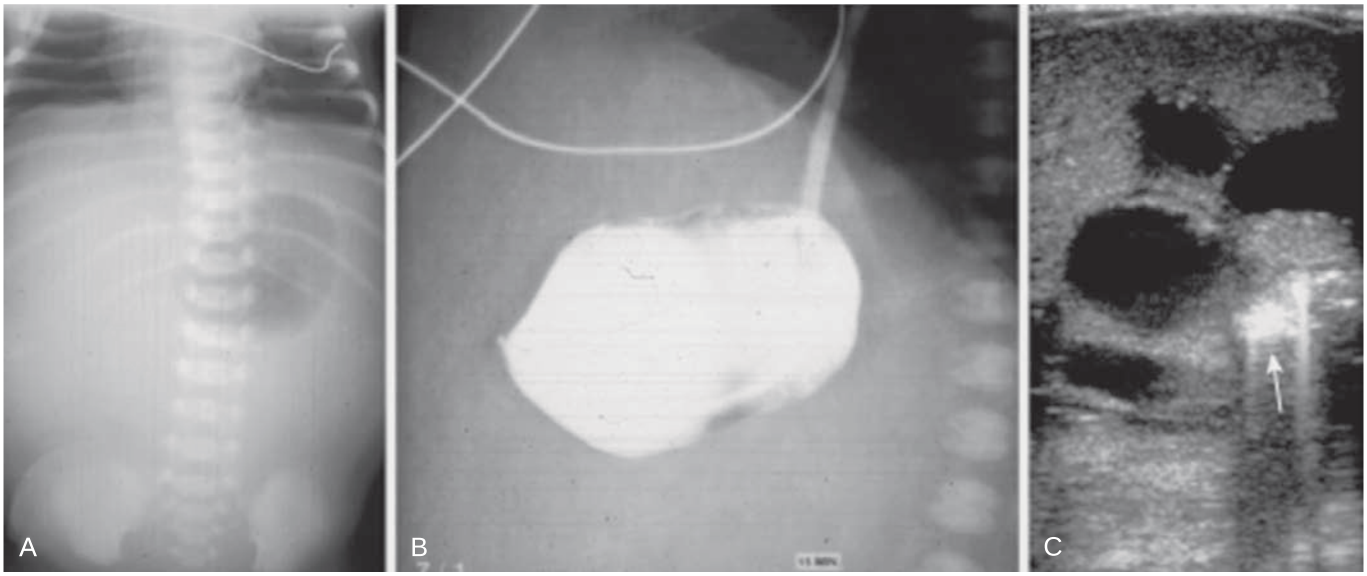


**Figure 99.6. Infant with pyloric atresia associated with multiple atresias.** (A) Abdominal radiograph shows some distension of the stomach with gas, and otherwise gasless abdomen. The distension of the flanks suggests that either the distal bowel loops are not collapsed, or that there is ascites. (B) UGI through orogastric tube shows blind-ending stomach, with no further passage of contrast. (C) Ultrasound examination shows gas within the blind-ending gastric antrum *(arrow)*. Other loops of bowel are distended with fluid due to the multiple atresias and retained gastrointestinal secretions, but there was no gas in any loop distal to the stomach.

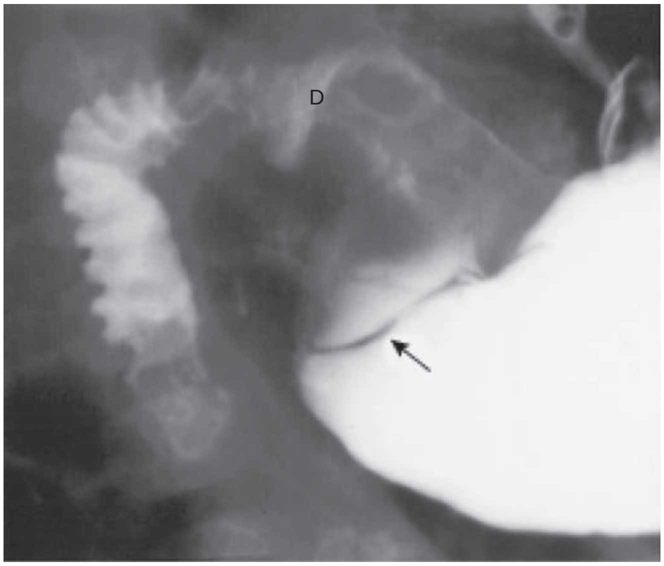

**Figure 99.8. Antropyloric web.** Spot image from UGI demonstrates barium in the antrum with a thin radiolucent band *(arrow)* representing a web in an older child who presented with long history of intermittent vomiting. *D*, Duodenal bulb.

resembling diaphragms on imaging have been reported.[54] Definitive diagnosis is made endoscopically.

***Treatment.*** Treatment of pyloric atresia is surgical, although mortality in cases associated with EB is high, as many of these children succumb to electrolyte imbalance, protein loss, and sepsis. The type of operation performed varies with the type of atresia that is present and ranges from membrane excision and pyloroplasty to gastroduodenostomy.[47,48,56] Antral membranes can be resected endoscopically.[60]

## ECTOPIC PANCREAS

***Overview.*** Ectopic pancreas is defined as the presence of pancreatic tissue outside of the pancreas without anatomic connection to the gland; it is most commonly found in the stomach, duodenum, and Meckel diverticulum, although it can be found in multiple locations, including the umbilicus, fallopian tube, liver, mediastinum, and lung.[61,62] Because most patients are asymptomatic, the reported incidence varies widely, between 0.5% and 14%.[62] Approximately 90% of gastric heterotopic pancreas lesions are located in the antrum and along the greater curvature.[61]

***Etiology.*** The etiology of ectopic pancreas remains unclear. One theory proposes that metaplasia of pluripotential endodermal cells, through errors in the Notch signaling pathway, give rise to pancreatic tissue in ectopic location; another theory suggests that embryonic pancreatic tissue is deposited in ectopic location through errors during the time of rotation of the foregut.[62–64]

***Clinical Presentation.*** Most patients are asymptomatic and therefore ectopic pancreas is usually an incidental finding.[65] If symptoms occur, it is typically in adulthood; children represented between 6% and 16% of symptomatic cases in series reporting both pediatric and adult patients.[66] In adults, symptoms occur more often in males, although in children girls represent a larger proportion of the total.[66] Typically the lesions are small and symptoms are secondary to inflammatory changes, such as pancreatitis and ulceration, resulting in abdominal pain or bleeding. When large enough, antral lesions can lead to gastric outlet obstruction.[61]

***Imaging.*** UGI demonstrates an intramural mound of tissue projecting into the gastric lumen in the prepyloric region along the greater curvature with a characteristic central umbilication (representing the attempt at duct formation). Diagnosis can be suggested only if the central umbilication is seen (Fig. 99.9). Endoscopic ultrasound demonstrates nonspecific findings such as a submucosal solid mass with intermediate echogenicity.[67] CT may show localized wall thickening or a small mass, which may demonstrate marked enhancement that can help to differentiate this

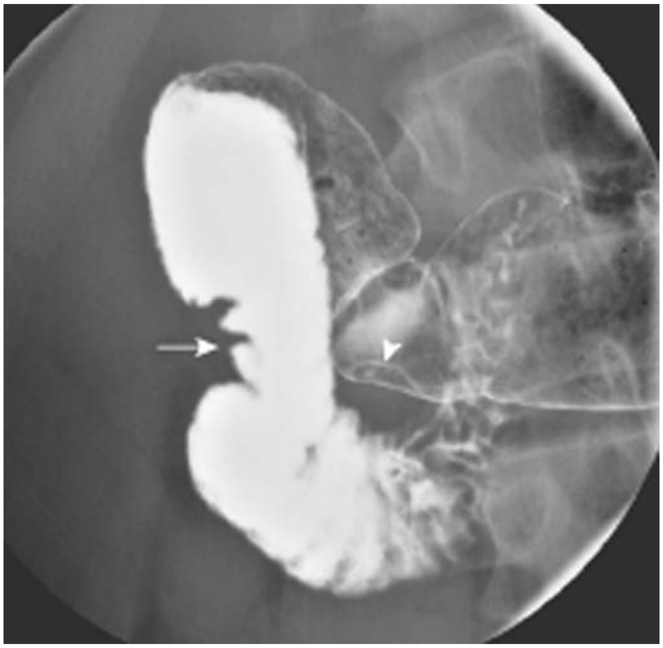

**Figure 99.9. Ectopic pancreas in a teenage girl with chronic vomiting.** Air contrast UGI demonstrates a small mass in the pylorus with central umbilication, proven at surgery to represent ectopic pancreas *(arrowhead)*. Annular pancreas/duodenal stenosis was also diagnosed, as demonstrated by narrowing along the second portion of the duodenum, also confirmed at surgery *(arrow)*.

lesion from gastrointestinal stromal tumor (GIST).[68] Distending the bowel lumen with negative oral contrast may be helpful.[69] MRI may help localize the ectopic pancreatic tissue by demonstrating an area with signal characteristics and enhancement similar to pancreatic tissue on all sequences; demonstration of ducts in the tissue or mass on MRI in a mesenteric lesion has been described.[67]

***Treatment.*** An ectopic pancreas diagnosed incidentally does not need treatment. Cases with symptoms are treated by surgical resection of the involved segment.[67]

## KEY POINTS

- Gastric duplication cysts are rare among the gastrointestinal duplications and are most commonly located along the greater curvature of the stomach.
- Microgastria is usually associated with other congenital anomalies such as the heterotaxy syndromes.
- The imaging hallmark of microgastria is a small midline stomach with significant reflux into a megaesophagus.
- Complete atresias involving the pylorus or antrum are extremely rare comprising less than 1% of all gastrointestinal atresias. Incomplete obstructions due to webs or diaphragms are the more commonly encountered form of this rare abnormality.

# 100 Hypertrophic Pyloric Stenosis

*Marta Hernanz-Schulman*

## OVERVIEW

Hypertrophic pyloric stenosis (HPS) is the most common urgent surgical entity affecting infants during the first 6 months of life.[1] Incorrectly assumed to be congenital by Hirschsprung in his seminal postmortem description in two patients,[2] empirical data indicate that pyloric stenosis is not present at birth; although some exceptions may exist, the symptoms and characteristic anatomic changes of pyloric stenosis typically present in infants between 3 and 12 weeks of age.[3–6] There are occasional case reports of the diagnosis of pyloric stenosis made earlier in life,[7] but they remain exceedingly rare.

The epidemiology varies with racial and geographic extraction, with an incidence of approximately 2–5/1000 births among children of European descent; however, among children of African American or Asian extraction, this decreases to approximately 0.7/1000 births. There is a familial predisposition that suggests a polygenic inheritance with greater penetrance in males. Among children of affected fathers, the risk is approximately 5% for sons and 2.5% for daughters, while among children of affected mothers, the corresponding risk is 20% for boys and 7% for daughters. Proband concordance in monozygotic twins is cited to be between 0.25 and 0.44, whereas that in dizygotic twins is reduced to between 0.05 and 0.10, very similar to that of nontwin siblings.[8] The incidence of pyloric stenosis is inversely proportional to birth order, with odds ratio to birth order cited as: 1, 2, 3, 4+, roughly equivalent to increased risk levels of 1.9, 1.5, 1.3, and 1.0, respectively.[8]

## ANATOMY

### Normal

The stomach is divided by the incisura angularis into a fundus and body proximally, and the antrum distally; the latter is further subdivided by the sulcus intermedius into a proximal pyloric vestibule, and a distal pyloric antrum or pyloric canal, which is approximately 2.5 cm in length, and terminates in the pyloric sphincter and orifice, which lead into the duodenum (Fig. 100.1A and B).[9]

### Abnormal

In infants with pyloric stenosis, the muscle of the pyloric antrum hypertrophies, is unable to relax, and the pyloric antrum is no longer distensible; the mucosa is edematous and thickened (Fig. 100.2A and B). This complex of nonrelaxing musculature and thickened mucosa resembles an "elongated" canal on imaging and presents an obstruction to gastric emptying.[4,10–12]

## ETIOLOGY

Although the diagnosis and surgical treatment of HPS have undergone a remarkable evolution over the last century, no fundamental leap has been made in elucidating its cause, which remains unknown. The final common pathway seems to be one of work hypertrophy of the circular muscle of the pyloric antrum, which becomes unable to relax; the mucosa becomes edematous and hypertrophied, sometimes markedly, rarely simulating a polypoid mass.[12–14]

Due to lack of an obvious etiologic agent or process, in a *cum hoc ergo propter hoc* reasoning, associated findings have long been linked to etiology. In the 18th and early 20th centuries, etiology was linked to associated paucity of omentum (likely due to emaciation) and to "higher development of the nervous system" in children of "intellectual classes" due to its more common occurrence and identification in children of northern European extraction and professional families,[15] connections that seem blatantly absurd to us in the 21st century. More recent scientific inquiry has centered on the hypertrophied muscle, which has been found to be also abnormal at the microscopic and biochemical level. The thickened muscle is depleted of inhibitory peptides such as vasoactive polypeptide; of synaptic vesicles, presynaptic terminals, and neural cell adhesion molecules; of markers for enteric glia; of interstitial cell of Cajal; and of nitric oxide synthase activity at the messenger RNA level. There are increases in insulin-like and platelet-derived growth factors. Immunoreactivity studies evaluating desmin content suggest immaturity of the intermediate filaments in the hypertrophied pyloric muscle.[16–26] Pathologic material in pyloric stenosis is thankfully no longer typically available, but older pathology reports are revealing of the histology of the abnormal pylorus, demonstrating that "varying degrees of submucosal edema are always present" typically with "a mild to moderate lymphocytic infiltrate in the submucosa and muscularis" (see Fig. 100.2B).[12] Today, this is substantiated on preoperative ultrasound (US) imaging, where the mucosa is seen to be thickened and edematous, and both muscle and mucosa are hyperemic when evaluated with color and spectral Doppler.[4,13] Prostaglandin E1 and E2 have been reported to induce proliferation of gastric mucosa[27] and are related to muscle contraction in the human gastrointestinal tract[20]; prostaglandin therapy has preceded the development of pyloric stenosis requiring surgery.[28] Prostaglandin E2 generation in the gastric mucosa and increased concentration in the gastric secretions of patients with pyloric stenosis have been reported.[29]

Genetic susceptibility loci have been identified, with cases mapped to loci on chromosomes 3p25.1, 5q35.2, 16q-24, 16p12-p13, and 11q14-q22, the latter affecting ion channels with a potential role in smooth muscle control and hypertrophy.[30–33] In patients with pyloric stenosis, simple nucleotide polymorphisms (SNPs) have been mapped to 3p25.1, 3p25.2, and 5q35.2, located in proximity to genes that control muscle and gut development. Differential activity levels in the early postnatal period suggest a parallelism in the development of HPS.[34,35] SNPs have also been mapped to 11q23.3, and associations with cholesterol metabolism have also been proposed.[36,37]

A hypothesis that a genetically influenced increased parietal cell mass leads to a vicious cycle of increased acid secretion, increased gastric contraction, and secondary development of muscular hypertrophy and mucosal redundancy with delayed gastric emptying has also been advanced.[38,39] This concept is supported by the redundant mucosa that fills the pyloric channel,[13,28,40,41] induction of HPS with infusion of pentagastrin,[42] and the rarity of HPS before the inception of feedings. Despite the extensive anatomic and biochemical changes documented in this condition, as early as 4 months after surgical relief of the obstruction, the anatomic changes as well as assays for nerve growth factor, interstitial cells of Cajal, and nitric oxide synthase activity revert to normal.[24,43]

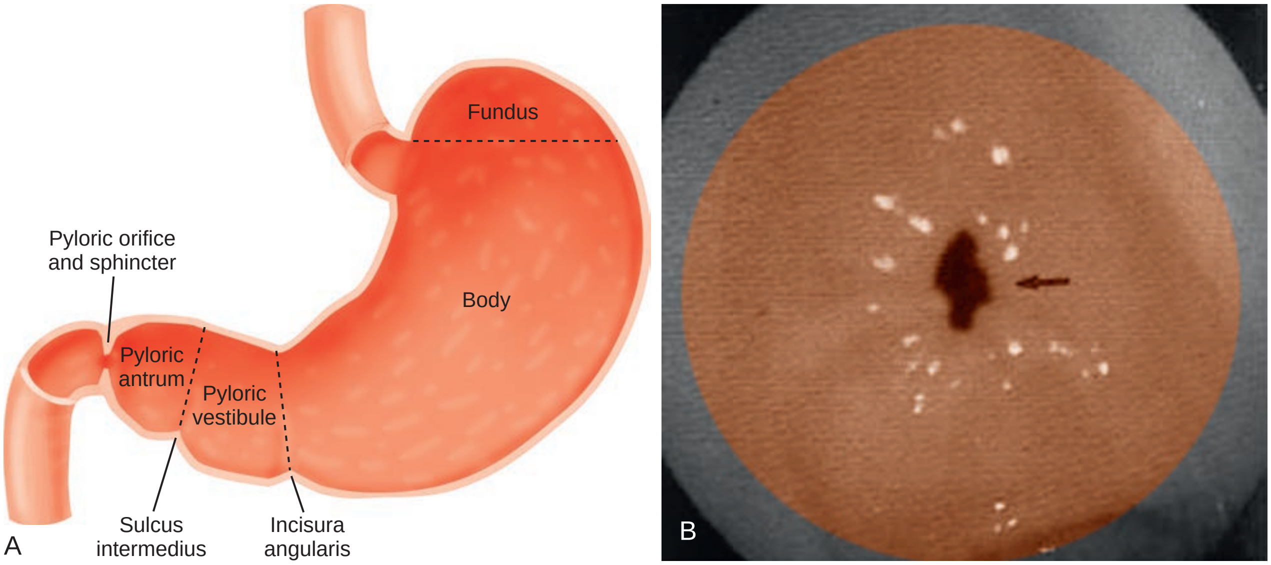

**Figure 100.1. Normal gastric and pyloric anatomy.** (A) Schematic illustration of gastric segmental anatomy. (B) Endoscopic appearance of the normal pyloric sphincteric orifice *(arrow)*.

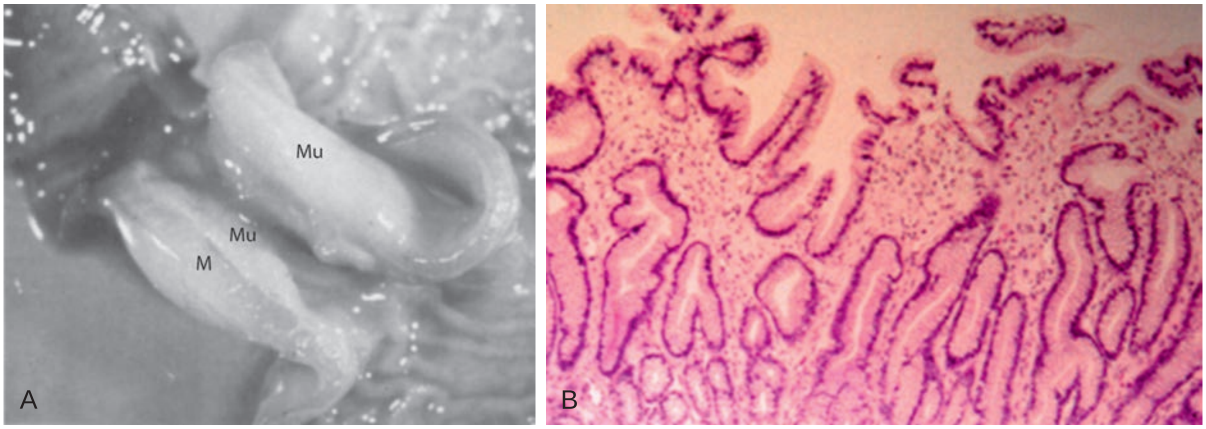

**Figure 100.2. Histopathologic anatomy in pyloric stenosis.** (A) Gross postmortem specimen of hypertrophied pylorus in an infant who succumbed to this condition. Note the thickened muscle *(M)* and the thickened mucosa *(Mu)* which would fill and obstruct the lumen of the unsectioned antropyloric canal. (B) Histologic specimen of antropyloric mucosa in infant with HPS with typical presentation, operative findings and postoperative recovery. The H&E (hematoxylin & eosin) stain shows mucosal hyperplasia with elongated, branched and mildly distorted pits, and abundant edematous lamina propria.

The macrolide antibiotic, erythromycin, is a prokinetic agent and has been associated with increased risk of developing HPS in some series, particularly when the infants are exposed very early in life, but further studies have determined that the link, if it exists, is weak and potential risk very small.[8]

As in the 19th century and despite our sophisticated tools, it remains difficult to extricate an initiating event from the multiplicity of associated abnormalities in this intriguing condition. The inciting event(s) of HPS remain obscure, and whether any or all of the multiple reversible abnormalities represent cause or effect of the initial condition remains a challenge for present and future investigators.

## CLINICAL PRESENTATION

Babies with HPS typically present with a history of forceful nonbilious vomiting, often described as "projectile." Although the color of the emesis may be yellow-tinged, if it is green, the differential shifts radically to malrotation and its emergent complication of midgut volvulus. In patients with HPS, vomiting may be relatively sudden in onset or be preceded by initially mild symptoms consistent with preexistent gastroesophageal reflux. Patients with long-standing HPS are voraciously hungry and may be sucking at their fists in a futile attempt to obtain nourishment. If the diagnosis is not made promptly, protracted vomiting and dehydration lead to a characteristic profile of electrolyte abnormalities, consisting of hypochloremic metabolic alkalosis secondary to the loss of hydrochloric acid from the stomach, with paradoxical aciduria, as renal mechanisms designed to maintain intravascular volume supervene to conserve sodium at the expense of hydrogen ion, which is excreted in the urine. Indirect hyperbilirubinemia may be found in a small minority of infants, secondary to decreased hepatic glucoronyl transferase activity induced by starvation. In patients who present after significant weight loss and are thin and dehydrated (thankfully few today), peristaltic waves may be seen on the wall of the scaphoid abdomen, progressing from the left upper quadrant across the epigastrium, flanked by a protuberant rib cage.[10] Fortunately, over the last several decades, the tendency has been for infants to present earlier, with less severe physical findings and laboratory abnormalities. Investigators have emphasized the changing pattern of presentation of infants with HPS, with a large majority of infants today diagnosed without evidence of metabolic abnormalities. The increased availability and diagnostic accuracy of US has been considered a factor in earlier diagnosis.[44–47]

## DIAGNOSIS AND IMAGING

### Physical Examination

Physical examination in experienced hands is often diagnostic by successfully palpating the *olive* or *pyloric tumor*, terms often used to designate the tactile detection of the olive-shaped thickened antropyloric muscle. This examination requires a calm infant and a committed and experienced examiner willing to dedicate 15 minutes or longer to the examination,[48] which may require decompression of the overdistended stomach via nasogastric tube.[49] If the muscle or "olive" is palpable, the examination is diagnostic. The sensitivity of abdominal palpation varies with the experience of the examiner, and ranges between 24% and 99%; specificity ranges between 92% and 99%.[49–53] False positives have been reported to be as high as 14% due to anatomic variants such as unusual extensions of the left lobe of the liver, and congenital abnormalities such as malrotation and duplication cysts; however, some of these reports do not specify the experience of the examiner.[54,55]

The diagnostic accuracy of US has generated a trend toward reliance on imaging rather than on physical examination and has led to a deterioration of the acumen of the clinical examination. In one retrospective study of two groups of patients separated by two decades, 212 evaluated between 1974 and 1977, and 187 patients between 1988 and 1991, investigators found that surgeons' success decreased from 99% to 79%; while that of nonsurgeons decreased from 47% to 33%.[52] In a series of 118 patients seen between 2006 and 2008, 100% of patients were evaluated with US, while the olive was palpated in only 13%.[45]

While the loss of clinical skills may be lamentable in some respects, and some have argued that imaging increases the financial cost of the workup of HPS, others have recognized that, despite "fading skills," the rapidity and accuracy of US diagnosis can result in "better patients," that is, better surgical candidates at the time of diagnosis.[44,45]

### Radiographic Studies

#### Plain Films

Plain films may strongly suggest the diagnosis, when revealing a markedly distended stomach, particularly if several peristaltic waves are seen, with little gas distally (Fig. 100.3),[56] although absence of these findings does not negate the diagnosis. In rare instances, HPS has been reported in association with isolated gastric pneumatosis that resolves after the stomach is decompressed (e-Fig. 100.4).[57]

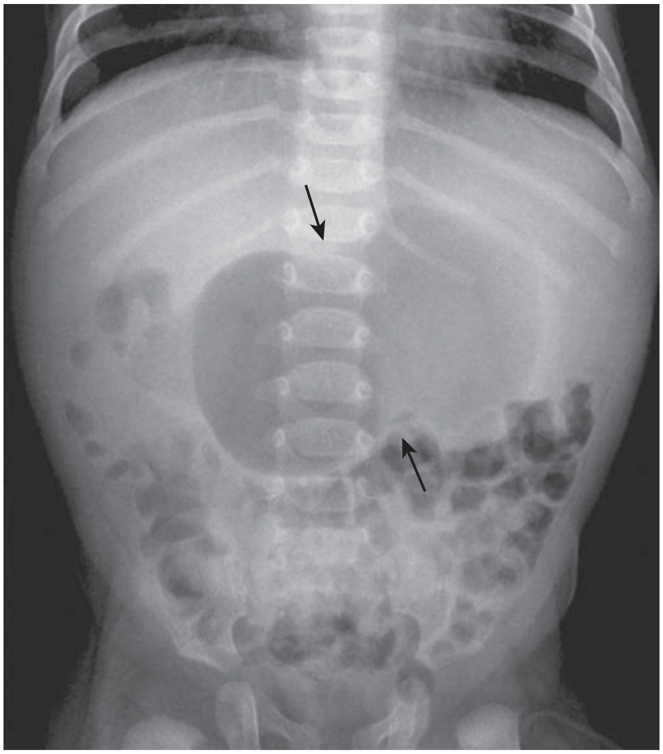

**Figure 100.3. Abdominal radiograph in infants with hypertrophic pyloric stenosis (HPS).** Abdominal radiograph demonstrates a distended stomach with a peristaltic wave *(arrow)*, with normal to mildly decreased distal gas. In the appropriate clinical setting, this is suggestive of pyloric stenosis.

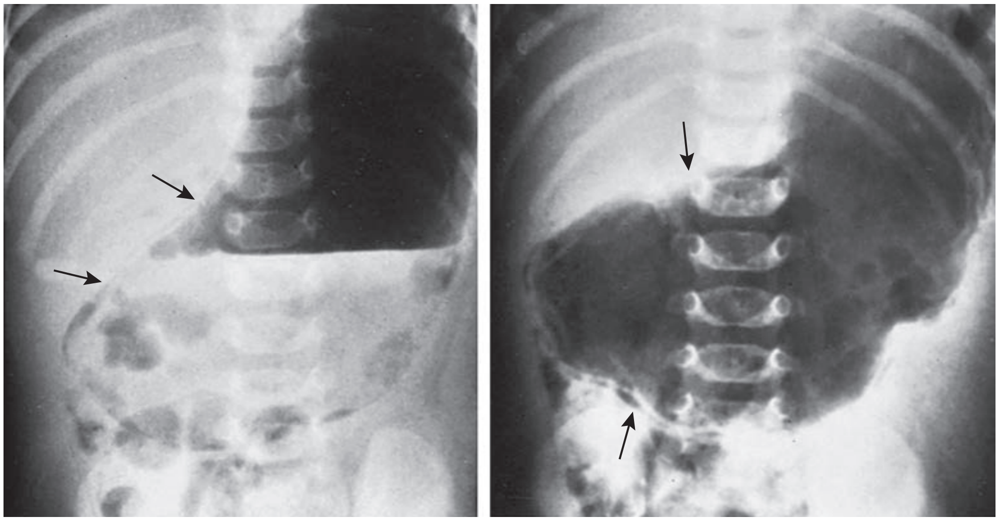
#### Upper Gastrointestinal Series

The upper gastrointestinal (GI) as a diagnostic tool in patients with HPS was introduced in 1932 by Neuwissen and Sloof, with proponents such as Rigler in the United States.[58] In 1964, Currarino advocated double contrast examination with compression spots.[59] Before the advent of real-time US imaging, the upper GI series was the mainstay for imaging diagnosis and may still be utilized by radiologists with limited pediatric sonographic experience. If US shows a normal antropyloric canal, an upper GI may be performed to evaluate and document other potential causes of the patient's vomiting, such as reflux or more distal obstruction. Barium or a water-soluble agent may be used for oral contrast; if the latter, use a low-osmolality contrast medium approximating physiologic serum osmolality, as the child may vomit and aspiration may occur. To obtain a technically satisfactory contrast study, it may be necessary to decompress the stomach with an enteric tube, as a large amount of preexistent gastric contents will dilute the contrast medium and increase the chance of vomiting and aspiration during the examination. If the enteric tube is used, placing it distally and introducing the contrast with the patient in the prone right oblique position tends to require less contrast material to outline the gastric outlet. Because the diagnosis depends on passage of contrast through the abnormal, obstructed channel, fluoroscopic examination can be lengthy.

In addition to delay in the passage of contrast from the stomach, several other radiographic signs are present in infants with pyloric stenosis (Fig. 100.5). The antropyloric channel of the stomach is narrowed, and as contrast begins to enter the narrowed channel, it may appear as a "beak," which evolves into a "string" or a "double track" sign as contrast courses between the interstices of the thickened mucosa within the antropyloric lumen, compressed by the thickened, unrelaxing antropyloric muscle. The canal typically curves upward and posteriorly. The enlarged muscle mass encroaches upon the lumen of the antrum proximally, resulting in the "shoulder sign." When the duodenal base is also deformed by the thickened muscle, the appearance may resemble an "apple core" lesion. The "pyloric tit" can occasionally be seen along the lesser curve just proximal to the impression of the pyloric mass; it represents contrast trapped within the lumen of the stomach, compressed between a peristaltic wave and the impression of the pyloric muscle upon the adjacent more distal portion of the stomach. Antropyloric contraction during peristalsis or "pylorospasm" can transiently mimic the findings in HPS; therefore the study should document the persistence of the abnormal findings to establish the diagnosis.



**e-Figure 100.4.** Gastric pneumatosis in an infant with hypertrophic pyloric stenosis (HPS). Supine abdominal radiograph in a 6-week-old girl with HPS shows a markedly dilated stomach with several peristaltic waves and decreased distal gas. There is intramural gas *(arrows)* which resolved within 24 hours after decompression with gastric intubation. *(Courtesy Dr. J. Leonidas, New Hyde Park, NY.)*

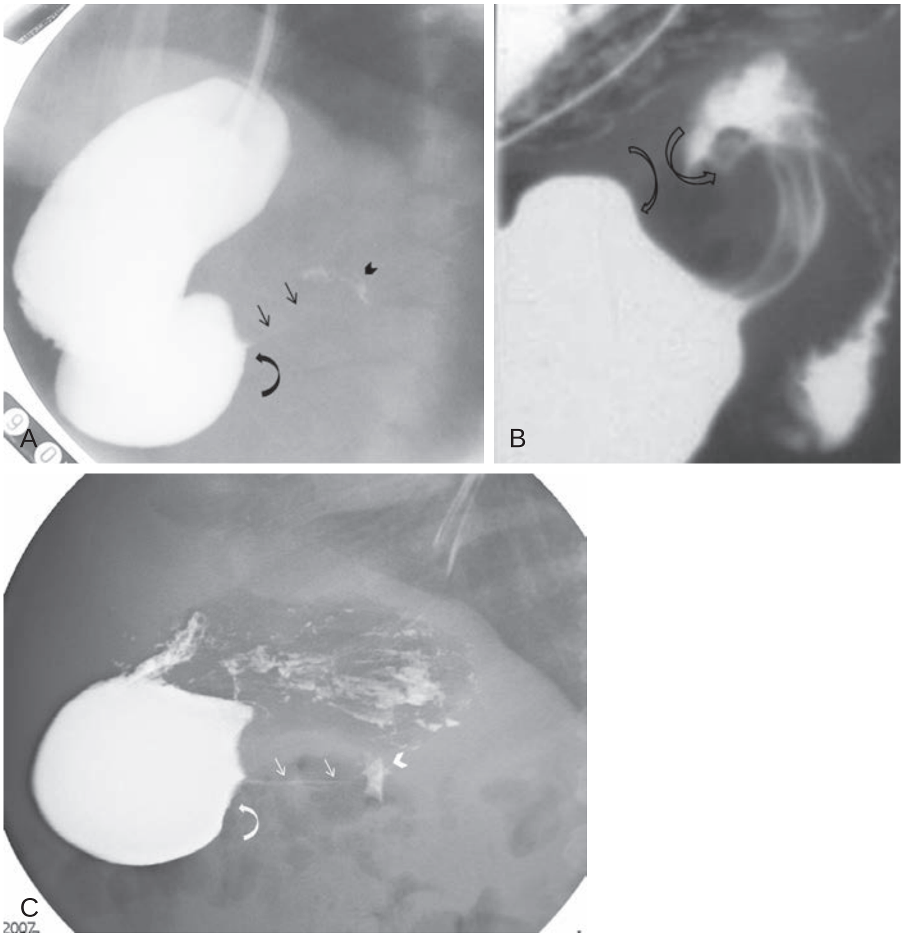


**Figure 100.5. Upper gastrointestinal imaging series in patients with hypertrophic pyloric stenosis (HPS).** (A) Orogastric tube was used to evacuate the stomach, and barium was instilled under fluoroscopic control. The image demonstrates a peristaltic wave and a small amount of contrast entering the narrowed canal, demonstrating both a beak *(curved arrow)* and string sign *(straight arrows)*. *Arrowhead* points to a small amount of contrast outlining the base of the duodenal bulb. (B) Oblique radiograph in another infant with HPS shows mass impression upon the proximal antrum and the distal duodenal base (*curved arrows* "shoulder signs"). The pyloric canal curves upwardly and posteriorly. Note the filling defect within the canal secondary to the hypertrophied mucosa, and the contrast tracks between the mucosal interstices, giving rise to what is termed the *double track sign;* there is a third linear track distally in the canal. (C) Oblique radiograph in another infant with HPS outlines deep shoulders on the gastric antrum *(curved arrow)* and a thin string sign *(arrows)*. The *arrowhead* points to the base of the duodenal bulb.

## Ultrasonography

The initial and seminal report of US as a diagnostic modality in infants with HPS was that of Teele and Smith, reported in the *New England Journal of Medicine* in 1977.[60] Since that time, US has become the modality of choice in the diagnosis of pyloric stenosis in most pediatric centers and is now considered the "gold standard" by many.[10,45,49] Similar to the clinical examination by manual palpation, the operator-dependent US examination requires a skilled and experienced examiner. Unlike the clinical examination, the US diagnosis can be performed quickly even on a crying infant, without the need to pass a gastric tube to empty the stomach or any other such relatively invasive and time-consuming maneuvers. Unlike the upper GI, the US examination does not require contrast to traverse the obstructed canal for diagnosis; again allowing for a rapid diagnosis, without the need of additional distension of the stomach, and without radiation exposure to the infant.

*Performance of the examination:* The examination is typically performed with linear transducers operating at a frequency of 7.5 MHz or higher. The time of the last feeding may be annotated on the image, and the degree of gastric distension related to the last feeding can give an initial clue as to the presence or absence of gastric outlet obstruction.

The examination is begun with the patient in the supine position. The transducer is placed in transverse position over the gastroesophageal junction, which is constant in location anterior to the aortic hiatus; the transducer is then swept along the length of the stomach, until the distal antrum and duodenal cap are identified; once the duodenal bulb is identified, the immediately proximal antropyloric canal can be evaluated for morphology and relaxation, thus identifying either pyloric stenosis or a normal antropyloric canal (Videos 100.1 and 100.2). The gallbladder and right kidney are typically, but not always, seen near the antropyloric canal, as the location of the antropyloric canal will vary with the degree of gastric distension.

*Criteria and dimensions:* Much emphasis has been placed on the measurements used to diagnose pyloric stenosis. Certainly, these are helpful and necessary but cannot be used in a vacuum without understanding of the underlying anatomy.

The report by Teele and Smith considered pyloric diameter as the major size criterion, likely due to the inability to resolve the internal anatomy of the abnormal pyloric complex by the poor detail depicted by the US equipment at the time. Muscle thickness became more important in subsequent reports with real-time capability; mucosal hypertrophy within the abnormal canal and increased flow on Doppler interrogation were also recognized in parallel with advances in equipment design and imaging detail.

Multiple studies have provided data to determine the normal and abnormal values. A 1986 prospective study of 200 infants[55] found a mean muscle thickness of 3.4 mm (range 3–5 mm), and a mean pyloric length of 22.3 mm (range 18–28 mm); despite the relative limitations of the US equipment of the day, the investigators were able to discriminate between normal and abnormal patients with 100% success rate. A study of 323 patients[61] found a mean muscle thickness was 4.8 mm (range 3.5–6 mm) and mean pyloric length 17.8 mm (range 11–25 mm); muscle thickness was found to be the most helpful discriminant, with an accuracy of 99.4%. In a 1991 series reporting on 145 consecutive patients,[5] a muscle thickness of 3 mm or greater was determined to be diagnostic of HPS, with muscle thickness <1.5 mm in 98% of normal patients. These results were validated in the series published by Hernanz-Schulman et al.[62] reporting on 152 infants with nonpalpable olives evaluated with sonography, in whom a maintained muscle thickness of 3 mm or greater was diagnostic of HPS, with no false positive examinations.

In younger and previously premature infants, there is a tendency for pyloric measurements to be smaller than in full-term, older infants at presentation.[62,63] In a more recent review of these patients, investigators found significant associations between pyloric dimensions and patient age and weight; however, these changes did not affect the existing diagnostic criteria for HPS, as a muscle thickness of ≥3 mm, and length ≥15 mm are diagnostic in all patient groups.[64]

The thicker the muscle and the longer the length of abnormal antropyloric muscle, the faster and more certain the diagnosis; however, literature and experience indicate that a *persistent* muscle thickness of 3 mm or greater along with a nonrelaxing antropyloric length of 11 to 14 mm or greater is diagnostic of pyloric stenosis. However, *persistence* is key, as a transient appearance of pyloric stenosis can occur in many normal patients (see the following text).

*Normal and abnormal pylorus:* The normal antropyloric channel has a sonographic appearance similar to that at upper GI, with relaxed, open lumen directly adjacent to the duodenal bulb via the pyloric orifice (Fig. 100.6).

The abnormal antropyloric canal, on the other hand, shows thickening of the muscle and mucosa to variable degrees. The mucosa can be markedly thickened in many patients, and may be mistaken for a polyp (Fig. 100.7). The length of the hypertrophied canal is variable, ranging from as little as 14 mm to greater than 20 mm. The lower limit of muscle thickness is 3 mm, a value that

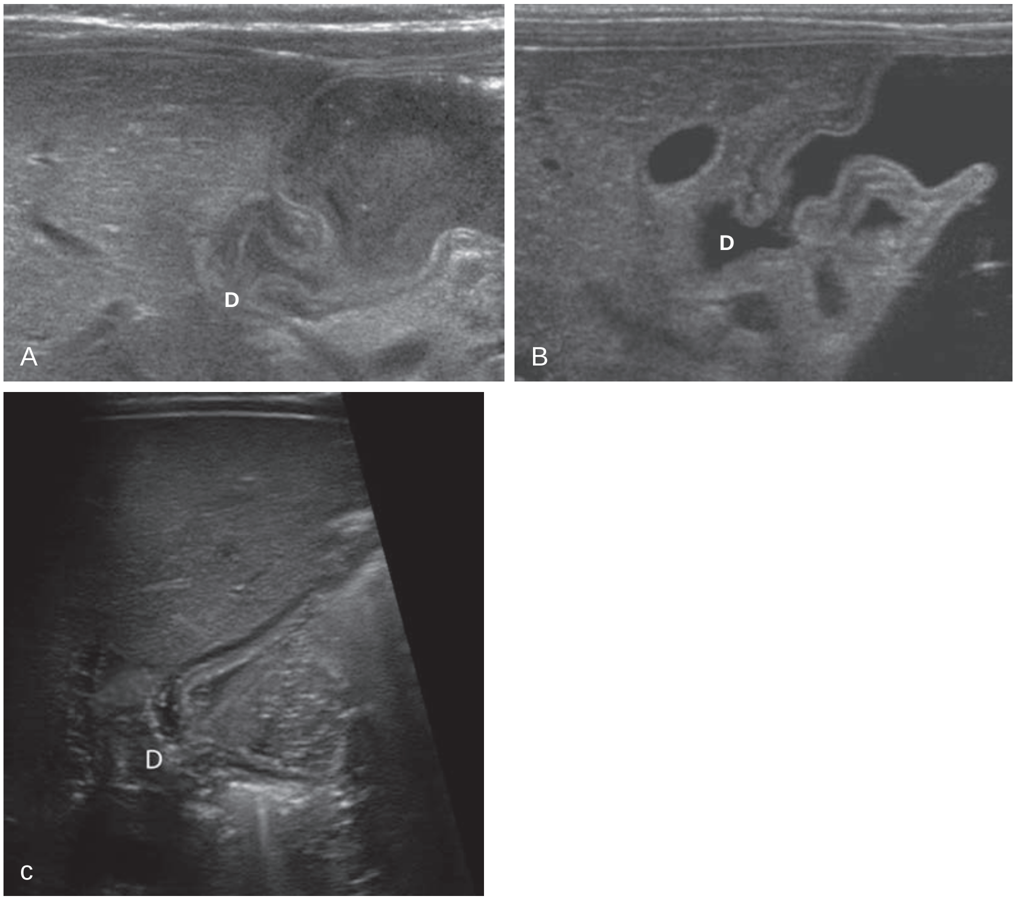

**Figure 100.6. Normal antropyloric canal in two infants.** (A) The stomach is filled with formula. Note that the antropyloric muscle is mildly thickened, but the mucosa is normal, and the antropyloric canal is distensible and filled with gastric contents. *D*, Duodenal bulb. (B) The stomach is filled with Pedialyte. Again, the antropyloric muscle is mildly thickened, but the lumen is distensible and filled with gastric contents. *D*, Duodenal bulb. (C) The antropyloric portion of the stomach is widely open, muscle layer is uniform and normal. *D*, Duodenal bulb.

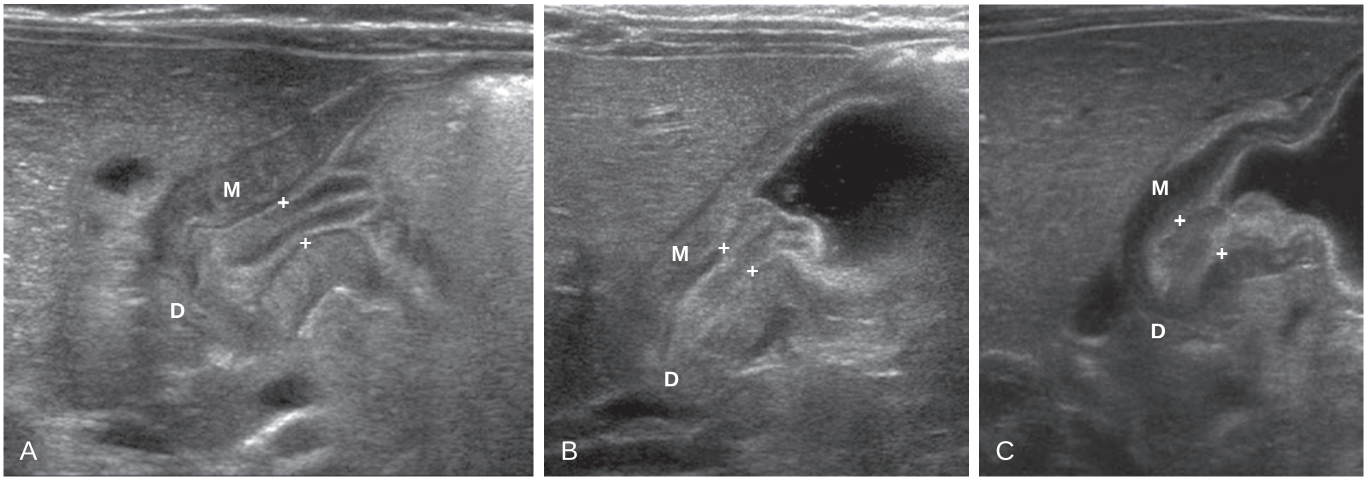

**Figure 100.7. Hypertrophic pyloric stenosis (HPS) in three infants.** (A) Abnormal pylorus in infant with HPS shows double layer of edematous mucosa (*between crosshairs*) sandwiched within the thickened muscle *(M)*, protruding into the gas and formula-filled antrum as the "nipple sign." *D*, Duodenal bulb. (B) Abnormal pylorus in another infant shows thickened muscle *(M)* and mucosa *(between crosshairs)* with protrusion into the proximal antrum. *D*, Duodenal bulb. Note the marked redundancy and prominence of the antropyloric mucosa, resembling a "polyp." (C) Another infant with progressive vomiting and poor weight gain. The muscle *(M)* is thickened to >3 mm, the mucosa *(between crosshairs)* measured 8 mm in thickness, protruding proximally into the fluid-filled antrum. *D,* Duodenal bulb. Again, notice the marked redundancy and prominence of the antropyloric mucosa, protruding into the antrum; it is easy to see how on endoscopy this could be mistaken for a "polyp."

is diagnostic if persistent without evidence of relaxation of the antropyloric canal throughout the examination.[10] Similar to Cohen et al.,[65] we emphasize that increased but transient contractions of the pylorus, or pylorospasm, may mimic pyloric stenosis in both appearance and measurement if the examination is performed quickly (Fig. 100.8A and B; e-Fig. 100.8C and D; Video 100.3). Evaluation of the antropyloric portion of the stomach over a period of time is important to confirm the diagnosis.

The muscle and mucosa typically show abundant flow as seen on color and spectral Doppler interrogation, although this is not a diagnostic criterion, but merely an associated finding in most patients (Fig. 100.9A; e-Fig. 100.9B and C). Although the patient might not have been fed for hours, the stomach is typically distended. It is important to realize that despite the lack of relaxation of the abnormal antropyloric canal, some gastric contents will pass through in many patients; HPS is not a complete obstruction, the fact on which diagnosis by upper GI is obviously based (e-Fig. 100.10; Video 100.4). In some patients, the muscle is very active, and visible contractions temporarily shorten and thicken, and lengthen and thin, the pyloric muscle; the appearance suggests that more proximal muscle, which has not lost its ability to relax and return to normal, is being actively recruited; this is an intriguing finding when considering the development and etiology of pyloric stenosis (Fig. 100.11; Video 100.5).

## Pitfalls

The normal pylorus might be difficult to visualize because of excessive amount of overlying bowel gas. In such cases, it is helpful to use the left lobe of the liver as an acoustic window, and angle inferiorly to identify the pylorus.

*False positives:* If the stomach is empty, or if the child lies supine such that the antrum is empty, or if there is active peristalsis, as noted earlier, the normal antropyloric canal may be mistaken for pyloric stenosis, particularly if the operator is inexperienced. First, if the stomach is empty, the child is unlikely to have HPS. However, exclusion of pyloric stenosis relies on demonstration of a normal antropyloric canal. If there is some fluid within the stomach, the child may be turned right side down, directing the fluid from the fundus into the antrum (Fig. 100.12A and B). If the stomach is empty, the child may be given a clear fluid, such as Pedialyte or glucose water; this will not only improve the ability to identify the pylorus and duodenal bulb, but will also allow definitive documentation of the normal anatomy (Fig. 100.12C and D).[10,62,66]

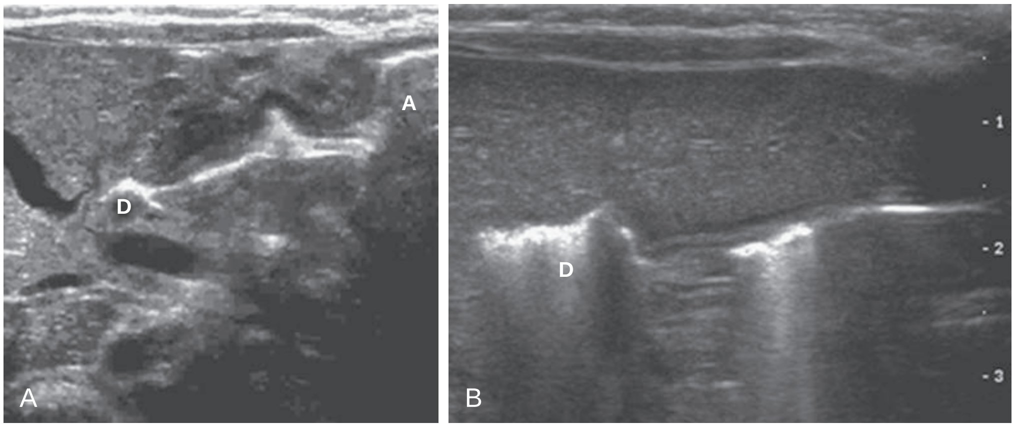
*False negatives:* In patients with HPS, the pylorus may be difficult to identify because a very distended stomach displaces it posterior to the antrum; this is also the cause of one of the false negative pitfalls in palpation (e-Fig. 100.13A). Some investigators have advocated emptying the stomach with a nasogastric catheter[67]; however, we prefer to turn the supine infant toward his/her left side, thus displacing the bulk of the fluid toward the fundus and away from the antrum, allowing the hypertrophied pylorus to rise anteriorly for optimal evaluation (e-Fig. 100.13B).

*Equivocal examinations:* Equivocal examinations are rare, but they occur when, after sufficient observation, the muscle measures between 2 and 3 mm in thickness. In such cases, the patient may be developing HPS, and follow-up examination is indicated if vomiting is unabated. It must be realized that neither the inciting event nor the time course for the development of HPS are known; the important point is to recognize that, although these patients do not have HPS, they are not entirely normal, and follow-up is needed if vomiting continues.[5,6,11]

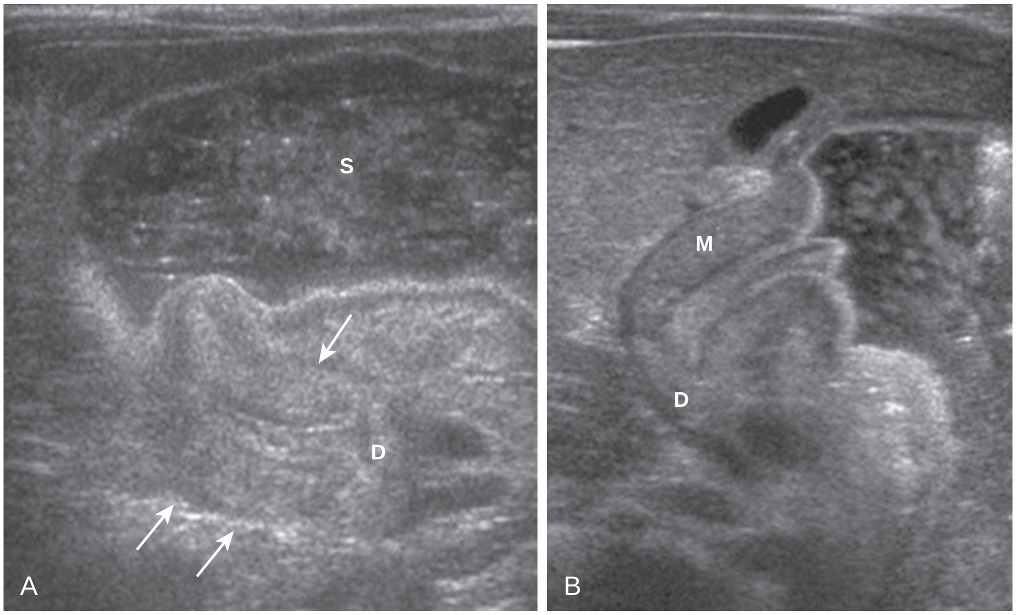
## DIFFERENTIAL DIAGNOSIS

Other entities that can mimic HPS on sonographic examination are antropyloric gastritis, with or without ulcer disease, and chronic granulomatous disease of childhood; however, these conditions present at a later age, and do not typically present a clinical uncertainty.

The most common antropyloric abnormality mimicking HPS on upper GI series is pylorospasm. Although spasm may also cause the pyloric muscle to appear thicker on US, this is a transient phenomenon usually distinguishable from pyloric stenosis or which may necessitate a follow-up examination, as previously discussed under equivocal examinations. Focal foveolar hyperplasia, or



**e-Figure 100.10. Air passing through both abnormal and normal pyloric canal (see** Video 100.4**).** (A) A 3-week-old boy with pyloric stenosis. Hyperechoic air is seen along the anterior wall of the gastric antrum *(A)* and continues through the hypertrophied antropyloric canal into the duodenal cap. This was observed on real-time. *D*, Duodenal bulb. (B) A 4-week-old boy with normal pylorus also shows hyperechoic gas moving through the nearly empty but normal antropyloric canal, into the duodenal bulb. *D*, Duodenal bulb.



**e-Figure 100.13. Pitfall when scanning an overdistended stomach in infant with hypertrophic pyloric stenosis (HPS).** (A) Image of the overdistended distal stomach in an infant with HPS shows the hypertrophied pylorus *(arrows)* folded behind the stomach *(S)*. *D*, Duodenal bulb. (B) When the infant is turned towards a left posterior oblique position, the hypertrophied pylorus is allowed to rise anteriorly, and is much more easily detected and detailed. Note the nipple sign as the pyloric mucosa protrudes into the fluid-filled antrum. *M*, Muscle; *D*, duodenal bulb.

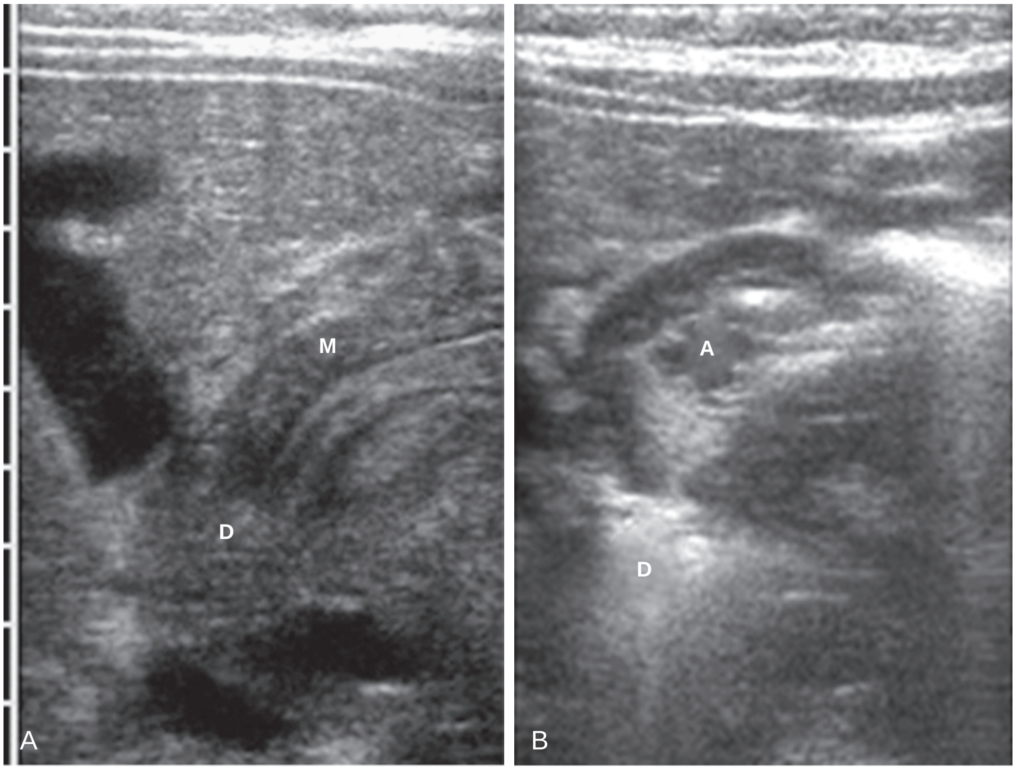


**Figure 100.8. Transient ultrasound findings (see** Video 100.3**).** (A) Antropyloric channel in infant with vomiting, shows narrowing with thickened muscle which measured up to 4 mm in thickness. *M*, Muscle; *D*, duodenal bulb. (B) Antropyloric channel in same infant as depicted in (A), 4 minutes later. The canal is open. *A*, Open antropyloric canal; *D*, duodenal bulb.

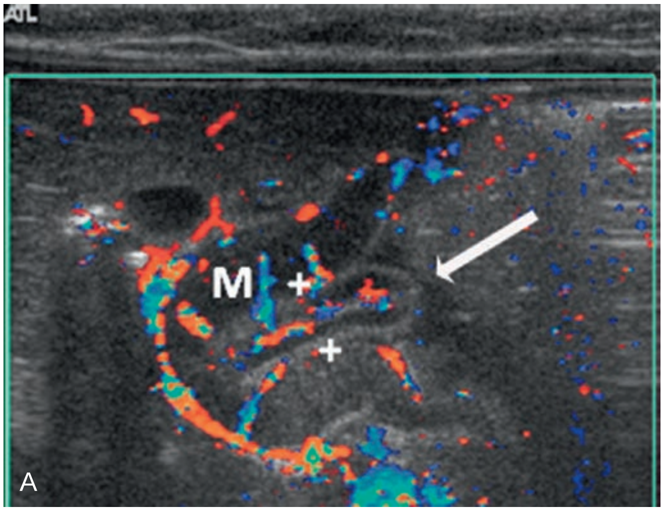

**Figure 100.9.** (A) Color Doppler image of antropyloric canal in infant with HPS. Note flow within the hypertrophied muscle *(M)* and mucosa (between crosshairs). Also note the antral nipple sign *(arrow)*.

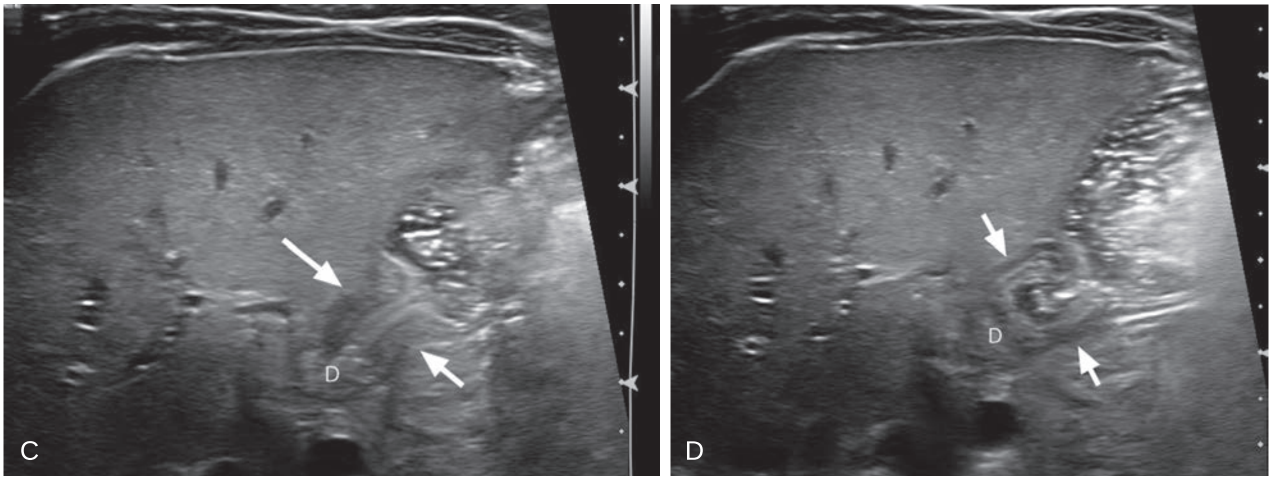
polypoid mucosa in the antropyloric portion of the stomach, is usually associated with a history of congenital heart disease and prostaglandin therapy, and resembles the thickened mucosa that is seen in patients with HPS. The lobulated mucosal mass has been reported as causing gastric outlet obstruction and has developed into full-fledged HPS in some cases.[27,28,68]

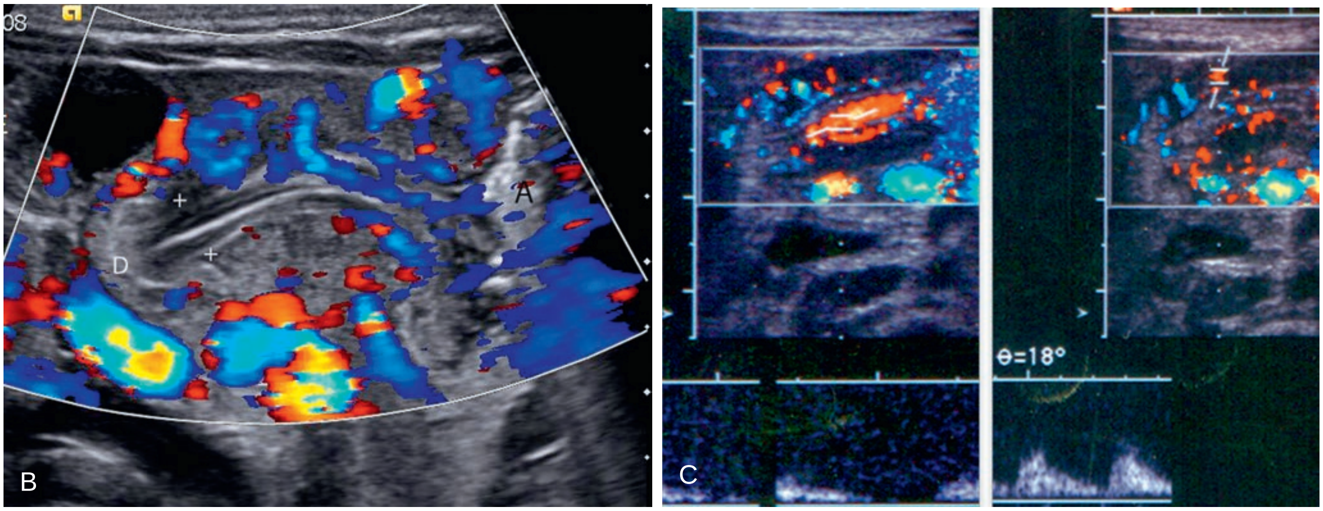
## DIAGNOSTIC ALGORITHM

Palpation of the pyloric mass is the first diagnostic examination by the physician to whom the child presents. In further evaluation and referral, consideration can be given to the investment of time and relative invasiveness of inserting an orogastric tube to evacuate the stomach. The choice is to make a direct referral to the surgeon for additional palpation or to the radiologist for a diagnostic imaging examination. The cost and time delay of obtaining a surgical consultation/clinic visit versus the cost and time delay to obtain an imaging examination are obvious considerations, and these circumstances may differ across geographical venues and clinical practices. If the pyloric mass is palpated by the surgeon, no diagnostic imaging is necessary; if it cannot be palpated by the surgeon, again consideration falls upon a diagnostic imaging examination. Waiting and re-examining the patient with prolongation of inpatient care is likely not cost-effective in most settings and may lead to delay in diagnosis and treatment. We do not advocate, as has been suggested in the past, sedating an infant at high risk for vomiting to increase sensitivity in palpating the pyloric mass.[50] Trial feeds have been advocated as well, with reported negative exploratory rates ranging between 1% and 4%.[69]

Some investigators have advocated the upper GI series as the first examination in patients with symptoms of HPS for two reasons: although US in experienced hands is extremely accurate in the diagnosis of HPS, it will not always be diagnostic in infants with vomiting from other causes. An upper GI series is deemed by some to be more cost-effective as the first imaging examination compared with US, as a follow-up upper GI may be requested in patients with normal US, increasing the monetary cost of diagnosis.[53,70] However, US is more informative than upper GI, as it



**e-Figure 100.8.** (C) Antropyloric channel in another infant with vomiting, shows narrowing with thickened muscle which measured up to 3.5 mm in thickness. *Arrows* point to the antropyloric muscle, *D*, Duodenal bulb. (D) Antropyloric channel in same infant as depicted in (C), 10 seconds apart. The canal is open *(arrows)*. *D*, Duodenal bulb.



**e-Figure 100.9.** (B) Color Doppler image of antropyloric canal in another infant with hypertrophic pyloric stenosis (HPS). Note flow within muscle and mucosa. *A*, Antrum; *D*, duodenum, crosshairs outline the more distal mucosa. (C) Spectral evaluation of color flow in antropyloric canal of another infant demonstrates flow waveform spectra in mucosa *(left)* and muscle *(right)*.

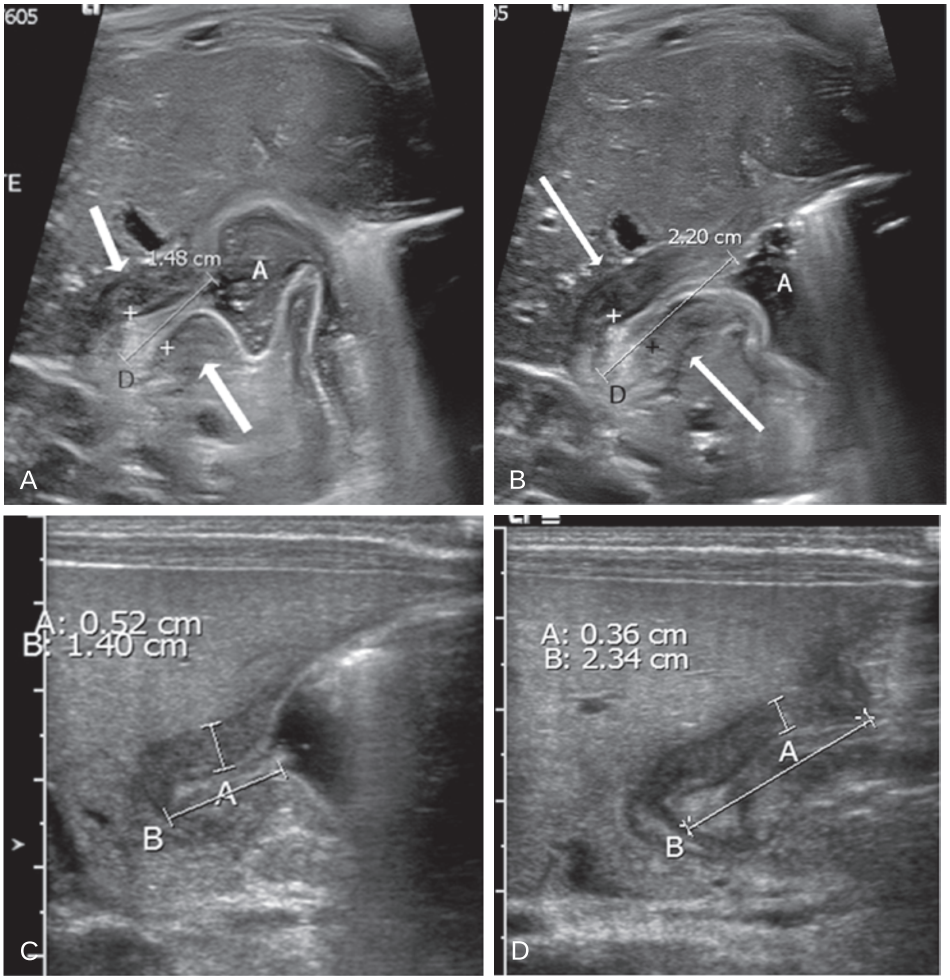


**Figure 100.11. Changing dimensions.** (A) Infant with HPS. Longitudinal image of antropyloric canal shows a thickened muscle, with relatively short abnormal canal, measuring 14.8 mm. *D*, duodenal bulb. Crosshairs define mucosa within canal, arrows point to the muscle complex. (B) Same patient 5 seconds later, shows lengthening of the abnormal canal now measuring 22 mm. *D*, duodenal bulb. Crosshairs define mucosa within canal, arrows point to the muscle complex. (C) A 4-week-old boy with HPS. Longitudinal image of antropyloric canal shows a thickened muscle *(between calipers, A)* measuring approximately 5.2 mm, and a relatively short canal *(between calipers, B)*, measuring 14 mm. *B* marking the longitudinal calipers overlies the duodenal bulb. (D) Same patient as in (C), 2 minutes later, shows a thinner muscle *(between calipers, A)* measuring approximately 3.6 mm, and a longer canal *(between calipers, B)*, measuring 23.4 mm. *B* marking the longitudinal calipers overlies the duodenal bulb.

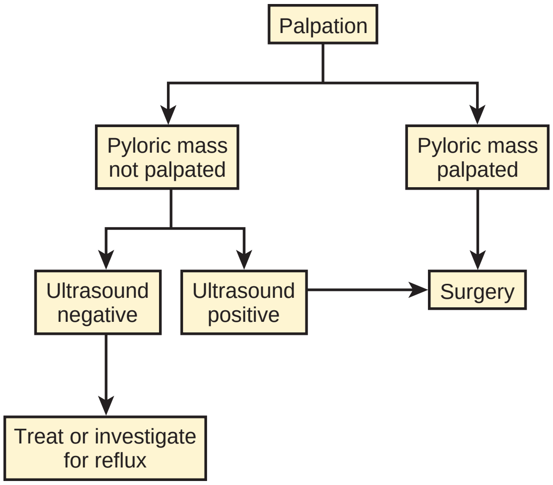
is able to image beyond the lumen of the pylorus and assess the thickness of the muscle while posing no need to distend the stomach by addition of contrast media. More importantly, as we adopt the as low as reasonably achievable (ALARA) approach as outlined by The Image Gently Alliance, we believe that US should be the first examination in patients suspected of HPS in whom imaging is indicated, particularly pertinent in these young infants in whom fluoroscopy could be prolonged.[10,62,71] If the US shows that the pylorus is normal, vomiting is clearly nonbilious, and the duodenum is normal in caliber, the likelihood is high that the cause of vomiting is reflux, which could be initially treated empirically or documented with scintigraphy (e-Fig. 100.14).

## TREATMENT

Introduced by Ramstedt in 1912, surgical pyloromyotomy via a right upper quadrant or semicircumbilical incision is the traditional therapy for infants with HPS. In this procedure, the muscle is incised, and the mucosa is allowed to protrude through the incision without resuturing (Fig. 100.15).

*Medical therapy:* Several publications have redirected attention to medical therapy, which is based on the theory that muscle spasm is a contributing factor to the muscular hypertrophy and obstruction. In a prospective trial of infants treated with surgical or medical therapy, medical therapy was successful in 85% of cases, with 2/14 requiring pyloromyotomy; mean time to full feeds was 2.7 days in the surgical group, and 5.3 days in the medically treated group.[72] In a larger prospective trial including 52 medically treated infants, there was an 87% success rate; mean hospital stay was 5 days in the surgical group and 13 days in the successfully medically treated group.[73] A subsequently published trial reported a 75% success rate of medical therapy, although the prolonged resolution of symptoms resulted in some of the parents in the medical treatment group opting for surgery before completion of medical treatment.[74] A more recent 2013 investigation on 180 medically treated infants compared with 397 surgical patients reported a 79% success rate



**e-Figure 100.14.** Diagnostic algorithm for infants suspected of having HPS.

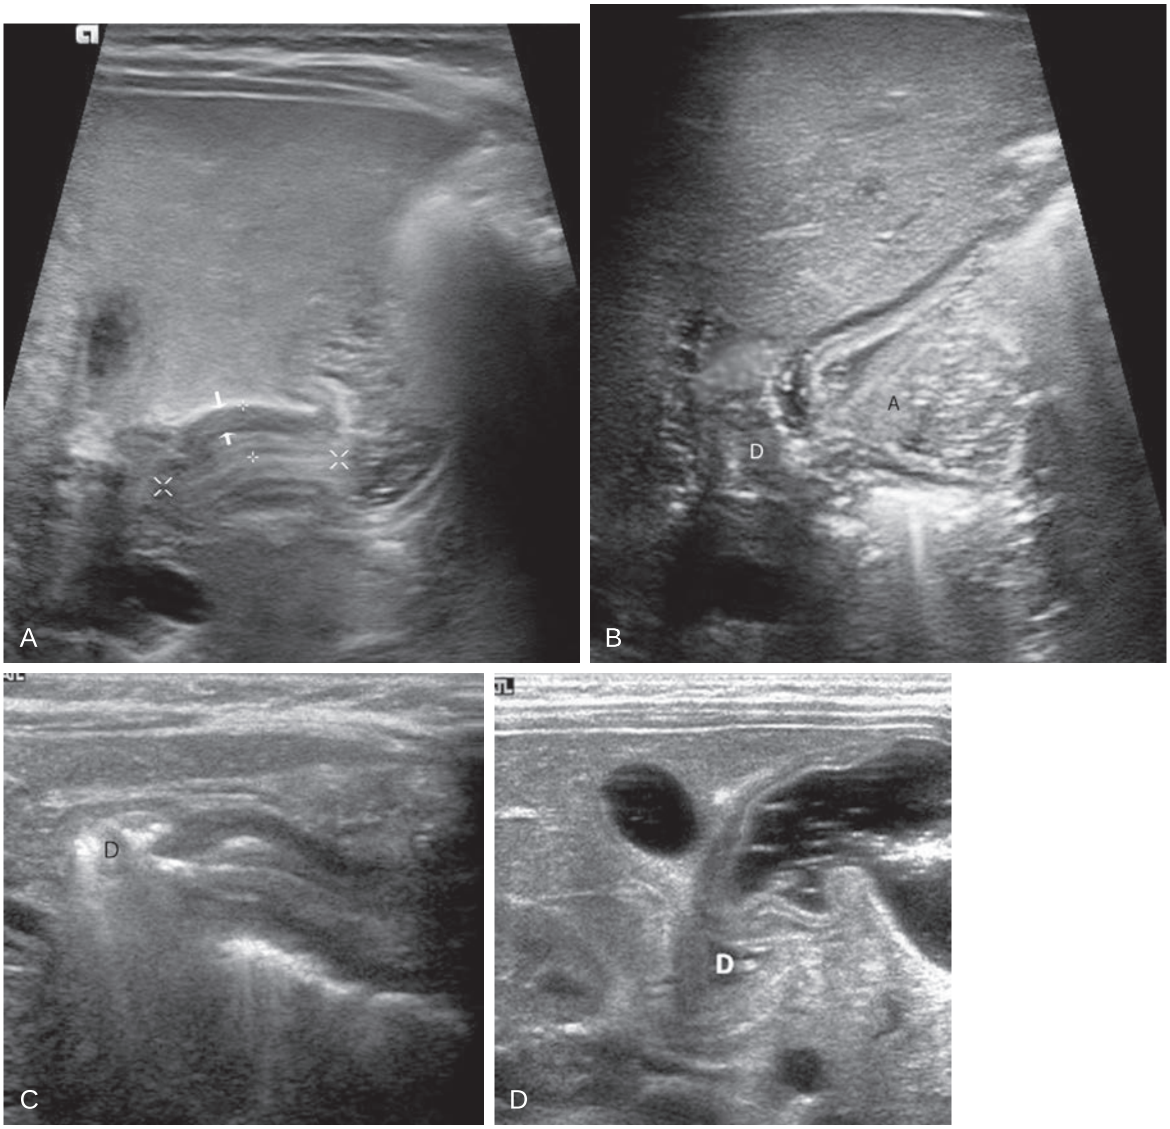


**Figure 100.12. Empty antrum mimicking HPS.** (A) A 2-month-old normal infant. With the child supine with a nondistended stomach, the empty antrum suggests HPS, with a muscle thickness measured at 4.9 mm and a length measured at 17 mm. However, please note that the muscle measurement is incorrectly placed, and includes the mucosa within the antral lumen; when the muscle alone was measured *(between white arrows)*, it measured 2 mm. (B) Same infant as in (A), a few minutes later. Turning the infant right side down, redirecting the gastric fluid into the antrum, shows normal distension of the antropyloric portion of the stomach and normal anatomy. *A,* Antrum; *D,* duodenum. (C) 8-week-old girl with vomiting. The stomach was initially empty, which is initial evidence against the presence of HPS in most infants. However, the collapsed distal antropyloric canal appears "elongated" thus mimicking some of the findings in pyloric stenosis. The muscle measured between 1.7 and 2.8 mm. *D*, Duodenum. (D) Same infant as in (C). After drinking Pedialyte ad lib, the antrum distends with a completely normal appearance. *D*, Duodenal bulb.

for the atropine group over a period of 8 days of therapy;[75] a second report found that continued projectile vomiting for greater than 3 days after medical therapy was predictive of failure and the need to convert to pyloromyotomy.[76]

*Laparoscopic pyloromyotomy:* Reported in 1991 by Alain et al.,[77] laparoscopic pyloromyotomy has been advocated recently by pediatric surgeons. Meta-analyses and prospective trials suggested that mucosal perforation might be more problematic with laparoscopy, but that wound infection appeared to be slightly less frequent. Data to date suggest that, once the learning curve for the laparoscopic approach is mastered, there is little difference in the overall outcome between these two procedures, with some prospective studies suggesting that the laparoscopic group shows less postoperative emesis and requires less postoperative analgesia, with improved cosmetic results as well.[78–84] A 2014 meta-analysis involving 1802 laparoscopic and 1028 open procedures found a very small although statistically significant higher incidence of incomplete pyloromyotomies in the laparoscopic group, although the adjusted difference was only 0.87%, raising the question of whether the difference is clinically relevant.[85]

Balloon dilatation has been attempted unsuccessfully in a limited number of patients; however, a potential role after failed pyloromyotomy or recurrent pyloric stenosis has been investigated with partial success in a very limited number of patients.[86–88]

## KEY POINTS

Radiographic findings on upper GI in HPS may include the following:

- Gastric distension and visible peristaltic waves on radiograph
- Narrowed, elongated, curved pyloric channel
- Beak sign
- String or double tract sign
- Shoulder sign
- "Pyloric tit" on lesser curve

Ultrasound findings in HPS include the following:

- Retained gastric contents
- Thickened, nonrelaxing antropyloric muscle measuring ≥3 mm
- Length of the abnormal channel typically ≥15 to 20 mm
- Redundant mucosa measuring similar or greater than muscle thickness
- Increased Doppler flow signal of mucosa and/or muscular layer

# 101 Acquired Disorders

Ellen Cecilia Benya

## OVERVIEW

Acquired disorders of the stomach in children are uncommon and may be the result of an underlying congenital predisposition, such as gastric volvulus; an inflammatory process, such as peptic ulcer disease (PUD); or a neoplastic or neoplastic-like condition. In addition to fluoroscopic contrast studies, ultrasonography (US), computed tomography (CT), and, less frequently, magnetic resonance imaging (MRI) and nuclear medicine may be used for evaluation.

## GASTRIC VOLVULUS

***Overview and Etiology.*** The stomach is normally fixed in the peritoneal cavity at the gastroesophageal (GE) junction and by the gastrohepatic, gastrosplenic, gastrocolic, and gastrophrenic ligaments (Fig. 101.1). Gastric volvulus is defined as an abnormal rotation of the stomach of more than 180 degrees around its long (organoaxial) or short (mesenteroaxial) axes (Figs. 101.2A and B). In the organoaxial type of gastric volvulus, there is an inversion of the position of the greater and lesser curves of the stomach, with the greater curvature positioned to the right and superior to the lesser curvature. In the mesenteroaxial type, the stomach rotates on its short axis, leading to a reversal of the relationship between the gastroesophageal junction and the antrum.[1]

***Clinical Presentation.*** Clinically, there are two primary scenarios. The first is the acute fulminant presentation, most often encountered in the mesenteroaxial type, with sudden and persistent vomiting and acute abdominal pain.[2] The chronic intermittent presentation is more often associated with the organoaxial type, with less specific symptoms including recurrent abdominal pain, vomiting, and gastric distension.[3] Predisposing factors for gastric volvulus include congenital or acquired absence of one or more of the fixating ligaments as isolated abnormalities, or occurring in association with a diaphragmatic defect, wandering spleen,[4] or heterotaxy syndrome.[5]

***Imaging.*** Abdominal radiographs in patients with gastric volvulus typically show marked gastric distension, often with a very unusual, "rounded" outline, or two air fluid levels on an upright view, with paucity of distal bowel gas indicating gastric outlet obstruction (Fig. 101.3A). Other findings include an unusual nasogastric tube course or diaphragmatic elevation. While plain radiographs are usually highly suggestive of the diagnosis, CT may be diagnostic in demonstrating the abnormal orientation and obstruction of the stomach and may detect the presence of heterotaxy or a wandering spleen (Fig. 101.3B).[4–6] Upper gastrointestinal (UGI) confirms the presence of gastric outlet obstruction and characterizes the type of gastric volvulus present (Fig. 101.3C). As noted earlier, in organoaxial volvulus, there is an inversion of the relationship of the greater and lesser curvatures, while in mesenteroaxial volvulus, the antrum and pylorus projects over the gastric fundus at the level of the GE junction; mixed types can also occur.[3]

***Treatment and Follow-up.*** Gastropexy is the treatment of choice and can be performed laparoscopically.[7–9]

## GASTRIC PERFORATION

***Overview and Etiology.*** Perforation of the stomach is an uncommon event, mainly seen in preterm and full-term neonates as a cause of massive pneumoperitoneum.[10] Potential etiologies include nasal ventilation, distal intestinal obstruction, ischemia, corticosteroid administration, or a combination of factors[11]; infants with esophageal atresia and distal fistula born prematurely are at particular risk if the diagnosis is not known before ventilatory support is instituted. Concomitant necrotizing enterocolitis has also been described.[12] Beyond the neonatal period, perforation is rare and usually secondary to trauma such as iatrogenic insertion of tubes and catheters, surgery such as fundoplication, caustic ingestion, or PUD.[2]

***Clinical Presentation.*** The most common presenting manifestations of perforation include sudden onset of abdominal distension, ileus, respiratory distress, and, less frequently, cyanosis, fever, vomiting, and bloody stool.[13]

***Imaging.*** Abdominal radiography is the imaging method of choice when perforation of the GI tract is suspected. As in other locations of GI perforation, abdominal radiographs will typically demonstrate free intraperitoneal air.

***Treatment and Follow-up.*** Gastric perforations require surgical repair. A higher mortality rate is seen in preterm and low birth weight infants who present with gastric perforation.[11]

## GASTRITIS AND GASTROPATHY

***Overview.*** Gastritis is a nonspecific term referring to conditions that result in inflammation of the gastric mucosa, such as PUD and/or *Helicobacter pylori* infection. In children, inflammatory changes in the stomach may also be the result of immunologic alterations (eosinophilic gastritis) or be related to other systemic entities such as Crohn disease or chronic granulomatous disease. Gastropathy is a disorder of the gastric mucosa that may demonstrate evidence of epithelial damage and regeneration but has little to no associated inflammatory change as seen in hypertrophic gastropathy (Menetrier disease).

### Peptic Ulcer Disease

***Overview and Etiology.*** PUD occurs less commonly in children than adults and, when seen, presents with duodenal ulceration more frequently than gastric ulceration (see Chapter 103).[14,15] The two main risk factors for PUD in children are *Helicobacter pylori* infection and nonsteroidal antiinflammatory medications.[15] *Helicobacter pylori*, a common human pathogen, is associated with both inflammatory conditions (chronic gastritis and PUD) and malignancy (gastric MALT "mucosa-associated lymphoid tissue" lymphoma).[16] Zollinger-Ellison syndrome results in PUD, with multiple, recurrent ulcerations seen in the distal duodenum and proximal jejunum due to the increased acid production generated by a gastrin-secreting tumor (Fig. 101.4).[17,18]

***Clinical Presentation.*** Symptoms of ulcer disease are varied and include abdominal pain, anorexia, early satiety, recurrent vomiting, and anemia.[19] In a few patients, PUD may result in severe gastrointestinal hemorrhage or acute abdominal pain due to perforation.[17]

***Imaging.*** Endoscopy has assumed the primary role in the diagnosis of ulcer disease.[19,20] Only rarely does UGI performed to evaluate the child with abdominal pain and vomiting demonstrate the presence of a gastric ulcer. Perforated ulcers may be identified

## Abstract:

Acquired disorders of the stomach in children are uncommon and may be the result of an underlying congenital predisposition, such as gastric volvulus; an inflammatory process, such as peptic ulcer disease (PUD); or a neoplastic or neoplastic-like condition. In addition to fluoroscopic contrast studies, ultrasonography (US), computed tomography (CT), and, less frequently, magnetic resonance imaging (MRI) and nuclear medicine may be used for evaluation.

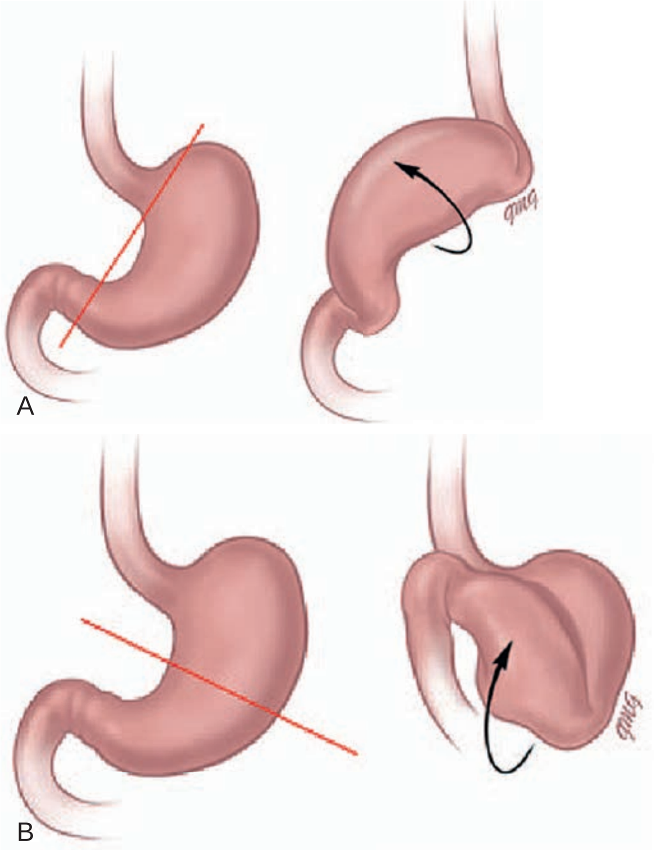

**Figure 101.2. Schematic drawing illustrating gastric volvulus.** (A) Organoaxial volvulus. Note rotation of the stomach along its long axis, such that the greater curvature is superior and to the right of the lesser curvature. The relationship of the gastroesophageal (GE) junction and the pylorus has not changed. (B) Mesenteroaxial volvulus. Note rotation of the stomach along its short axis, with reversal of the relationship of the GE junction and the pylorus. *(From Timpone VM, et al. Abdominal twists and turns: part I, gastrointestinal tract torsions with pathologic correlation.* AJR Am J Roentgenol*. 2011;197[1]:86–96.)*

on CT in the evaluation of a child with acute abdominal pain (e-Fig. 101.5).

***Treatment and Follow-up.*** Current therapy usually consists of a proton pump inhibitor to decrease acid production as well as antibiotics for *H. pylori*-associated ulcer disease.[19]

## Hypertrophic Gastropathy (Menetrier Disease)

***Overview and Etiology.*** Hypertrophy of the gastric rugal folds in association with protein-losing enteropathy in childhood is labeled Menetrier disease, or hypertrophic gastropathy of childhood.[20] The clinical, pathologic, and etiologic factors differ from the adult form. In adults, the disease is chronic and premalignant. In children, the disease is self-limited, with a peak age of 5 years at presentation. The etiology of the disease remains unknown; however, associated *H. pylori* and/or cytomegalovirus infection has been reported.[21,22]

***Clinical Presentation.*** Presentation typically includes acute vomiting, diarrhea, upper abdominal pain, and anorexia. Peripheral edema is usually present and may be associated with ascites and pleural effusions.[21] Rarely, there may be signs of gastrointestinal bleeding when there is ulceration of the gastric rugae.

***Imaging.*** This condition should be considered when diffuse and polypoid gastric fold thickening is seen involving the fundus and sparing the antrum on UGI, US, or CT studies (Fig. 101.6).[23,24] FDG-PET studies are not routinely performed but may show hypermetabolic activity in the regions of gastric wall thickening.[24] Differential diagnostic considerations include eosinophilic gastritis, *H. pylori*–related gastritis, gastric Crohn disease, Zollinger-Ellison syndrome, primary gastric lymphoma, and gastrointestinal stromal tumor (GIST).[24] Endoscopy with biopsy is needed for definitive diagnosis.

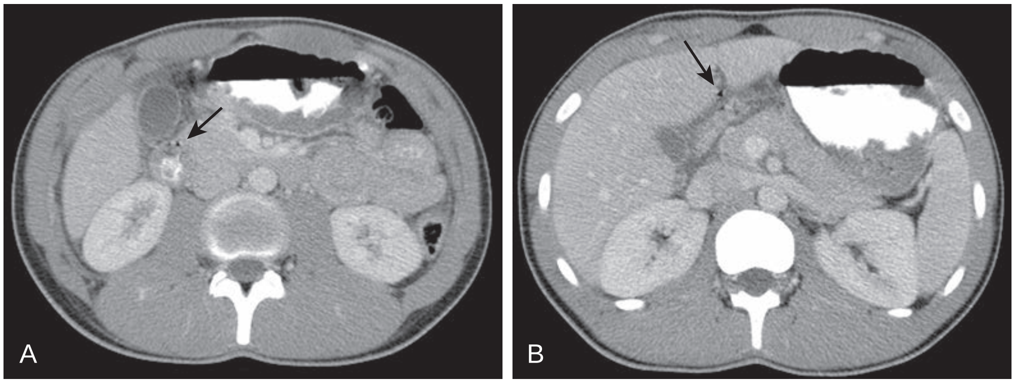
***Treatment and Follow-up.*** The entity in children is self-limited.[20] After correction of hypoproteinemia, complete recovery usually occurs within 2 to 4 weeks.[21]

## Chronic Granulomatous Disease

***Overview and Etiology.*** Chronic granulomatous disease (CGD) of childhood is a rare hereditary disorder of phagocyte function. It is most commonly inherited as an X-linked recessive gene mutation but also as an autosomal recessive defect, with three autosomal recessive mutations identified. The genetic mutation leads to a defect in activation of NADPH oxidase within the phagocytes that leaves them unable to kill and digest catalase-positive bacteria and fungi.[25,26] Histologically, there is granuloma formation within the thickened antral wall, which may develop due to chronic antigenic stimulation from organisms not killed by the defective phagocytes.[27]

***Clinical Presentation.*** Individuals with CGD develop recurrent infections, inflammation, and granulomas.[25] Involvement of the antrum resulting in gastric outlet obstruction occurs in the X-linked recessive form more commonly than in the autosomal recessive form and presents at a mean age of 44 months,[28] usually with severe vomiting.

***Imaging.*** Narrowing of the gastric antrum is a distinctive manifestation of CGD, occurring in 16% of cases.[29] Gastric outlet obstruction related to CGD is most commonly diagnosed by ultrasound or UGI series but may also be detected on abdominal CT studies done to evaluate other infectious complications such as hepatic abscesses. Ultrasound and CT studies demonstrate the circumferential antral wall thickening (Fig. 101.7). In addition to demonstrating antral narrowing, UGI series or nuclear medicine gastric emptying study can evaluate the degree of gastric obstruction. The differential diagnosis of gastric antral involvement includes PUD, Crohn disease, and eosinophilic gastritis.[30,31]



**e-Figure 101.5. Perforated duodenal ulcer in 16-year-old boy on nonsteroidal antiinflammatory regimen.** (A) Contrast-enhanced CT image shows marked thickening of the duodenal wall and small amount of free air *(arrow)*. (B) Image slightly more cephalad shows fluid about the duodenum, and additional free air extending toward the area of the falciform ligament *(arrow)*.

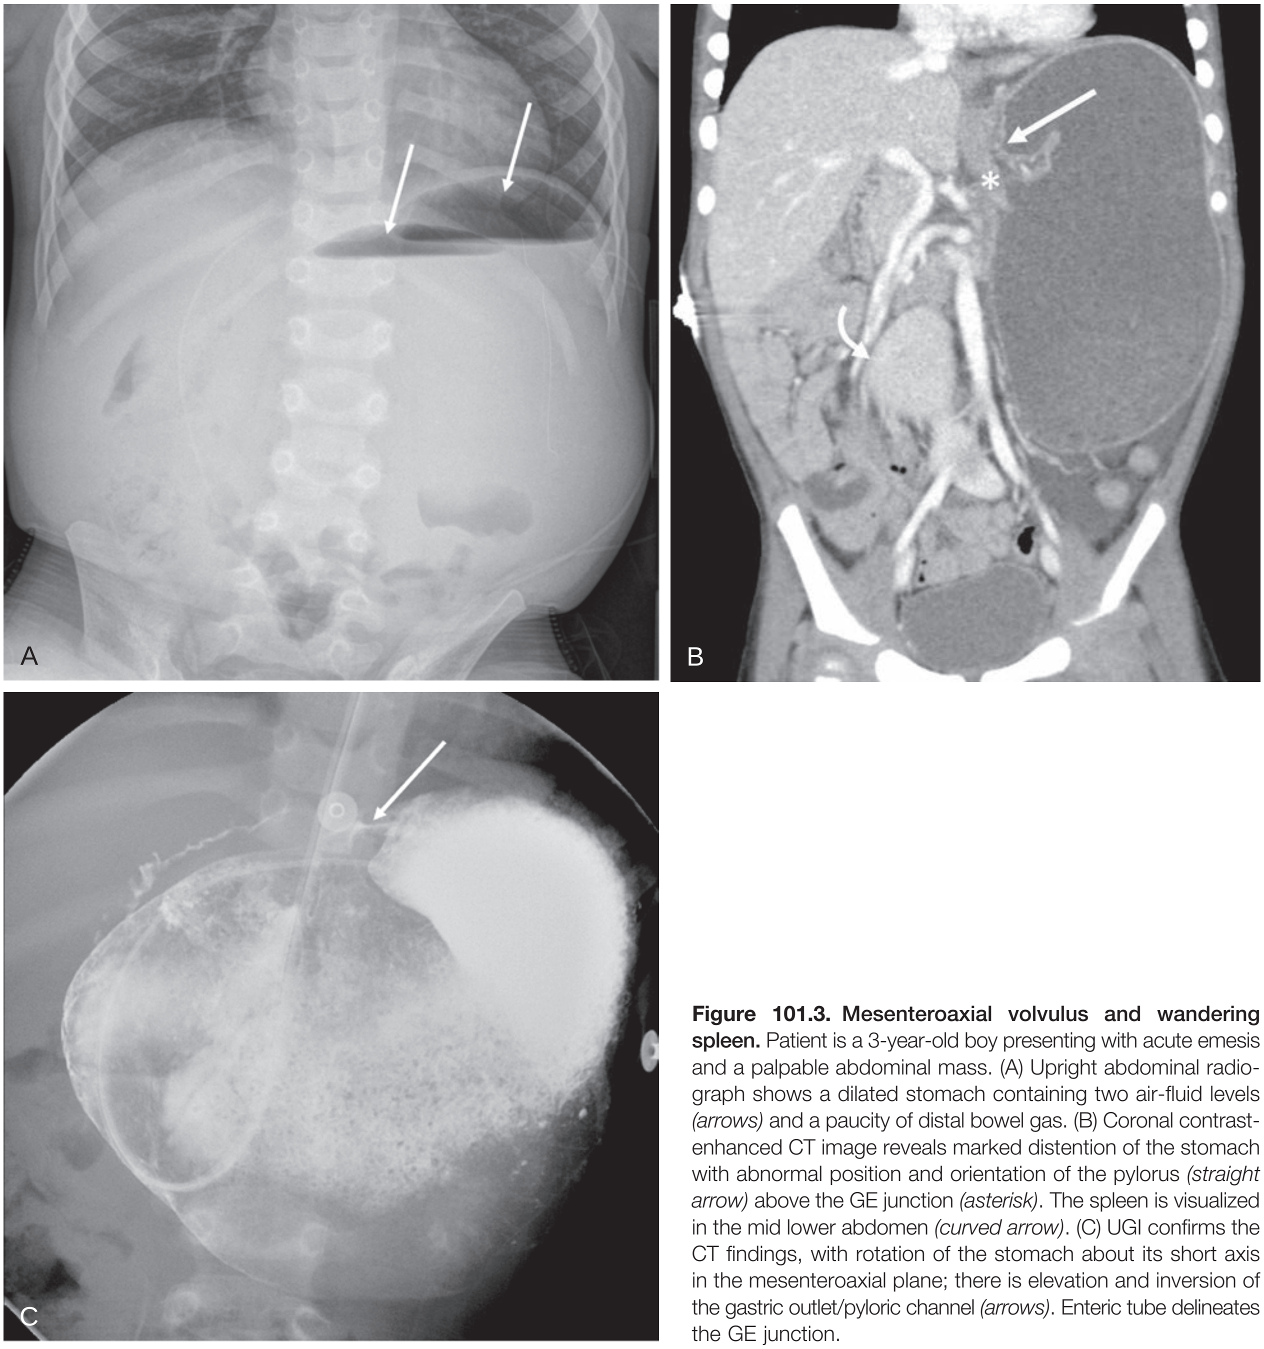


**Figure 101.3. Mesenteroaxial volvulus and wandering spleen.** Patient is a 3-year-old boy presenting with acute emesis and a palpable abdominal mass. (A) Upright abdominal radiograph shows a dilated stomach containing two air-fluid levels *(arrows)* and a paucity of distal bowel gas. (B) Coronal contrast-enhanced CT image reveals marked distention of the stomach with abnormal position and orientation of the pylorus *(straight arrow)* above the GE junction *(asterisk)*. The spleen is visualized in the mid lower abdomen *(curved arrow)*. (C) UGI confirms the CT findings, with rotation of the stomach about its short axis in the mesenteroaxial plane; there is elevation and inversion of the gastric outlet/pyloric channel *(arrows)*. Enteric tube delineates the GE junction.

***Treatment and Follow-up.*** Most patients respond in a few weeks to conservative medical management with nutritional support, steroids, and antibiotics.[28]

## Eosinophilic Gastritis

***Overview and Etiology.*** Eosinophilic gastroenteritis is a rare, poorly understood disorder, which may involve the esophagus, stomach, duodenum, small bowel, or colon. It can present any time between infancy and advanced age.[32] Eosinophilic gastritis differs from allergic gastritis, which histologically only involves the mucosal layer of the stomach and is caused by a specific antigen, most frequently cow's milk protein or soy milk protein.[33] Diagnostic criteria for eosinophilic gastritis include presence of gastrointestinal symptoms and biopsies demonstrating eosinophilic infiltration of the mucosal, muscular, and/or subserosal layer of the bowel without evidence of bacterial or parasitic infection or extraintestinal disease causing eosinophilia.[34,35]

***Clinical Presentation.*** Patients present with symptoms of abdominal pain, anorexia, failure to thrive, gastrointestinal bleeding, anemia, gastric obstruction, protein-losing enteropathy, and ascites.[32] Peripheral eosinophilia is usually but not always present.[36] Bowel obstruction and pancreatitis are more unusual manifestations of this condition.[32]

***Imaging.*** On UGI, findings of eosinophilic gastritis may include rigidity of the gastric antrum, thickened gastric folds, and mucosal nodules (Fig. 101.8).[37] On ultrasound, the predominantly antral abnormality can mimic findings seen in hypertrophic pyloric

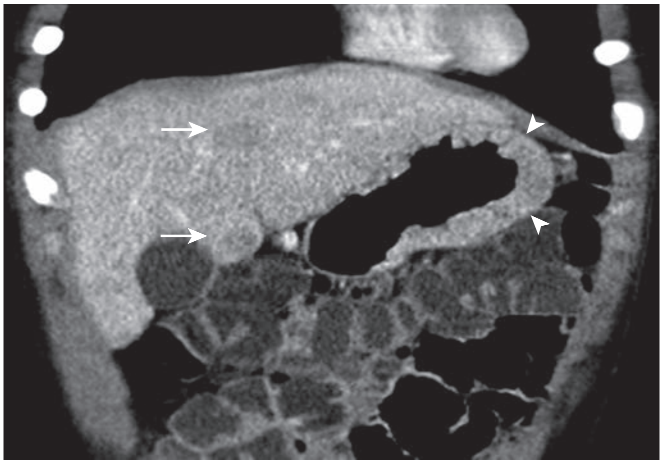

**Figure 101.4. Zollinger-Ellison syndrome secondary to a pancreatic gastrinoma in a 10-year-old boy.** Coronal contrast-enhanced CT image shows marked segmental thickening of the gastric fundus and body *(arrowheads)*. Two hypodense lesion in the liver are consistent with metastases *(arrows)*.

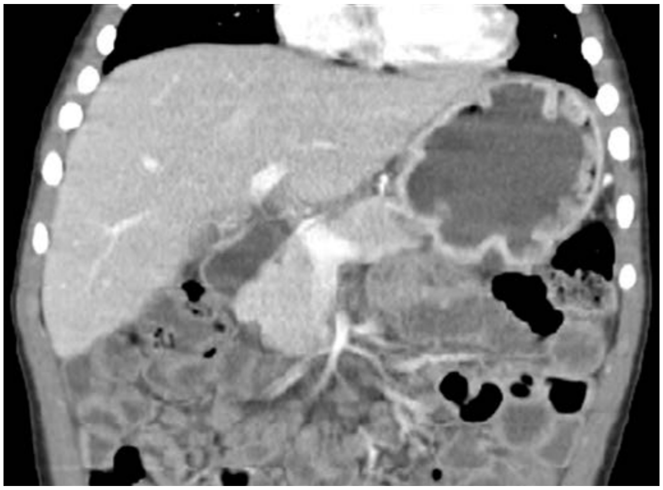

**Figure 101.6. Menetrier disease.** Coronal-reformatted contrast-enhanced CT image shows the typical thickening of the gastric folds in the fundus of the well-distended stomach in a 4-year-old boy presenting with 10 days of vomiting with streaks of blood, palpebral edema, and hypoalbuminemia. Menetrier disease was confirmed with endoscopy and gastric biopsy.

stenosis, and this condition should be suspected if such findings are seen in conjunction with eosinophilia.[38] However, in the majority of cases, radiologic imaging studies are normal.[32,39]

***Treatment.*** A variety of dietary and drug treatments have been employed for eosinophilic gastroenteritis with no consensus regarding the optimal regimen.[32] Oral corticosteroid treatment is currently the most frequently utilized therapy for eosinophilic gastroenteritis.[34,35]

## GASTRIC MASSES: FOREIGN BODIES, TUMORS, AND TUMOR-LIKE CONDITIONS

### Gastrointestinal Foreign Bodies

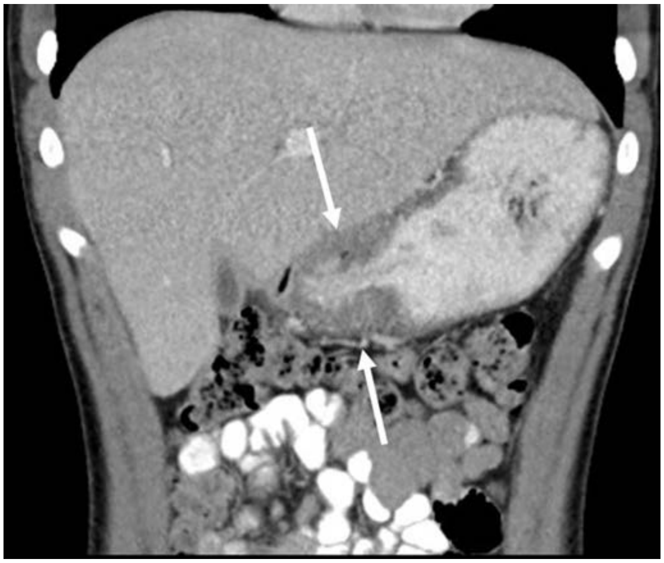

**Figure 101.7. Chronic granulomatous disease in a 15-year-old boy with intermittent epigastric pain, and occasional vomiting.** Coronal contrast-enhanced CT image shows marked circumferential thickening of the antral wall *(arrows)*.

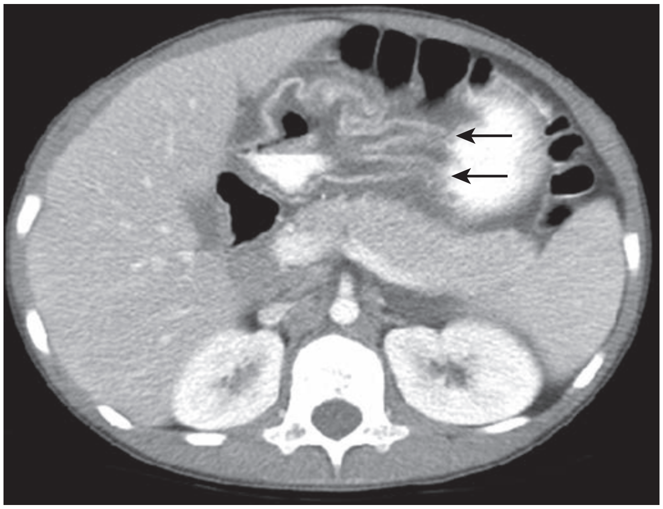

**Figure 101.8. Eosinophilic gastritis in a 14-year-old with chronic abdominal pain, failure to thrive, and nausea.** Axial contrast-enhanced CT image shows marked thickening of the gastric rugae predominantly in the antrum *(arrows)*. There is mural stratification indicating edema. Note the lack of subcutaneous fat in this child with failure to thrive.

***Overview and Etiology.*** The ingestion of foreign objects is relatively common in pediatric patients with peak age occurrence between 6 months and 3 years. Significant morbidity occurs in approximately 1% of children after foreign body ingestion[40] (see also Chapter 98).

Coins and smooth, blunt objects account for most ingested foreign bodies.[41] Complications, when they occur, are related to position (esophageal or gastric), size, shape, and sharpness of the foreign object, as well as its composition. Button batteries, especially those containing lithium and those larger than 20 mm in diameter, can lead to severe esophageal tissue injury from high pH resulting from the generation of hydroxide radicals. Finding the battery in the stomach does not exclude the possibility that esophageal injury might have occurred[42] (Fig. 101.9A). Multiple magnet ingestion (Fig. 101.9B) may result in tissue damage with formation of enteroenteric fistulae or bowel ischemia/necrosis and subsequent perforation due to attraction of magnets when present in adjacent bowel loops.[42]

***Imaging.*** Approximately 64% of foreign bodies are radiopaque and can be identified on plain films.[43] Nonradiopaque-ingested objects include those made of wood or plastic. Radiographs from nose to anus are indicated when foreign body ingestion is suspected. Fluoroscopy studies using water-soluble contrast may be useful to identify nonradiopaque foreign bodies.[41] US imaging of the stomach after water ingestion has been described to locate intraluminal foreign objects and to monitor progression through the gastrointestinal tract.[44]

***Treatment and Follow-up.*** Although 90% of foreign bodies that have cleared the esophagus will pass spontaneously, experts recommend removing sharp objects before they enter the duodenum.[41,45] Once the foreign body has passed the stomach, the stool should be checked to verify that the object has been expelled. If, after a week, the child has not excreted the object, a radiograph should be obtained to determine its location if present.[46] Button batteries and multiple magnets require special attention. All button batteries seen in the esophagus must be removed emergently due to their associated high morbidity and mortality rates. Guidelines for removal of button batteries from the stomach are evolving.[40,44,47,48]

## Bezoars

***Overview and Etiology.*** Bezoars are foreign bodies within the stomach or other portions of the gastrointestinal tract that form from the accretion of nondigestible materials and increase in size over time. The three most common types are: trichobezoars composed of ingested hair, phytobezoars composed of plant matter, and lactobezoars composed of undigested milk curds (Table 101.1). *Trichobezoars* usually result from swallowing of multiple small amounts of hair plucked from the head, or fibers from fur, rugs, or garments. The hairs or fibers become lodged in the gastric mucosal folds and over a period of time; an intraluminal mass or bezoar develops, forming a cast of the lumen of the stomach. Occasionally, a tail of material from the bezoar may extend into the duodenum and small bowel leading to the "Rapunzel syndrome" with potential complications, including small bowel intussusception, perforation, and bowel obstruction.[49,50] Patients with developmental delay and psychiatric illnesses are at increased risk for bezoars. Lactobezoars may occur in infants with a history of prematurity receiving a highly concentrated formula, with additional risk factors including poor neonatal gastric motility and dehydration.[49]

***Clinical Presentation.*** Patients with bezoars can be asymptomatic or present with relatively nonspecific symptoms, such as epigastric discomfort. Other complaints may include bloating, nausea and vomiting, early satiety, halitosis, dysphagia, and failure to thrive; rarely GI bleeding and acute abdominal pain can occur.[49]

**TABLE 101.1** Types of Bezoar According to the Ingested Material

| | |
|---|---|
| Phytobezoar | Nondigestible food particles found in fruits (dates, persimmons) and vegetables (cellulose, hemicellulose, lignin) |
| Trichobezoar | Hair bezoar. Associated with young females and/or patients with psychiatric illnesses who ingest hair, carpet, rope, string, etc. |
| Lactobezoar | Compact mass of undigested milk concretions traditionally described in preterm neonates on highly concentrated formula |
| Pharmacobezoar | Conglomeration of medications or medication vehicles |
| Others | Mixture hair, fruit, and fiber<br>Worms |

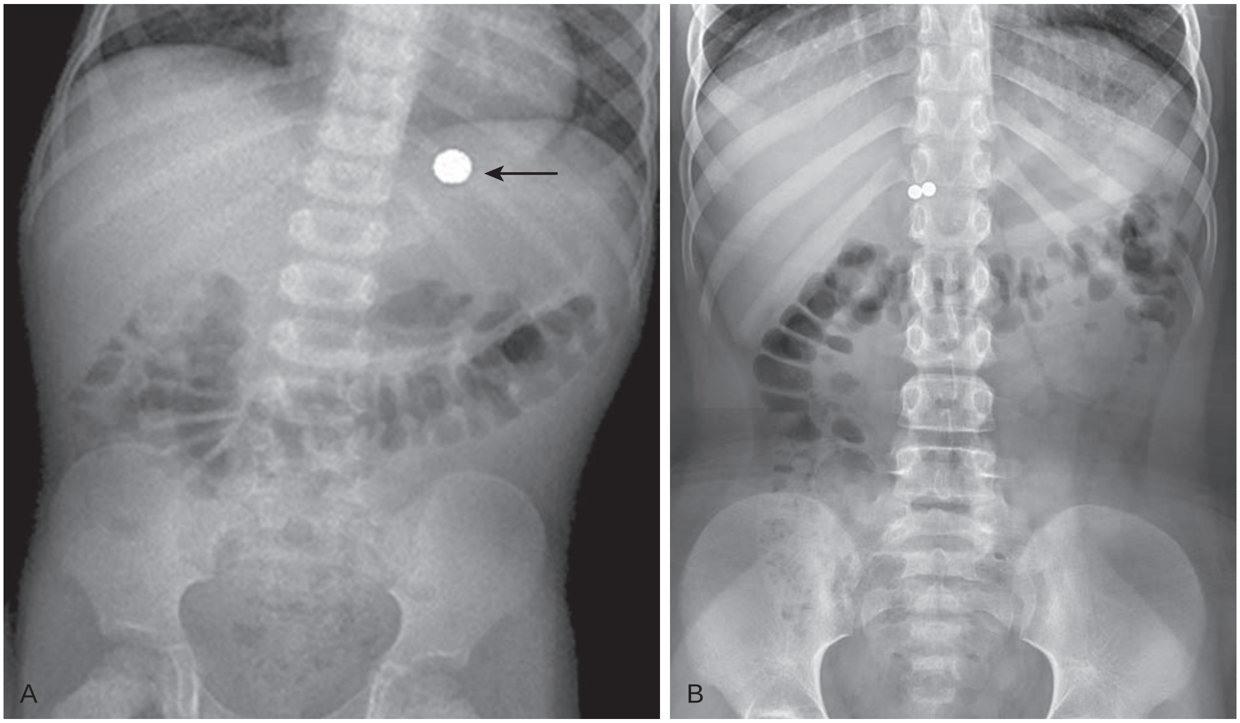

**Figure 101.9. Ingested gastric foreign bodies** (A) Ingested watch battery in a 2-year-old child. Supine radiograph shows the ingested battery with irregular outline indicating corrosion *(arrow)* in the gastric fundus. (B) A 6-year-old was playing with magnets, which were accidentally swallowed. Two opposed magnets are clearly seen in contact within the gastric antrum. *(Courtesy Marta Hernanz-Schulman, Nashville, TN.)*

***Imaging.*** Plain radiographs may demonstrate a mass within the stomach if outlined by gas, in addition to gastric distension without history of ingestion of a large meal. Fluoroscopic contrast studies will show the mass as contrast coats the bezoar and infiltrates within its interstices, producing the characteristic mottled appearance (Fig. 101.10A). CT can also identify a bezoar, typically without the need for ingestion of contrast and may also identify additional bezoars (Fig. 101.10B), as well as potential complications such as obstruction or perforation.[2,50]

***Treatment and Follow-up.*** Therapeutic options for treating amenable bezoars include fragmentation and dissolution with enzymatic therapy, or gastric lavage with saline in cases of lactobezoars, and subsequent dietary modification. In cases of motility disorders, the administration of prokinetic agents is important to prevent recurrence. Surgical or endoscopic extraction is reserved for trichobezoars or for those instances in which the previously described measures fail.[49,50]

## Gastric Tumors

***Overview and Etiology.*** Gastric tumors in children are rare but include gastric polyps, lymphoma, GIST, leiomyosarcoma, teratoma, and inflammatory pseudotumor.

Polyps, which may occur anywhere along the GI tract, are the most common gastric tumor in children. Isolated gastric polyps are usually benign, with a hyperplastic inflammatory histology most frequently identified.[51] Polyps can be part of a syndrome, such as hamartomatous polyps in Peutz-Jeghers syndrome, or fundic gland polyps in familial adenomatous polyposis.[51] Gastric polyps may be seen in up to 60% of patients with familial polyposis syndrome,[52] and lifelong endoscopic surveillance of these patients is warranted because of the potential for malignant transformation of adenomatous polyps.[53] An increased risk of malignancy is also seen in patients with Peutz-Jeghers syndrome.[54–56]

Primary gastric lymphoma can be divided into mucosa-associated lymphoid tissue (MALT) lymphoma and non-MALT lymphoma. MALT lesions typically arise in response to a stimulus such as *H. pylori* infection and are rare in children.[57,58] Non-MALT primary gastric lymphomas are also rare and are usually high-grade non-Hodgkin lymphomas of B-cell origin, usually of the Burkitt type.[59]

GIST are mesenchymal neoplasms derived from the muscle wall of hollow viscera in the GI tract, most of which are positive for mutations in the *KIT* and *PDGFRA* (platelet derived growth factor alpha receptor) tyrosine kinase genes. These tumors are very rare in pediatric patients, predominantly occurring in young girls and differing in pathogenesis from adult GIST typically with an epitheloid rather than spindle cell cytology.[60,61] These tumors are usually located in the gastric antrum, are frequently multifocal, and may be associated with a paraganglioma (Carney-Stratakis syndrome); pulmonary chondroma and extra-adrenal paraganglioma (Carney triad); and neurofibromatosis type-1.[60,61]

Leiomyoma and leiomyosarcoma are also mesenchymal neoplasms, but unlike GIST, these tumors demonstrate smooth muscle markers and are KIT and PDGFRA negative. They are much less prevalent in children, with peak age at presentation in the sixth decade. Although polypoid leiomyomas are the most common smooth muscle neoplasm arising in the GI tract, they are very

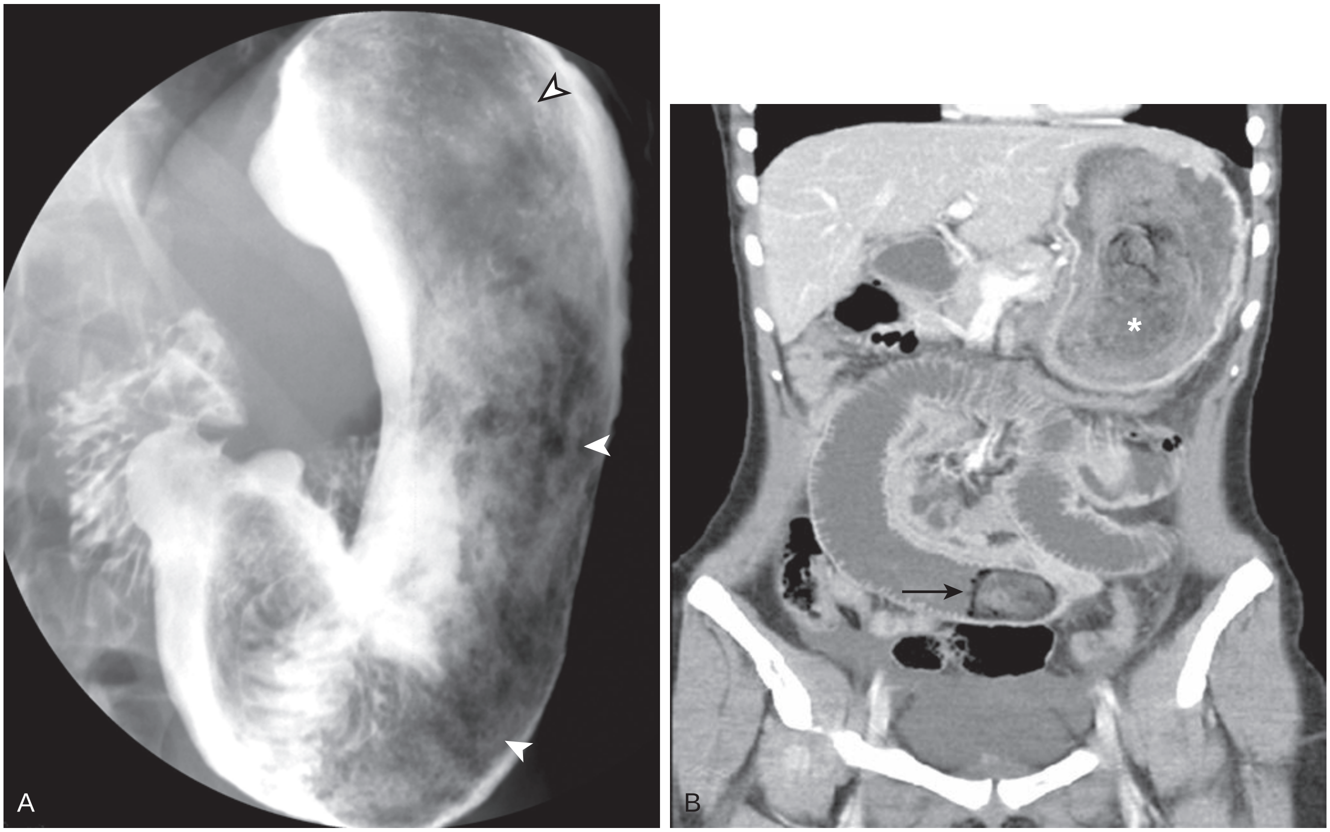

**Figure 101.10. Gastric bezoars A.** (A) Lactobezoar in a 6-month-old infant. Oblique view of an upper GI series shows a well-defined oval filling defect in the gastric lumen *(arrows)* subsequently confirmed to be a lactobezoar. (B) Trichobezoar in an adolescent girl with anorexia nervosa. Coronal contrast-enhanced CT image shows a trichobezoar *(asterisk)* of multiple densities forming a cast within the gastric lumen. An additional trichobezoar in the mid jejunum *(arrow)* is causing proximal small bowel obstruction.

rare outside of the esophagus and rectosigmoid; likewise, the malignant leiomyosarcoma is very rare in the stomach.[62]

Gastric teratomas make up less than 1% of teratomas in pediatric patients, and occur much more frequently in the sacrococcygeal region, the mediastinum, and gonads.[63] Gastric teratomas show a striking male predominance and present early in life in neonates and infants.[64,65]

Inflammatory pseudotumor, also known as plasma cell granuloma and inflammatory myofibroblastic tumor, is composed histologically of lymphocytes, plasma cells, myofibroblastic spindle cells, and collagen.[66] It is most common in the lung but can rarely occur in the stomach and is associated with microcytic anemia, hypergammaglobulinema, and elevated sedimentation rate.[67]

***Clinical Presentation.*** With the exception of gastric polyps, which may be discovered incidentally, the clinical presentation of all gastric tumors is similar and may include GI bleeding, anemia, abdominal pain, palpable mass, and, less frequently, gastric outlet obstruction. In cases of lymphoma, constitutional symptoms can be present.

***Imaging.*** Polyps can be seen on UGI series as pedunculated or sessile smooth mucosal lesions arising from the gastric wall. Adenomatous polyps are usually antral and multiple. The appearance is similar on CT, requiring appropriate gastric distension to secure the diagnosis. Oral positive or negative contrast material is usually helpful (e-Fig. 101.11).

In the rare primary and the more common secondary gastric lymphoma, CT reveals focal or diffuse mural masses that can protrude into the gastric lumen (Fig. 101.12) or cause mass effects upon adjacent structures. Multifocal intestinal involvement can be present, as well as hepatosplenomegaly, and regional or distant adenopathy. On UGI series, mucosal nodularity, rugal thickening, and masses with or without associated ulceration can be seen.[58] PET/CT is used in staging of lymphoma in children to assess disease activity and involvement of distant sites, particularly in lymph nodes that do not meet size criteria for pathologic involvement.[68,69]

Other mass lesions, such as GIST, are similarly seen on CT as masses with extension into the gastric lumen (Fig. 101.13) or mass effect upon adjacent structures. Inflammatory myofibroblastic tumor in the stomach tends to present as an infiltrative lesion which may demonstrate low attenuation areas as well as calcifications (Fig. 101.14).[70,71] Extension beyond the stomach is best appreciated on cross-sectional imaging, such as CT or MRI. PET/CT is useful in the assessment of distant metastases.[60]

***Treatment and Follow-up.*** Mass lesions identified on imaging studies require endoscopic evaluation for confirmation and biopsy. Treatment varies depending on the tumor histology.

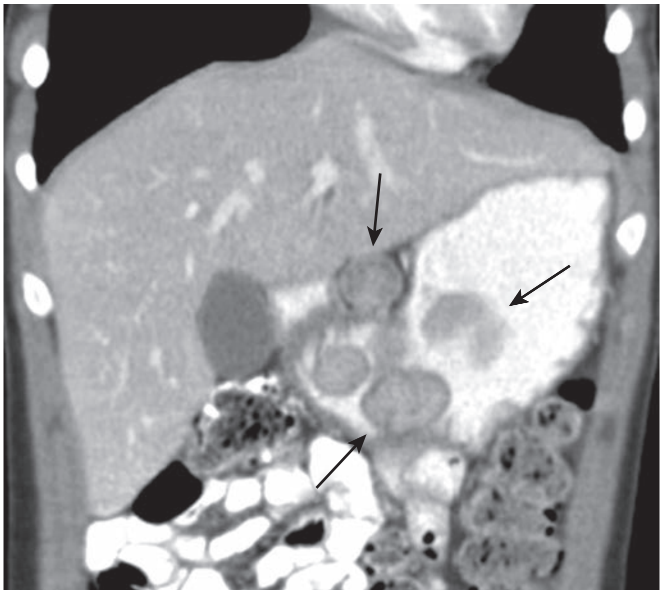

**Figure 101.13. Multifocal gastrointestinal stromal tumor in an adolescent girl presenting with chronic abdominal pain and anemia.** Coronal contrast-enhanced CT image shows multiple masses *(arrows)* arising from the wall of the gastric antrum.

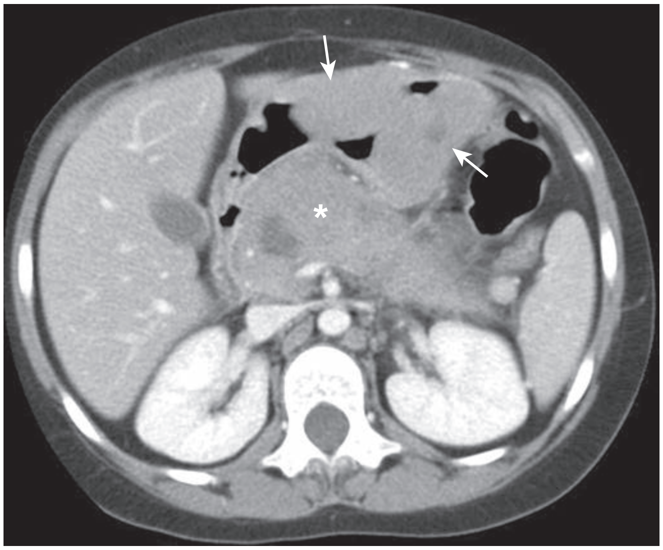

**Figure 101.12. Burkitt lymphoma in a 14-year-old African American girl presenting with vomiting and fever.** Axial contrast-enhanced CT image shows two large smooth and homogeneous masses *(arrows)* arising from the gastric wall protruding into the gastric lumen *(arrows)*. There is also a large more heterogeneous mass involving the pancreas *(asterisk)*.

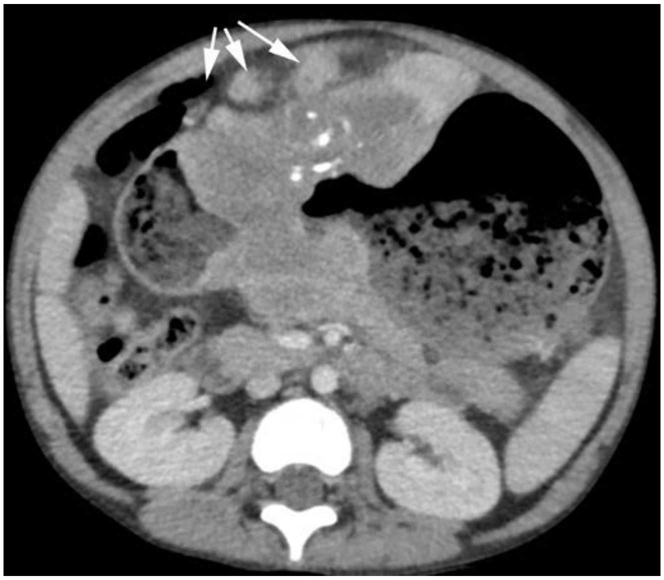

**Figure 101.14. Inflammatory myofibroblastic tumor of the stomach.** Axial contrast-enhanced CT image of 4-year-old girl presenting with abdominal pain demonstrates an infiltrative solid tumor with calcification. Two omental implants *(arrows)* are also visible. *(Courtesy Marta Hernanz-Schulman MD, Nashville, TN.)*

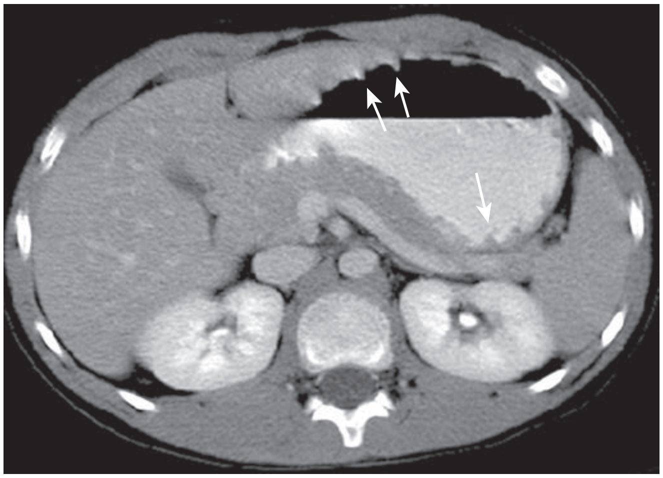

**e-Figure 101.11. Multiple gastric polyps in a patient with Gardner syndrome.** The patient is status post total colectomy. Axial contrast-enhanced CT image shows multiple tiny polyps arising diffusely from the gastric wall protruding into the lumen *(arrows)*, confirmed at endoscopy.

## KEY POINTS

- There are two types of gastric volvulus with different presentations. The organoaxial type usually presents with chronic abdominal pain, vomiting, and gastric distension. The mesenteroaxial type typically has a sudden presentation, with vomiting and acute abdominal pain.
- Ingested magnets and batteries, particularly lithium batteries, pose risk of esophageal or intestinal injury.
- Predisposing factors for bezoars are psychiatric problems, previous gastric surgery, gastroparesis, cystic fibrosis, and renal failure, among others.
- Gastric wall thickening in children can be due to several conditions. When it involves the antrum, eosinophilic gastritis and CGD are considerations. When it involves the fundus and body, Menetrier disease can be considered.

# 102 Duodenum and Small Bowel: Congenital and Neonatal Abnormalities

*Marta Hernanz-Schulman*

## PART I: DUODENUM

Congenital anomalies of the duodenum often present with obstructive symptoms and consist of intrinsic obstructing lesions, such as duodenal atresia and stenosis, or extrinsic lesions that affect the duodenum, such as midgut volvulus or Ladd bands, annular pancreas, preduodenal portal vein, and duplications cysts; intrinsic and extrinsic lesions may coexist in the same patient.

### Intrinsic Lesions: Duodenal Atresia and Stenosis

***Overview.*** Duodenal atresia and stenosis represent a spectrum ranging from complete to partial obstruction, and corresponding presentation that ranges from prenatal life to late childhood or even adulthood. Duodenal atresia represents approximately one-half of all intestinal atresias, with a reported incidence of approximately 1 : 7,000 live births.[1,2] The classification of duodenal atresia by Gray and Skandalakis is most often cited[3,4] and is similar to that of more distal atresias: type I atresia (approximately 90% of cases) consists of a membrane that may obstruct completely or partially; in type II atresia, the segments are connected by a fibrous cord; in type III atresia, there is a gap separation with a mesenteric defect.

***Etiology.*** The lumen of the duodenum is obliterated during the 4th to 6th weeks of gestation due to rapid cell division, and it normally recanalizes by the 12th week; duodenal atresia is believed to result from failure of this recanalization process. This differs from atresia of the small and large bowel, which is believed to result from a vascular accident later in gestation.[5,6] The recanalization error theory was first suggested in 1900 but is very difficult to confirm.[7] Recent studies suggest that disruptions in fibroblast growth factor receptor 2 (FGFR2) function and retinoic acid signaling pathways may play a role in the development of duodenal and possibly other intestinal atresias.[7–10]

***Clinical Presentation.*** In approximately half of patients, duodenal atresia does not occur in isolation but rather as part of a syndrome or association, such as Down or esophageal atresia. Polyhydramnios, resulting from the proximal bowel obstruction, is seen in 30% to 50% of patients and leads to premature birth in half.[3,6,8] Thus the clinical presentation is often modified by associated anomalies and by prematurity.

Postnatally, infants with atresia typically present with vomiting within the first 24 hours of life; however, one-third of infants presenting in the neonatal period will have severe stenosis.[6] The infants who have not been diagnosed prenatally will present with bilious vomiting in greater than two-thirds of the cases, in which the obstruction is sited distal to the ampulla of Vater.[11] However, the obstruction occurs proximal to the ampulla of Vater in as many as 23% of patients,[12] and these will present with nonbilious vomiting. Thus the presentation of infants with duodenal stenosis can overlap that of infants with the much more common diagnosis of pyloric stenosis and may be initially encountered at ultrasound (Fig. 102.1). Because the duodenal obstruction is proximal, abdominal distension is not a typical finding, although epigastric fullness may be present secondary to the dilated stomach and duodenum.

Patients with less severe forms of duodenal stenosis may not come to medical attention until later in life, depending on the degree of obstruction. In such patients, presentation may be relatively nonspecific, such as failure to thrive, or rarely pancreatitis, secondary to reflux into the pancreatic duct, proximal to the site of obstruction.[13,14] Late presentation secondary to obstruction may be precipitated by ingestion of a foreign body that fails to pass and may exacerbate the degree of obstruction, leading to abdominal pain and/or vomiting (e-Fig. 102.2).[15,16] Annular pancreas and malrotation are seen in approximately one-third of cases.[6]

Associated anomalies are common in patients with duodenal atresia/stenosis. Approximately 25% to 40% of infants with duodenal atresia/stenosis have Down syndrome; conversely, approximately 4% of infants with Down syndrome have duodenal obstruction.[6,17] Hirschsprung disease has been reported in approximately 1% to 3% of patients with duodenal atresia and Down syndrome.[18,19] Approximately 5% of infants with esophageal atresia, with or without fistula, will also have duodenal atresia.[20] Heterotaxy with left isomerism/polysplenia has been reported in patients with duodenal diaphragm/intraluminal diverticulum.[13,21,22] Duodenal atresia can also be part of several familial syndromes with autosomal inheritance, such as Feingold syndrome (autosomal dominant) and Fryns syndrome (autosomal recessive).[23]

***Imaging.*** Abdominal radiographs are the starting point in the evaluation of a child with suspected gastrointestinal (GI) obstruction. In the neonate with duodenal atresia, the abdominal radiograph demonstrates the classic “double bubble” representing the dilated stomach and duodenum.[24,25] Because obstruction has been present in utero, the obstructed proximal duodenum is typically large, approximately one-half to one-third the size of the stomach (Fig. 102.3A); at times the pylorus is wide open, and the two bubbles are not distinctly separated (Fig. 102.3B) but should still be recognized. This appearance on the abdominal radiograph is diagnostic, and confirmatory contrast examinations are unnecessary. Rarely, air can be seen distally in a patient with complete atresia; this occurs when the atresia is flanked by the branches of an anomalous bifid common bile duct, with separate insertions into the duodenum above and below the point of atresia. Air or contrast may be seen refluxing into the anomalous ducts, which allow the contents of the obstructed proximal duodenum to course into the distal duodenum, bypassing the point of obstruction (Fig. 102.4).[12,26,27] In patients with duodenal atresia associated with esophageal atresia with a distal fistula, plain films will demonstrate the double bubble and are diagnostic (e-Fig. 102.5); perforation may occur if these infants need to be mechanically ventilated.

In patients with duodenal stenosis, distension of the stomach and proximal duodenum and decrease in distal gas is commensurate with the degree of obstruction present. However, if the stenosis is mild or the stomach is decompressed via enteric tube, the plain

## Abstract:

This chapter describes congenital anomalies of the duodenum and of the small bowel. Duodenal lesions described include intrinsic lesions, such as duodenal atresia and stenosis, extrinsic lesions including annual pancreas, preduodenal portal vein and duplications cysts, and malrotation and its complications, particularly midgut volvulus.

Small bowel lesions include small bowel atresias and stenoses, apple peel mesentery and other causes of obstruction or atresia including meconium ileus, both simple and complicated. Meckel diverticulum and its complications, small bowel duplication cysts, and other abnormalities such as omental and mesenteric cysts are also discussed.

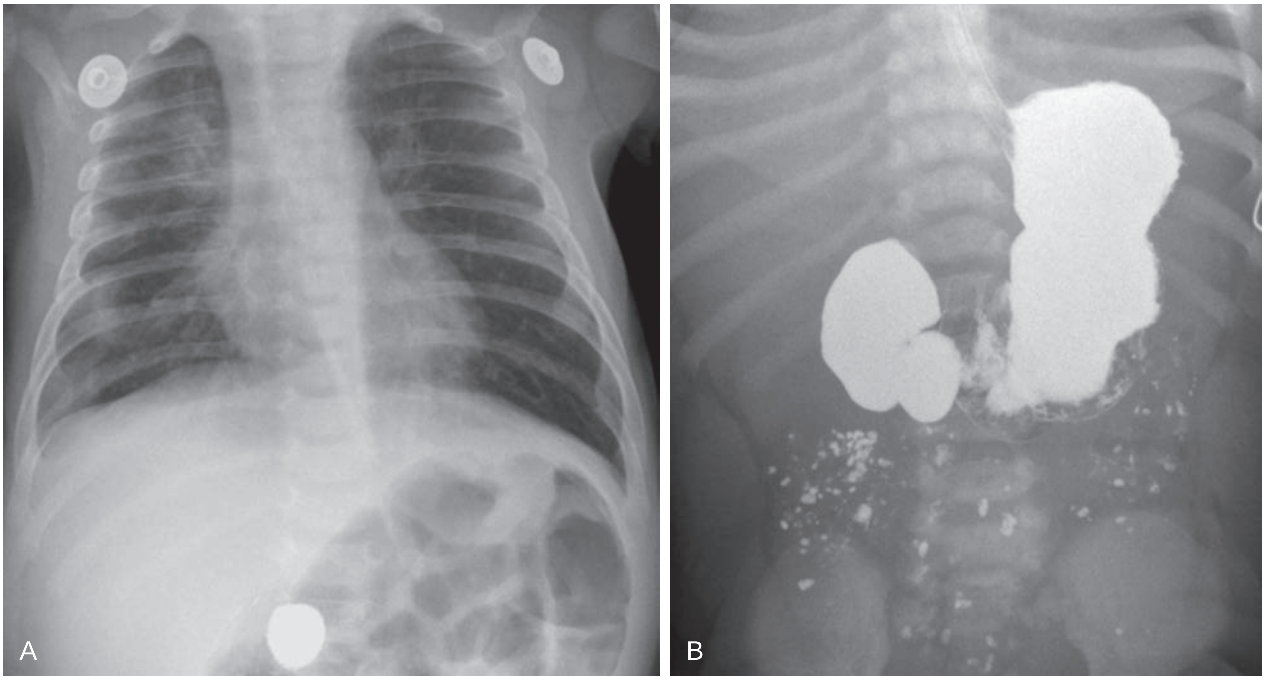
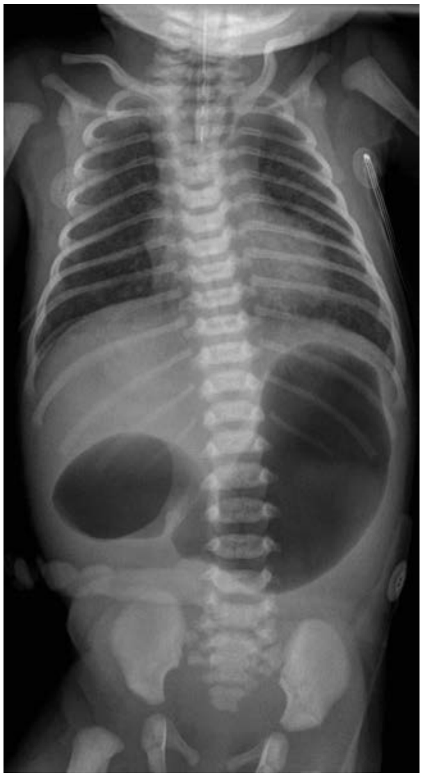
heterotopic gastric mucosa
mesenteric cysts
mesothelial cysts



**e-Figure 102.2. Duodenal stenosis with foreign body.** (A) Chest radiograph of a 6-month-old shows a rock that had been ingested several weeks previously. (B) Subsequent UGI demonstrates a dilated duodenum proximal to a web, which was confirmed at surgery. The rock is obscured by the barium.



**e-Figure 102.5. Duodenal and esophageal atresia.** Radiograph of a 1-day-old infant shows the orogastric tube in the proximal esophageal pouch; abdominal double bubble indicates a distal fistula and duodenal atresia. This patient is at risk for perforation if there is a need for positive pressure ventilation.

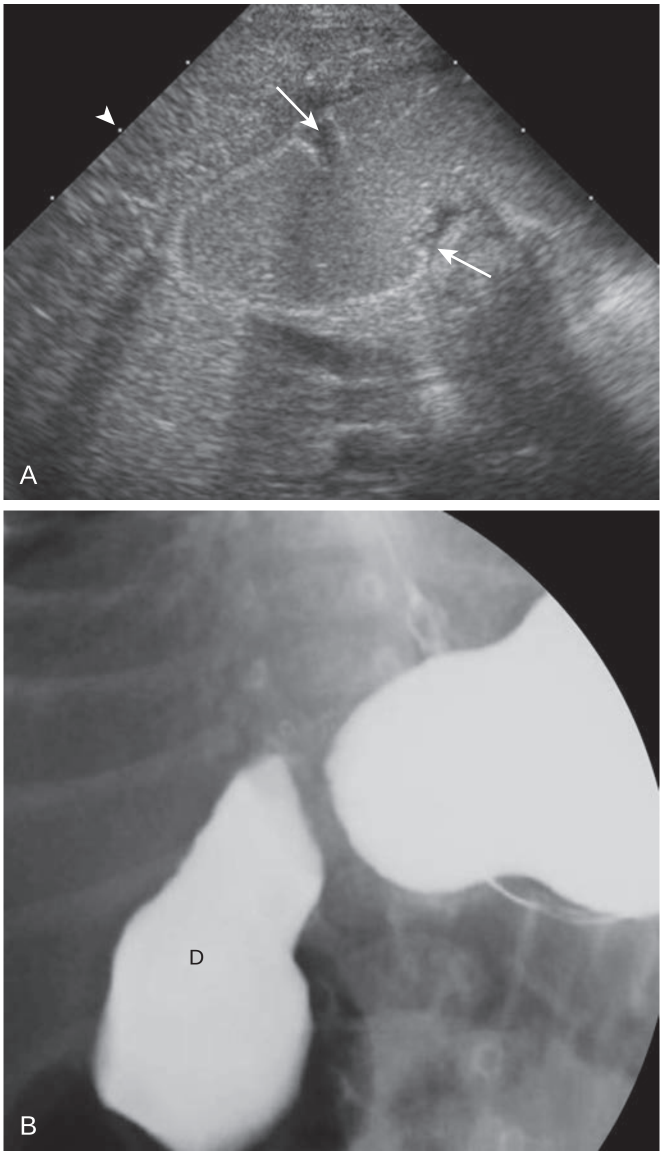


**Figure 102.1. Duodenal stenosis.** (A) Ultrasound image of 4-week-old girl with nonbilious vomiting and suspected pyloric stenosis shows a widely dilated pylorus *(arrows)* and duodenal bulb. The diagnosis of duodenal stenosis was confirmed at subsequent surgery. (B) Upper GI demonstrates a dilated duodenum *(D)*. Note that there is distal bowel gas.

abdominal radiographs may be nonrevealing or even misleading (e-Fig. 102.6).

An upper gastrointestinal (UGI) series may be needed to diagnose duodenal stenosis if potentially associated malrotation is a concern or if surgery is to be delayed (Fig. 102.7).[28] Contrast enema has been done in the past to assess the rotation of the bowel, but this examination is not helpful if it is normal or if the cecum is high-riding; cross-sectional imaging may be done in such cases for further evaluation,[29] discussed in greater detail later in this chapter.

On the UGI examination, patients with duodenal stenosis will demonstrate a partial obstruction (Fig. 102.8); when a web is present, the membrane may be seen as a thin linear filling defect (see Fig. 102.8B). In older patients, the elongated membrane may have the appearance of an intraluminal diverticulum or "windsock" (see Fig. 102.7). As noted earlier, some children with duodenal stenosis may present after ingestion of a foreign body too large to pass through the narrowed canal or orifice (see e-Fig. 102.2). In patients with duodenal atresia simulating duodenal stenosis secondary to bypass of the obstruction by anomalous ducts, contrast may be seen within the ducts, as discussed earlier (see Fig. 102.4B).

***Treatment.*** Treatment of duodenal atresia and stenosis is surgical. When Ladd described surgical correction of duodenal obstruction in 1932,[30] the reported mortality was approximately 40%. In 1990, Kimura et al. described the technique of diamond-shaped anastomosis, which has become standard procedure for open repair, with a mortality of 5% to 10% now largely due only to associated anomalies, particularly those involving cardiac lesions.[31,32] More recently, laparoscopic duodenoduodenostomy has been introduced, with increasingly good results, and reported improvement in return of bowel function, resulting in reduced length of hospital stay.[31,33–35]

## Extrinsic Lesions: Annular Pancreas, Malrotation, Preduodenal Portal Vein, and Duplication Cysts

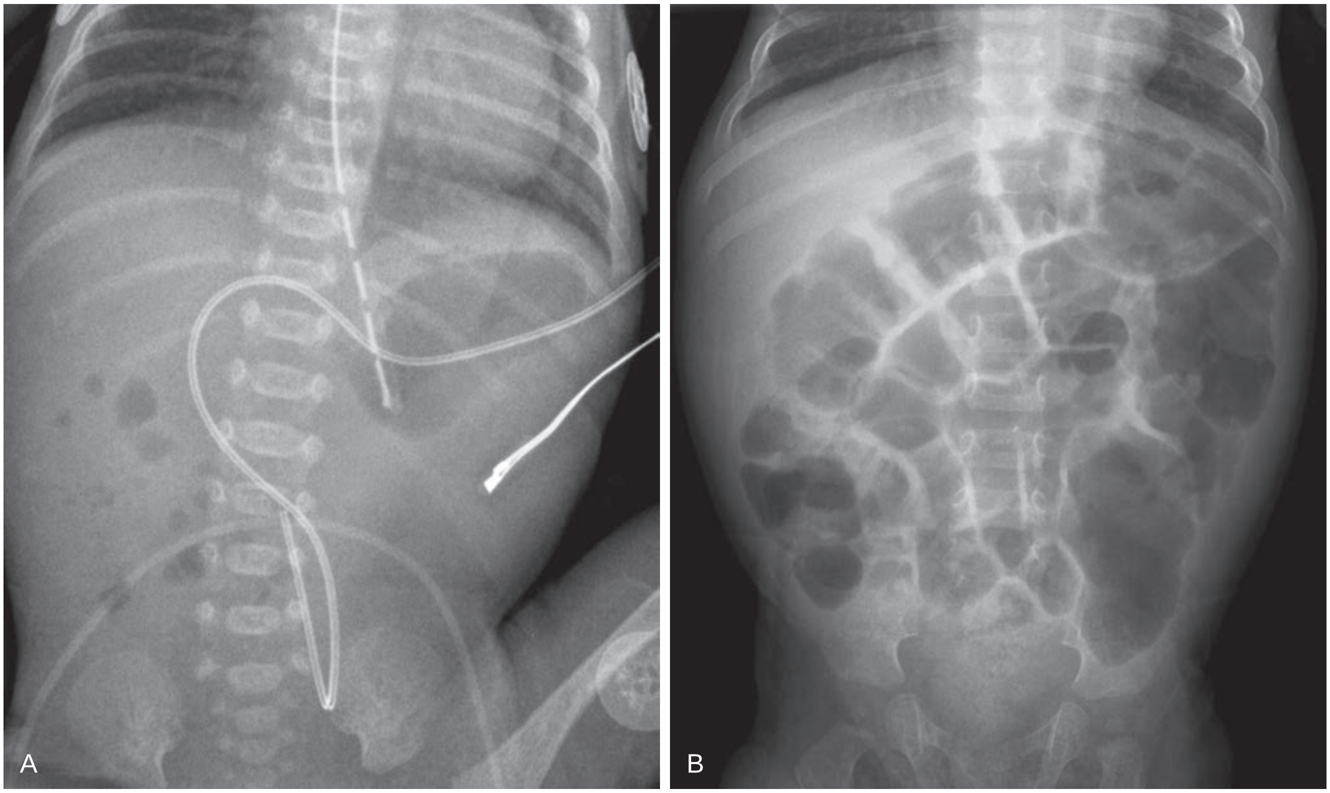
### Annular Pancreas

***Overview.*** Annular pancreas refers to encirclement of the descending portion of the duodenum by pancreatic tissue. The prevalence of annular pancreas is not known, as asymptomatic cases are not always identified; among adults, autopsy series prevalence varies between 1–15 : 100,000 adults, while endoscopic retrograde cholangiopancreatography (ERCP) studies in symptomatic patients indicates a prevalence of 1–4 : 1000.[36,37] In children, the incidence is estimated at approximately 1–12 : 15,000 births,[38] with a 2 : 1 male:female ratio.[39] Annular pancreas may result in extrinsic duodenal obstruction; however, most cases of duodenal obstruction with annular pancreas are most likely the result of an associated intrinsic duodenal abnormality.[3]

***Etiology.*** The pancreas arises as a ventral and larger dorsal bud from the duodenum. Normally the ventral bud rotates and fuses with the dorsal bud. When the ventral bud becomes tethered to the duodenum before the onset of the rotation, or if the ventral bud fails to rotate completely before fusion, the result is the annular pancreas.[3,37,40] The pancreatic annulus, the portion surrounding the duodenum, frequently has a separate duct entering the duodenum, opposite the ampulla of Vater. Duodenal contents may reflux through this duct into the annulus. Studies in transgenic mice have shown that the annular tissue is derived from the ventral bud; molecular studies have implicated the hedgehog signaling pathway and the transmembrane 4 superfamily 3 gene *(TM4SF3)*.[41]

***Clinical Presentation.*** Children present with vomiting or feeding intolerance, with a median age of 1 day at diagnosis.[37] Presentation in older children who do not have duodenal obstruction is similar to that in adults, with pancreatitis and jaundice.[37,39,42,43] Associated anomalies are common, and these include malrotation, esophageal atresia, anal atresia, and cardiac defects, particularly in patients with trisomy 21 and Cornelia de Lange syndrome[17,37]; annular pancreas has also been reported in patients with heterotaxy.[44]

***Imaging.*** Plain films will show duodenal dilatation in those patients in whom there is intrinsic and/or extrinsic obstruction. UGI will show narrowing of the descending portion of the duodenum (Fig. 102.9A). On ultrasonography, a ring of pancreatic tissue may be seen about the descending portion of the duodenum, although the duodenum might be difficult to follow, and the appearance may resemble a mass at the level of the head of the pancreas (Fig. 102.9B). Computed tomography (CT) likewise can show the pancreatic tissue surrounding the duodenum (Fig. 102.9C and D), probably more clearly if aided by positive luminal contrast in the duodenum. Magnetic resonance imaging (MRI) also may show the ring of pancreatic tissue (Fig. 102.9E), but magnetic resonance cholangiopancreatography (MRCP) will show more definitive findings outlining the annular course of the pancreatic



**e-Figure 102.6. Duodenal stenosis.** (A) Radiography of a 1-day-old premature twin infant with bilious aspirates shows minimal distal bowel gas. Duodenal stenosis was shown on subsequent UGI (see Fig. 102.8A) and confirmed at duodenoduodenostomy. (B) Radiograph of an 8-month-old with Down syndrome, admitted for investigation of failure to thrive. Despite the abundant distal bowel gas, duodenal stenosis with membrane was demonstrated on UGI (see Fig. 102.8B) and confirmed at subsequent surgery.

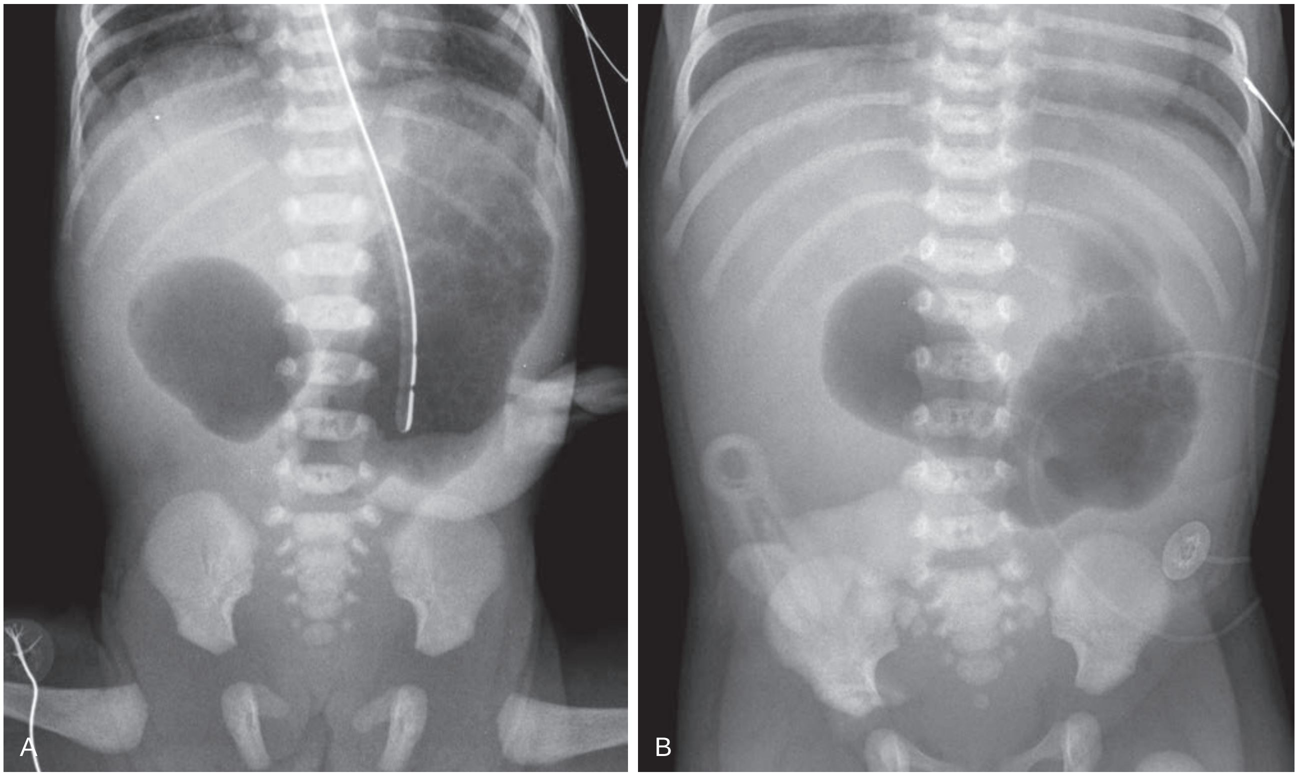


**Figure 102.3. Duodenal atresia.** (A) Radiograph of a 32-week gestation premature infant on day 1 of life, with prenatally diagnosed duodenal atresia shows the classic double bubble, with a distended stomach and duodenum, and no distal gas. (B) Full-term infant with prenatal diagnosis of duodenal atresia. The radiograph shows a gaping pylorus through which there is wide continuity between the dilated stomach and the dilated duodenum, with no distal gas.

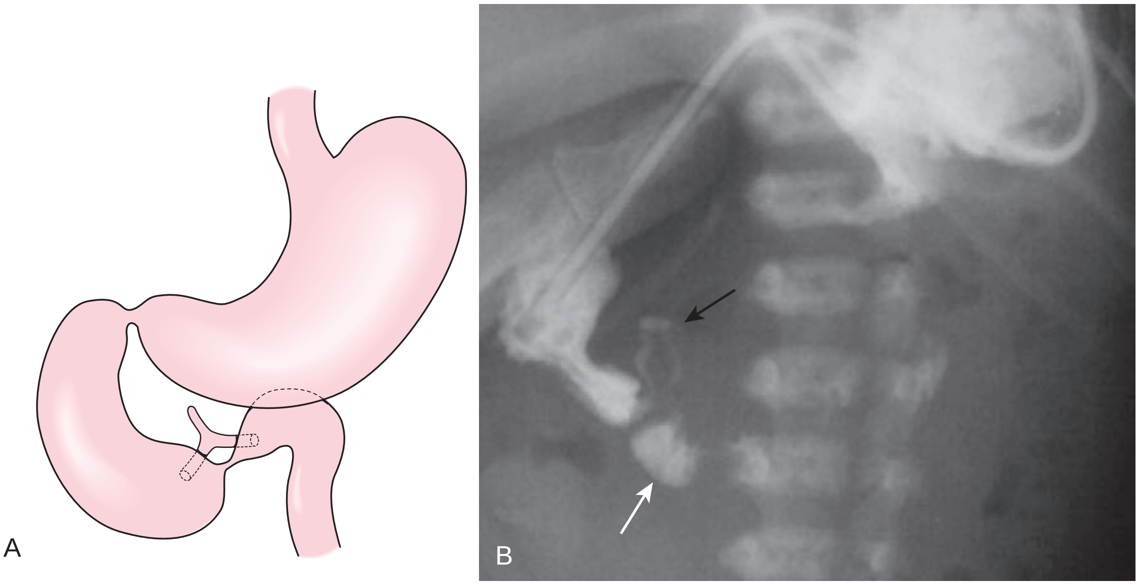

**Figure 102.4. Duodenal atresia with anomalous ducts.** (A) Schematic rendering of duodenal obstruction bypass by dual anomalous ducts. (B) UGI in a neonate with duodenal atresia, showing contrast in the ductal system *(black arrow)* bypassing the site of atresia into the distal segment *(white arrow)*. *(Reproduced with permission from Komuro H, et al. Bile duct duplication as a cause of distal bowel gas in neonatal duodenal obstruction.* J Pediatr Surg. *2011;46[12]:2301–2304.)*

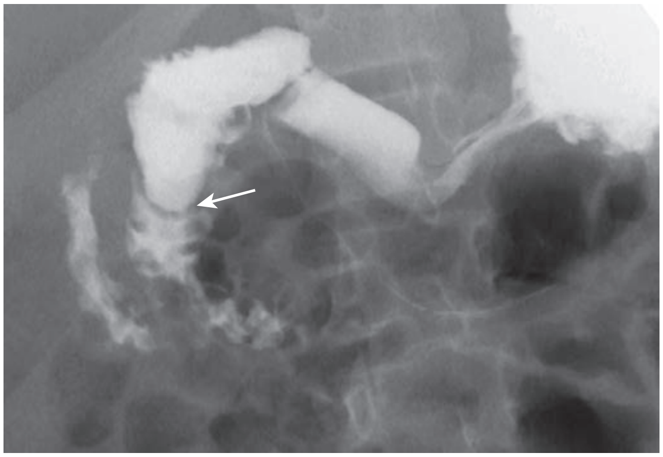

**Figure 102.7.** Duodenal web and malrotation UGI in adolescent with history of intermittent abdominal pain shows a duodenal web *(arrow)*. Note that duodenal contrast does not cross to the left of midline, indicating malrotation.

ducts (Fig. 102.9F), analogous to the findings seen at ERCP (e-Fig. 102.10).

***Treatment.*** As in the case of intrinsic duodenal obstruction, treatment is surgical bypass; interruption or division of the pancreatic tissue around the duodenum is not indicated, due to the likelihood of postoperative leakage or pancreatitis.[3] More recently, laparoscopic surgery has also been undertaken with good results in experienced hands.[33,45]

## Malrotation

**Overview.** The embryonic midgut, which is supplied by the superior mesenteric artery and extends from the distal descending duodenum to the distal transverse colon, undergoes 270 degrees of counterclockwise rotation (as viewed from the front) through a complex series of steps to achieve its final position, with the duodenojejunal junction in the left upper quadrant and the cecum in the right lower quadrant.

The term malrotation indicates that the normal rotation of the midgut was not completed, and therefore represents a misnomer, as the term "incomplete rotation" would more accurately characterize the resulting spectrum of abnormalities, which affect both the duodenojejunal and the cecal poles of the midgut, singly or in unison. The prevalence of malrotation is difficult to determine, inasmuch as asymptomatic cases may not be recognized; it has been most often quoted as 1 : 500 live births,[46–50] which seems excessive as that is similar to the incidence of pyloric stenosis (2–5 : 1000). More recent information suggests that malrotation is far less common, approximately 3.9 per 10,000.[51]

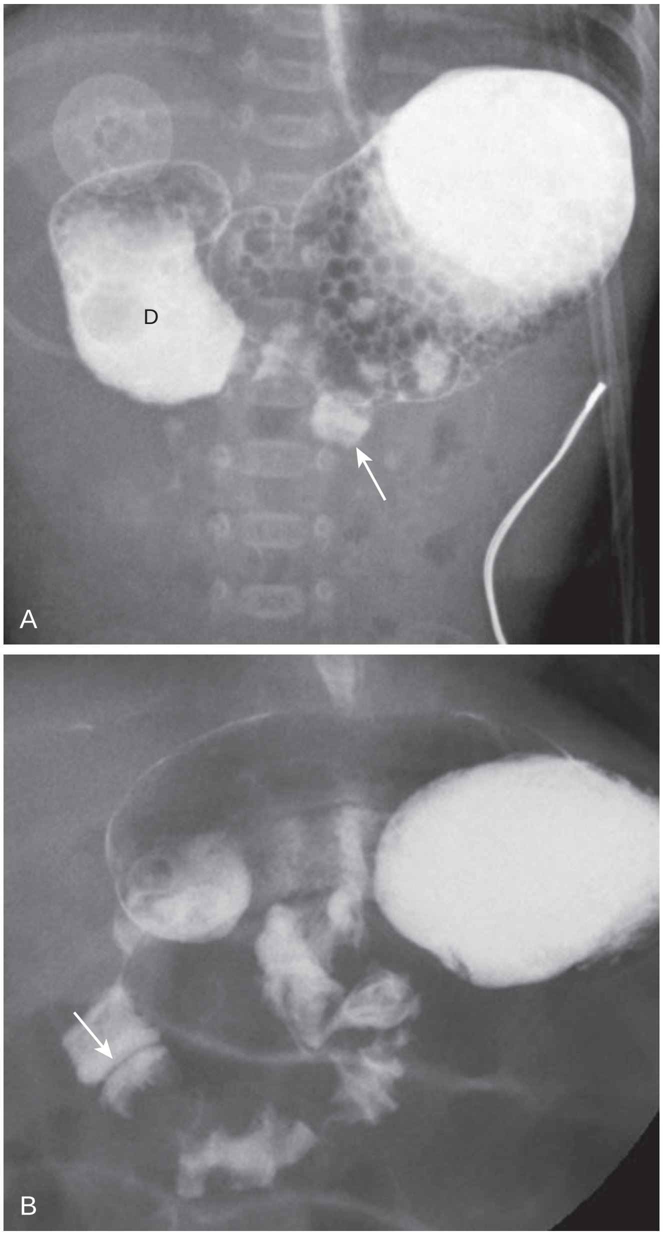

**Figure 102.8. Duodenal stenosis.** (A) UGI from same infant as shown in e-Fig. 102.6A shows the duodenal obstruction, with dilatation of the duodenum *(D)* and decreased duodenal caliber distally *(arrow)*. (B) UGI from same infant as shown in e-Fig. 102.6B shows a duodenal web *(arrow)*.

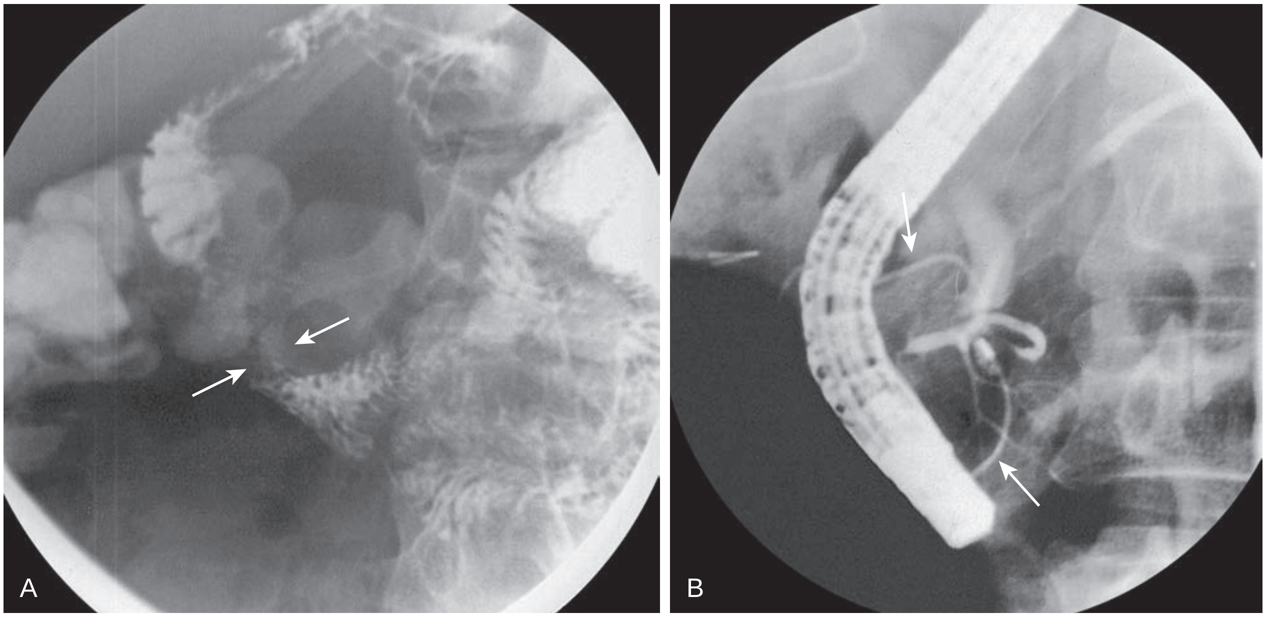
**Etiology.** To understand the etiology of malrotation, or incomplete rotation, the normal process of rotation must be understood. The gut begins as a straight tube, with the duodenojejunal junction and the cecum along a straight line. As the gut begins to grow, it forms a primary loop about the axis of the superior mesenteric artery, with the apex at the omphalomesenteric duct: the proximal portion is the prearterial (duodenojejunal) limb, and the distal portion is the postarterial (ileocecal or cecocolic) limb. Postnatally, the site of the Meckel diverticulum marks the junction of the pre- and postarterial limbs. Initially, the duodenum and cecum rotate 90 degrees counterclockwise, such that the duodenojejunal junction comes to lie in the right upper quadrant, and the cecum comes to lie in the left lower quadrant. At approximately 6 weeks of gestation, continued growth of the intestinal tube results in herniation of the bowel into the umbilical cord and a second counterclockwise turn of 90 degrees at the duodenojejunal junction. By the 10th week of gestation, the bowel begins its return into the abdominal cavity, beginning with the prearterial segment, and the duodenum undergoes its final 90 degrees of rotation and fixation at the ligament of Treitz in the left upper quadrant; the cecum similarly undergoes its final 180 degrees of rotation, to terminate in the right lower quadrant, and undergo fixation to the posterior peritoneum through shortening and resorption of its dorsal mesentery. The bowel is thus suspended from a mesentery, which is attached to the posterior abdominal wall, and which extends from the left upper to the right lower quadrants (Fig. 102.11). The configuration of the duodenal C-loop mirrors the 270 degrees of rotation that it has undergone.[46,48,52–54] The final steps in bowel



**e-Figure 102.10. Annular pancreas.** (A) Oblique view of the duodenal C-loop during an upper gastrointestinal series shows extrinsic narrowing *(arrows)*. (B) Image from subsequent ERCP confirms circumferential pancreatic ducts *(arrows)* and annular pancreas. *(Courtesy of Dr. George Taylor, Boston, MA.)*

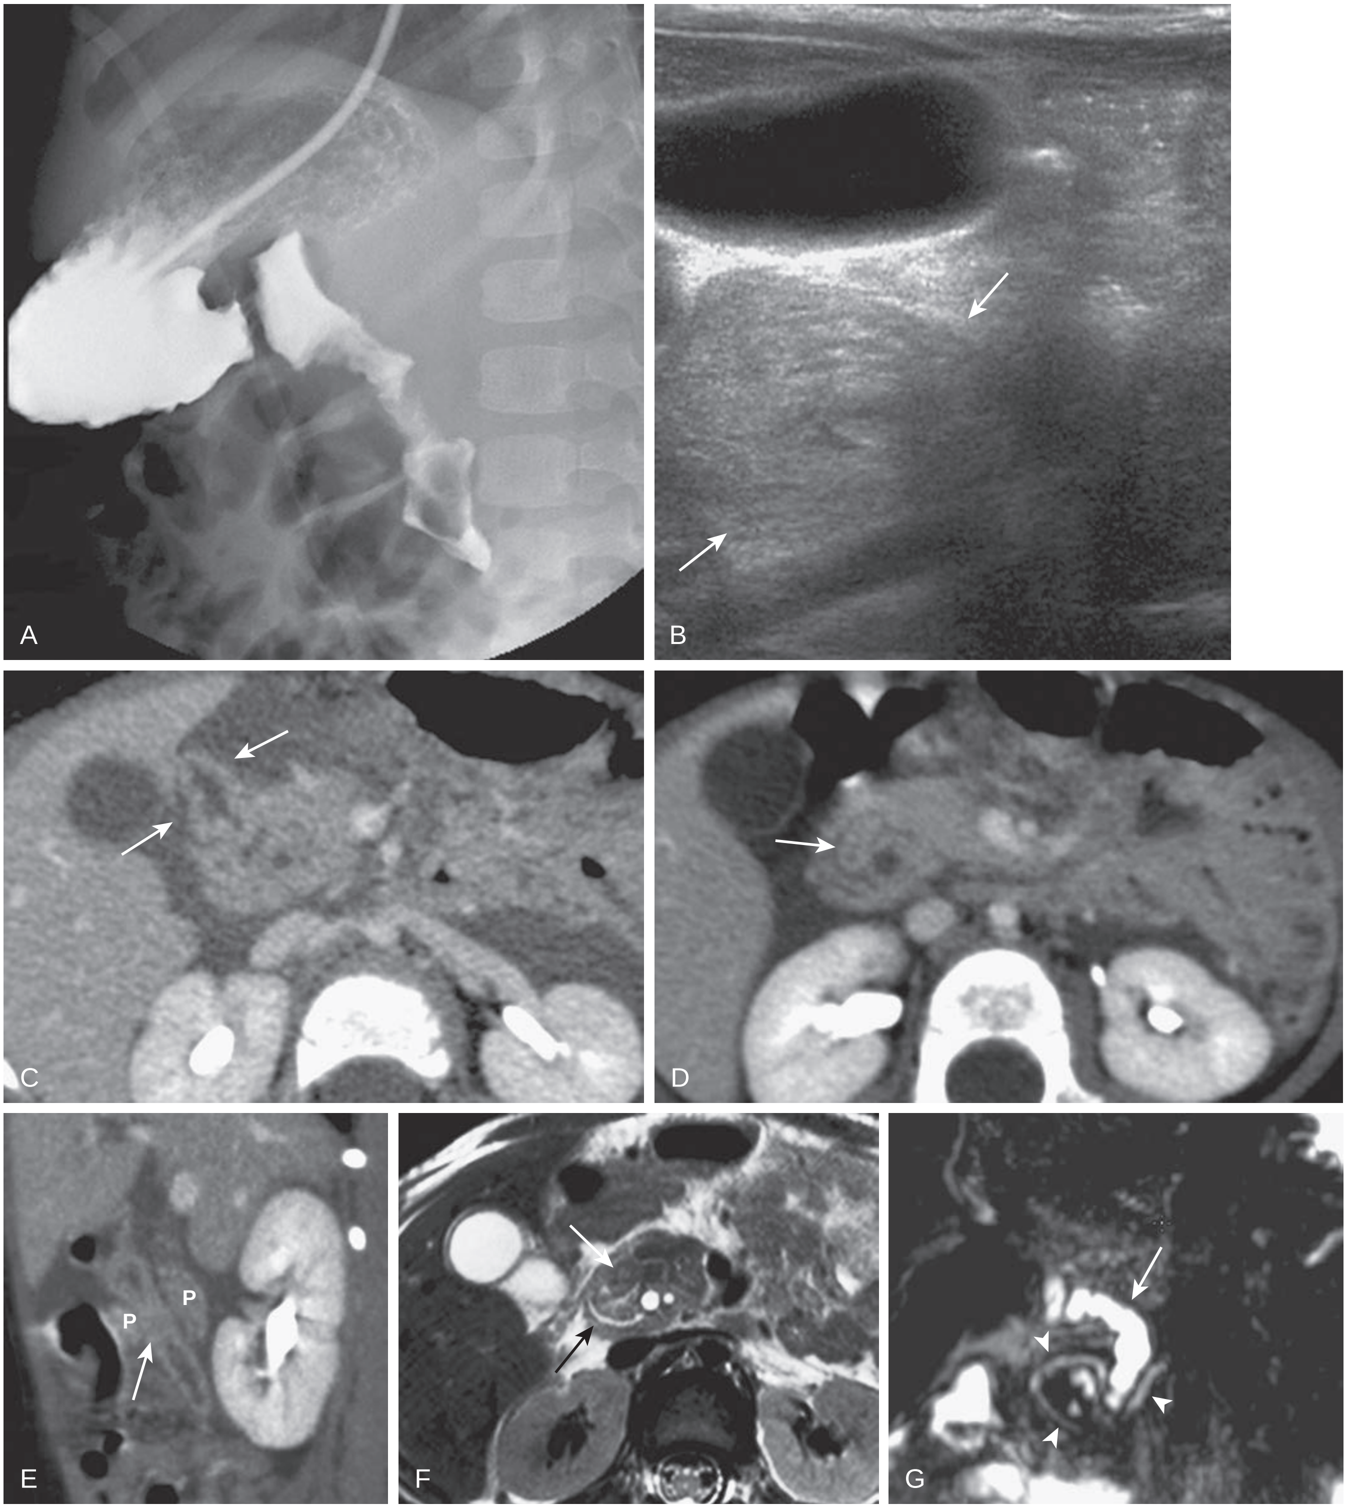


**Figure 102.9. Annular pancreas.** (A) UGI in 2-year-old girl with annular pancreas demonstrates a circumferential impression upon the descending duodenum. The patient had presented with pancreatitis; UGI was done after her symptoms had subsided to assess for an underlying element of duodenal obstruction. (B) Ultrasound at initial presentation shows a thickened head of the pancreas *(arrows)*. (C–E) Contrast-enhanced CT at initial presentation shows the duodenum *(arrows)* entering the head of the pancreas (C), within the head of the pancreas *(arrow)* (D), just lateral to the dilated common bile duct. Sagittal reformat (E) shows the duodenum *(arrow)* with pancreatic tissue *(P)* anterior and posterior to its descending portion. Free fluid is secondary to pancreatitis. (F) Axial T2-weighted magnetic resonance (MR) image shows the duodenum *(white arrow)* within the head of the pancreas, with circumferential pancreatic tissue, outlined by a portion of the encircling pancreatic duct *(black arrow)*. (G) MRCP delineates the pancreatic duct *(arrowheads)* and its circumferential course at the head of the pancreas. *Arrow* points to the dilated common bile duct. *(Courtesy of Melissa A. Hilmes, Nashville, TN.)*

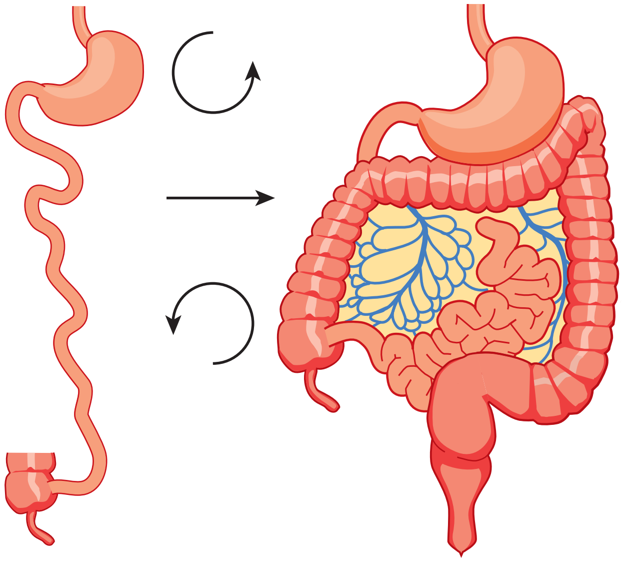

**Figure 102.11. Normal rotation of midgut.** The midgut starts as a straight tube; 270 degrees of counterclockwise rotation of the duodenojejunal junction places it in the left upper quadrant, while 270 degrees of counterclockwise rotation of the cecum places it in the right lower quadrant. After rotation is completed, normal fixation of the bowel results in the midgut being suspended from a broad-based mesentery, with retroperitoneal attachment at both ends.

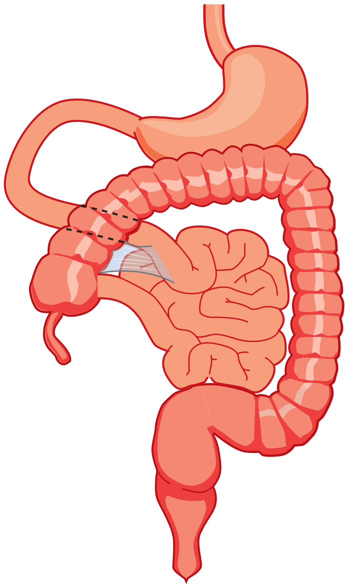

**Figure 102.12. Malrotation.** As the gut rotation proceeds beyond the initial 90 degrees ("nonrotation") and is arrested before the normal 270 degrees, the duodenojejunal junction and the cecum approximate, resulting in suspension of the midgut from a narrow mesenteric pedicle without normal attachments. This arrangement is at high risk for midgut volvulus.

rotation and fixation involve resorption of the dorsal mesenteries of the ascending and descending colon and elongation of the ascending colon with descent of the cecum, processes that are ongoing until several months of postnatal life.[49]

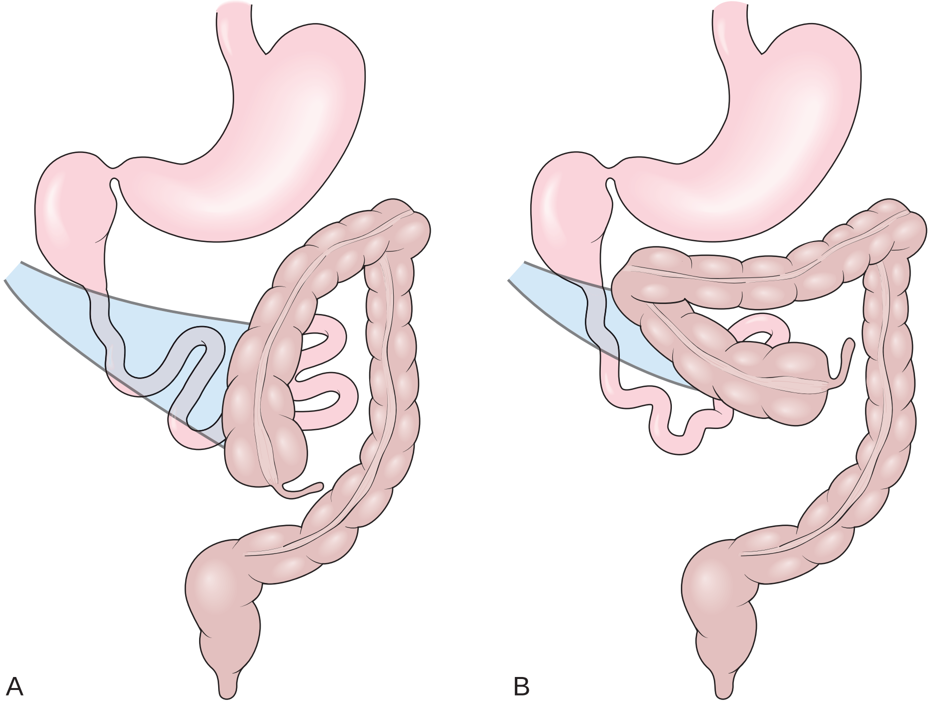
Malrotation arises when the process of normal rotation is arrested, and this can occur at any point along the 270-degree arc of rotation of the duodenojejunal or cecal segments. If it is arrested after the initial 90 degrees of counterclockwise rotation, the duodenojejunal junction and the small bowel will be located on the right side of the abdomen, and the cecum and the rest of the colon will be located in the left side of the abdomen, with the terminal ileum entering the cecum from right to left. Despite the fact that the initial 90 degrees of counterclockwise rotation have occurred in both the duodenojejunal junction and the cecum, this arrangement is nevertheless known as *nonrotation*, because of the parallel appearance of the small and large bowel and the absence of the duodenal C-loop; this type of malrotation is characterized by a relatively long mesenteric pedicle. Progression of the rotation process beyond the nonrotation stage brings the duodenojejunal junction and the cecum into closer proximity, and arrest along this spectrum typically results in a shorter mesenteric pedicle from which the bowel is suspended (Fig. 102.12), which increases the risk for midgut volvulus. Reversed rotation is a rare form of malrotation, in which the gut undergoes 90 degrees of clockwise rotation, instead of the normal 270 degrees of counterclockwise rotation. Starting from the initial straight tube, this rotation results in the location of the duodenojejunal junction in the left upper quadrant and of the cecum in the right lower quadrant. However, in these cases, the ceco-colic loop returns into the abdomen first, and this results in location of the transverse colon, not the duodenum, between the aorta and the superior mesenteric artery.[55,56]

There are also several disorders of fixation that commonly occur in patients with malrotation. Ladd bands are the result of abnormal mesenteric attachments that are formed in patients in whom the rotational process is incomplete. These bands, named after Dr. William E. Ladd, typically extend from the liver edge to the malrotated cecum, crossing over and causing obstruction and kinking of the duodenum (e-Fig. 102.13); however, they can rarely occur more distally, crossing over the jejunum, ileum, or colon.[52,57]

Internal hernias are the result of abnormal or incomplete fixation of the ascending or descending portions of the colon, resulting in a defect through which the bowel can herniate. Herniation into a defect in the ascending colon results in a right paraduodenal or mesocolic hernia, whereas herniation into a descending colonic defect results in a left paraduodenal or mesocolic hernia.[48,52] In persons with normal bowel rotation, failure of complete fixation of the ascending colon, cecum, or sigmoid colon can result in volvulus of these structures, typically not occurring until late adult life.

**Clinical Presentation.** The presentation of patients with malrotation depends on whether there is obstruction, whether the obstruction is acute or chronic, and on associated malformations. Presentation may occur in utero, and the neonate may demonstrate short bowel secondary to in utero bowel necrosis and resorption, or with apple-peel type of atresia.[58,59] In asymptomatic patients, malrotation may be discovered in the course of evaluation for other clinical concerns.

***Acute Midgut Volvulus.*** It is important to differentiate the midgut volvulus that occurs in patients with malrotation from the segmental volvulus that can occur in multiple other conditions, which involves only a small segment of small or large bowel, many of which will be discussed later. In midgut volvulus, the duodenum rotates clockwise about the axis of the superior mesenteric artery (Fig. 102.14) and is obstructed at its third portion, distal to the ampulla of Vater. Because approximately 60% to 80% of patients with midgut volvulus present in the first month of life,[47,49,52,60,61] the typical presentation is that of a previously well neonate who experiences the acute onset of bilious vomiting. The infant may experience crampy abdominal pain, which could be confused with colic. If the obstruction is significant, the abdomen may become initially scaphoid after distal intestinal contents are evacuated; this lack of distension, together with lack of abdominal tenderness during this early stage, may lead to underappreciation of the urgency



**e-Figure 102.13. Ladd bands.** Illustration of two instances (A and B) in the spectrum of malrotation, demonstrating dense peritoneal bands (Ladd bands) extending from the cecum to the right upper quadrant, crossing over and obstructing the duodenum. These bands can cause obstruction without volvulus, but if there is a volvulus, the bands must be divided after reduction of the volvulus to relieve the obstruction.

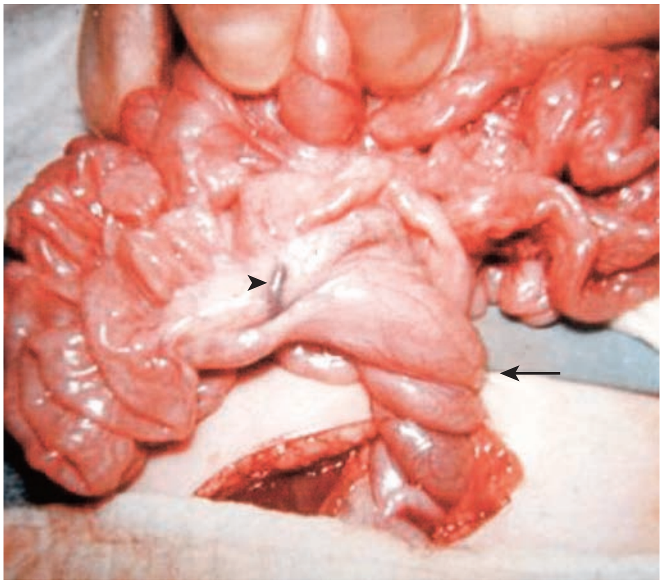


**Figure 102.14.** Acute midgut volvulus. At surgery, the duodenum is twisted clockwise *(arrow)* about the axis of the superior mesenteric artery *(arrowhead)*.

of the condition. Vascular compromise may lead to intraluminal bleeding and hematochezia, seen in 10% to 15% of patients with volvulus.[48] As ischemia of the midgut continues, the abdomen becomes distended and firm, with physical signs of peritonitis, and the patient will present in shock with cardiovascular collapse.[52]

Diagnosis of malrotation and midgut volvulus is even more challenging in premature infants. Preterm infants are less likely to present with bilious vomiting and instead display nonspecific signs and symptoms, including apnea and gastric retention, culminating in abdominal distension and shock with necrotic bowel at operation.[62,63]

***Chronic Midgut Volvulus.*** Partial or intermittent midgut volvulus tends to present more insidiously, with an average duration of symptoms of 28 months or more before the diagnosis.[52] There is usually a history of abdominal pain, which is often vague and intermittent but could be severe, often associated with intermittent vomiting and/or failure to thrive. Impairment of venous and lymphatic flow leads to signs and symptoms of malabsorption.[64,65] The correct diagnosis is frequently delayed, with interim diagnoses including central or psychogenic vomiting, milk or other food allergies, and various malabsorption syndromes, such as celiac disease.[28,52,66,67]

### Other Presentations

***Ladd Bands.*** Patients with duodenal obstruction secondary to Ladd bands may present acutely, with sudden onset of bilious vomiting, or may present with more chronic symptoms such as failure to thrive and intermittent abdominal pain.[52] Patients may also present with more distal obstruction.[57]

***Internal Hernias.*** Either right or left paraduodenal or mesocolic hernias produce symptoms by entrapment of bowel. Left hernias are more common and herniate through the fossa of Landzert; right hernias extend through the fossa of Waldeyer. These present with abdominal pain and vomiting secondary to obstruction, which can progress from partial to complete obstruction, and to ischemia and bowel necrosis.[68,69]

**Associated Conditions.** Malrotation occurs as part of a constellation of anomalies in as many as 30% to 60% of patients, depending on the reporting series.[52,60] Malrotation can occur in patients with duodenal stenosis and annular pancreas, which have been previously discussed but can also be found in patients with other intestinal atresias.[6,60] Malrotation can also be found as part of the spectrum of findings in patients with Hirschsprung disease and anorectal malformations, cloacal exstrophy, Eagle-Barrett (prune belly) syndrome, megacystis-microcolon-intestinal hypoperistalsis (Berdon syndrome), Cornelia de Lange, Marfan, and Meckel syndrome.[46,48,60,70] Malrotation is reported to be 25 times more common than in the general population in patients with trisomy 13, 18, and 21.[46,71] Malrotation is an intrinsic component of entities in which gut rotation cannot occur, such as gastroschisis, omphalocele, and Bochdalek diaphragmatic hernia; it is also extremely common if not invariable in patients with heterotaxy.[72–75]

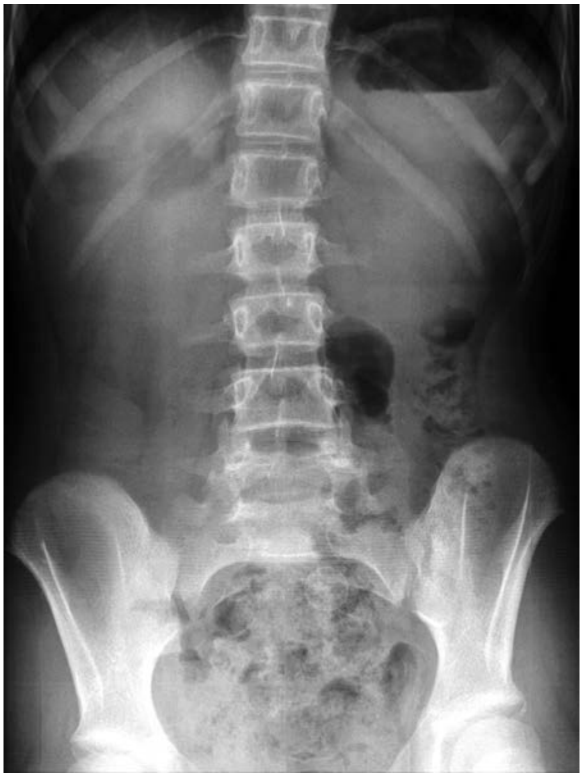

**Figure 102.15.** Nonrotation. Abdominal radiograph in an adolescent with nonrotation. Note that there is no evidence of colon in the right abdomen. The stool-filled colon is confined to the left side of the abdomen.

**Imaging.** Plain abdominal radiographic findings in patients with malrotation without obstruction or volvulus may show an abnormal distribution of stool, with absence of stool pattern in the right lower quadrant.[66] In patients with nonrotation, all colonic stool may be seen confined to the left half of the abdomen (Fig. 102.15). However, although it may occasionally be suspected, malrotation is not a plain film diagnosis.

In patients with volvulus, the radiographs may be completely normal at the onset of the bilious vomiting (Fig. 102.16A) and should not lead to a false sense of security. As unabated or increased duodenal obstruction occurs, distal bowel contents are evacuated; this lack of abdominal distension may again lead to a false sense of security or to the suspicion of pyloric stenosis if the stomach is distended and the significance of the bilious vomiting is overlooked (Fig. 102.16B). It is important to note that in acute volvulus the duodenum may be distended, but typically duodenal distension is subtle (Fig. 102.16C), different from the obvious double bubble of duodenal atresia, because the time span for the development of dilatation is typically much shorter.

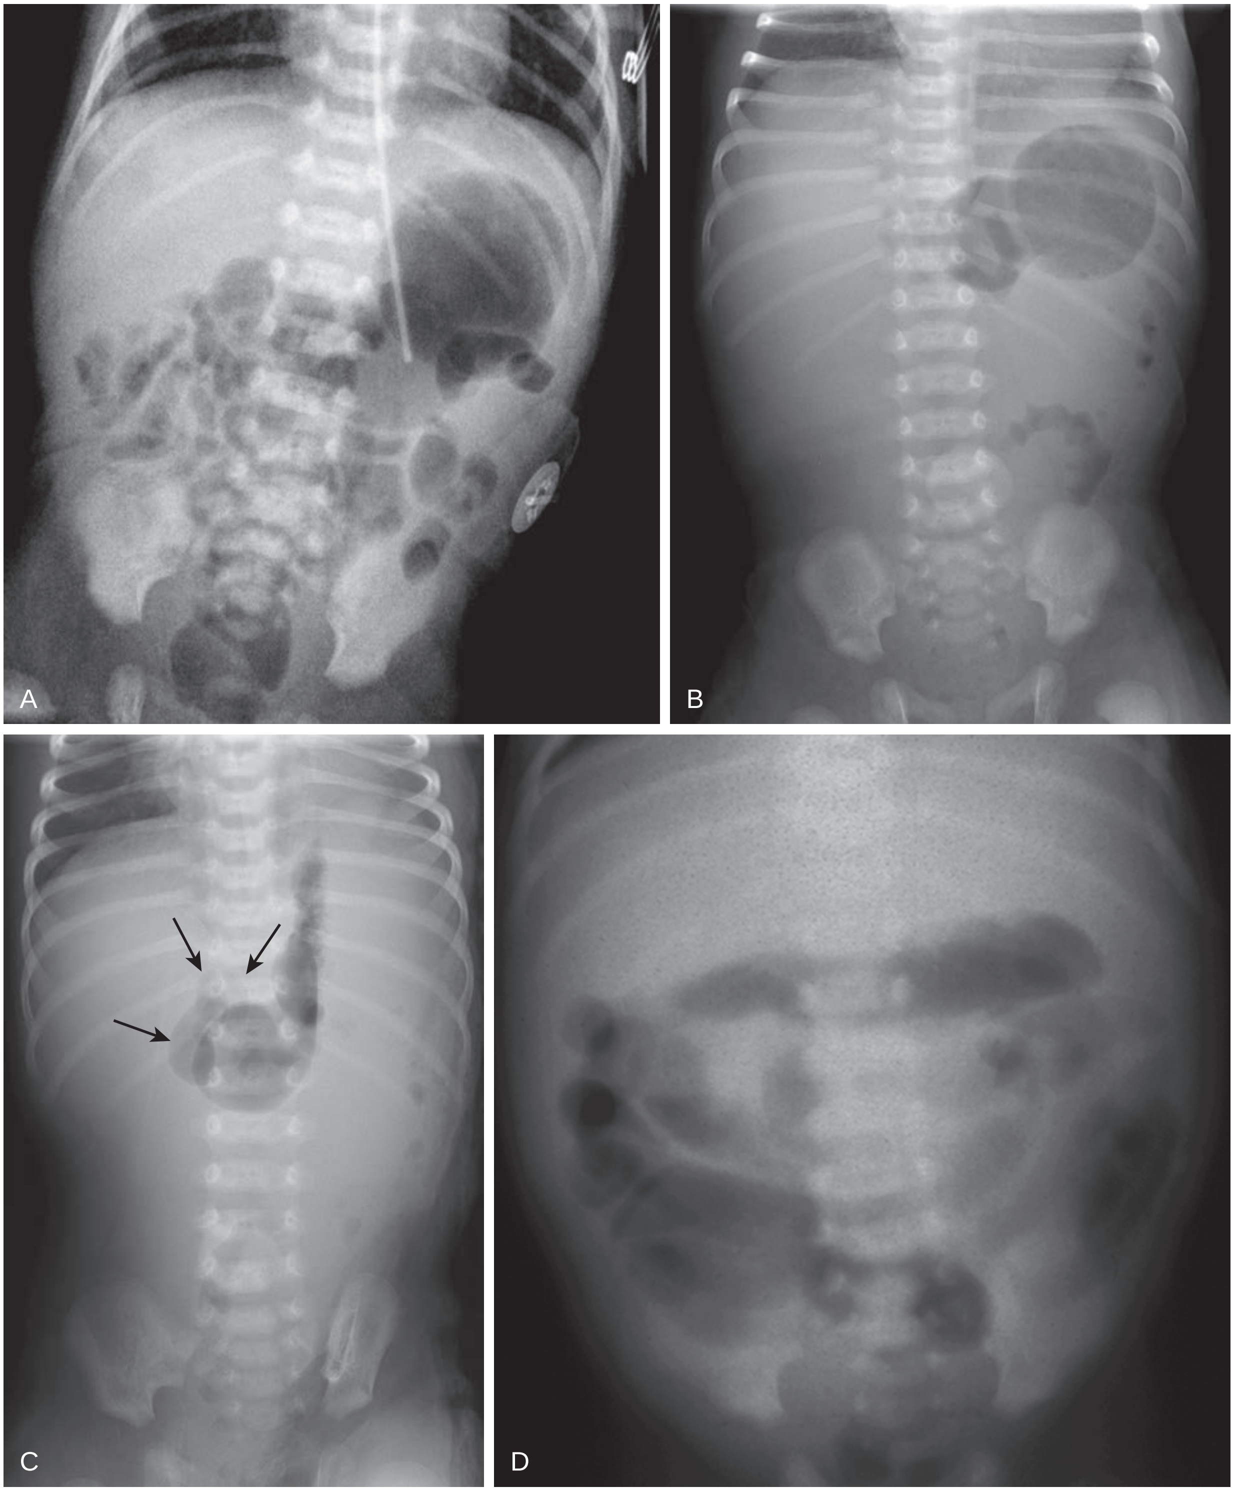

**Figure 102.16. Malrotation and midgut volvulus.** (A) Abdominal radiograph in 2-day-old infant with bilious vomiting and midgut volvulus. The bowel gas pattern is easily interpreted as within normal limits; a normal abdominal radiograph does not exclude the presence of volvulus. (B and C) Supine (B) and left decubitus (C) radiographs in 7-day-old infant with bilious vomiting and midgut volvulus. In (B), although the stomach is normal in size, there is discrepancy between the size of the stomach and the marked lack of gas distally. No distension of the duodenum is appreciated. In (C), the decubitus radiograph reveals gaseous distension of the duodenum, which was not appreciated on the supine image. This duodenal distension coupled with the history of new onset of bilious vomiting, and the paucity of distal gas, are extremely concerning for acute volvulus. (D) Radiograph of a 2-week-old infant with bilious vomiting for several days shows a severe ileus pattern, with fluid and gas distending loops of bowel throughout the abdomen. His bowel was necrotic at subsequent surgery, and the infant expired.

Ominous plain radiographic findings of supervening ischemia in patients with volvulus include abdominal distension, separation of the gas within bowel loops secondary to increased luminal fluid, tubular appearance of bowel loops, and fold thickening. Diffuse fluid and gaseous distension of the bowel suggests gangrenous bowel and a poor prognosis (Fig. 102.16D).

In premature infants, bilious vomiting may be absent, and the clinical picture may be nonspecific and suggestive of the more common entities of sepsis and necrotizing enterocolitis[62,63]; radiographs obtained at the time of systemic manifestations may show dilated bowel loops and suggest profound ileus and/or necrotizing enterocolitis (e-Fig. 102.17).

***Upper Gastrointestinal Tract.*** Although cross-sectional imaging is increasingly recognized as accurate in the evaluation of malrotation and volvulus, in most centers, UGI is considered the standard examination.

Documentation of normally rotated bowel can be challenging, and technique is very important. In pediatric patients, documentation of the normally rotated C-loop needs to be made on passage of the first bolus of contrast from the stomach; missing this opportunity can result in confusing and misleading findings. The course of the duodenum must be documented in both frontal and lateral projections, as the lateral view is essential to document the parallel orientation of the ascending and descending portions of the retroperitoneal duodenum.[48,76,77] On the frontal view, the duodenojejunal junction, recognized by the acute flexure as the duodenum returns to the peritoneal cavity, should be located just to the left of the left pedicle of the adjacent lumbar vertebra, at the same craniocaudal level as the bulb. The lateral view should show ascending and descending portions entirely superimposed anterior to the spine—anterior deviation of the ascending limb is abnormal. The technique is discussed and illustrated in Chapter 84.

The radiologist should be familiar with normal variants of the duodenum, such as duodenum inversum, in which the duodenum shows parallel ascending and descending course to the right of the spine, before crossing to the left and emerging into the peritoneal cavity at a normally positioned ligament of Treitz (Fig. 102.18, Video 102.1).[78,79] Conversely, it is imperative that the abnormal course of a malrotated duodenum in patients without volvulus be recognized, including abnormal location of the duodenojejunal junction on the frontal image (Fig. 102.19A) and abnormally anterior course of all or part of the duodenum on the lateral view.

In symptomatic patients with malrotation, the UGI examination may reveal the volvulus itself, showing a spiral twisting of the duodenum as it wraps around the axis of the superior mesenteric artery, classically described as a "corkscrew" (Fig. 102.19B). When there is complete obstruction, the contrast column may terminate in a beaklike configuration, as the contrast is propelled into the entrance of the spiral, but cannot proceed further (Fig. 102.19C).

In patients with obstruction secondary to Ladd bands, the duodenum may demonstrate a kinked configuration which at times resembles a Z-shape instead of the normal C-loop.[80] The Z-shape is the result of tacking down and kinking of the duodenum by the abnormal attempts at fixation and at times may be difficult to differentiate from volvulus (Fig. 102.19D).

***Contrast Enema.*** In the mid-20th century, barium enema was advocated in the investigation of patients suspected of malrotation and volvulus in the belief that cecal position would define the presence or absence of malrotation, while avoiding introduction of barium contrast proximal to the obstructed duodenum. However, with the understanding that up to 30% of patients with malrotation and its complications could have a normally rotated cecum, and with the realization that a high-riding cecum in a neonate may in fact be normally rotated,[28,81–83] the contrast enema is no longer favored as the appropriate first examination. In problem cases when the UGI is confusing, a follow-through small bowel to determine cecal position may be helpful. Although the caveats just noted regarding cecal position, and additional pitfalls in antegrade recognition of the cecum if the appendix or terminal ileum are not clearly visualized, a clearly abnormal cecal position, especially in children with an equivocal location of the duodenal-jejunal flexure, is diagnostic of malrotation. If there is continued concern, cross-sectional imaging, discussed later, can be considered.[84]

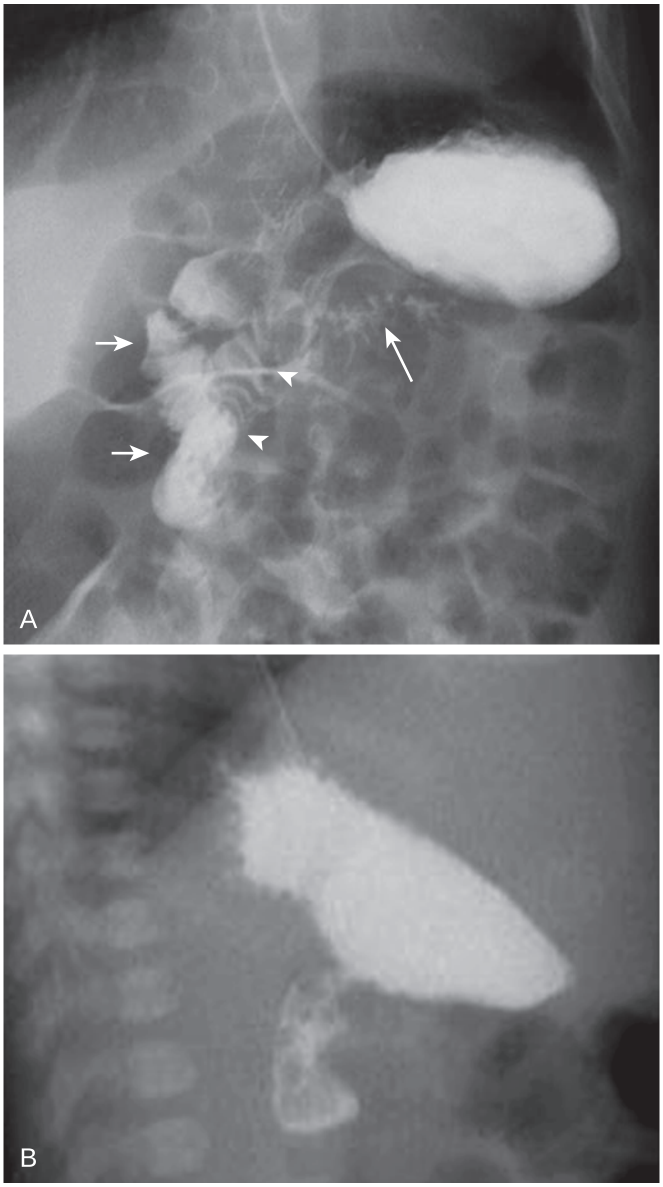

**Figure 102.18. Duodenum inversum.** (A) Frontal UGI image (A) of infant with duodenum inversum, a normal variant. Note that, after the vertical course of the duodenum on the right *(short arrows)* it ascends *(arrowheads)* to the right of the midline, before crossing to a normally positioned duodenojejunal junction at the ligament of Treitz *(large arrow)*. (B) Lateral view in a patient with duodenum inversum shows normal posterior position of the duodenal course, with superimposed ascending and descending limbs. (See Video 102.1.)

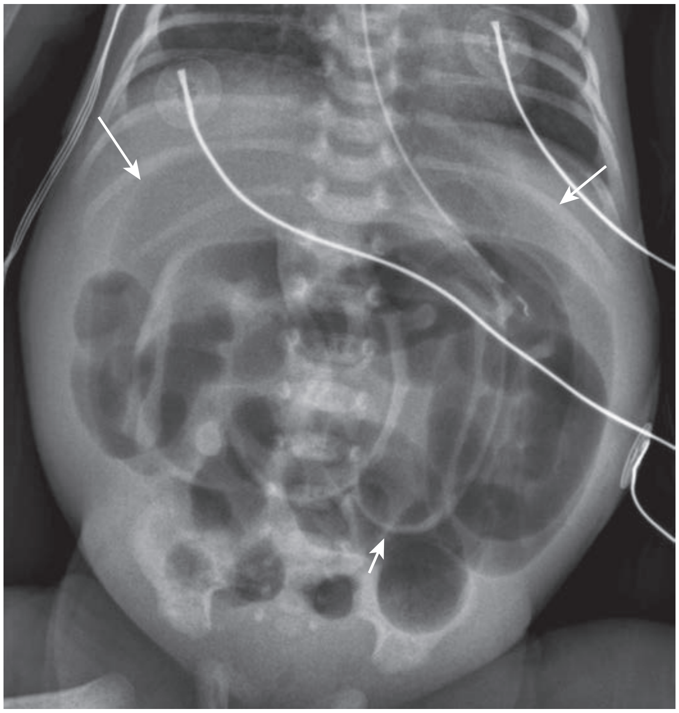
### Challenging Cases

***Overview and Pitfalls.*** A clearly abnormal course of the duodenum renders the diagnosis of malrotation straightforward. Unfortunately, false-positive and false-negative results may occur in as many as 15% and 6% of cases, respectively.[85–88] False positive interpretations usually result from failure to recognize normal



**e-Figure 102.17.** Midgut volvulus in a premature infant. The infant was tolerating increased feedings, when overnight he began having nonbilious residuals and had systemic symptoms consistent with sepsis. Radiograph shows generalized dilatation of bowel loops and free air *(arrows)*. At surgery, there was malrotation with midgut volvulus and bowel necrosis.

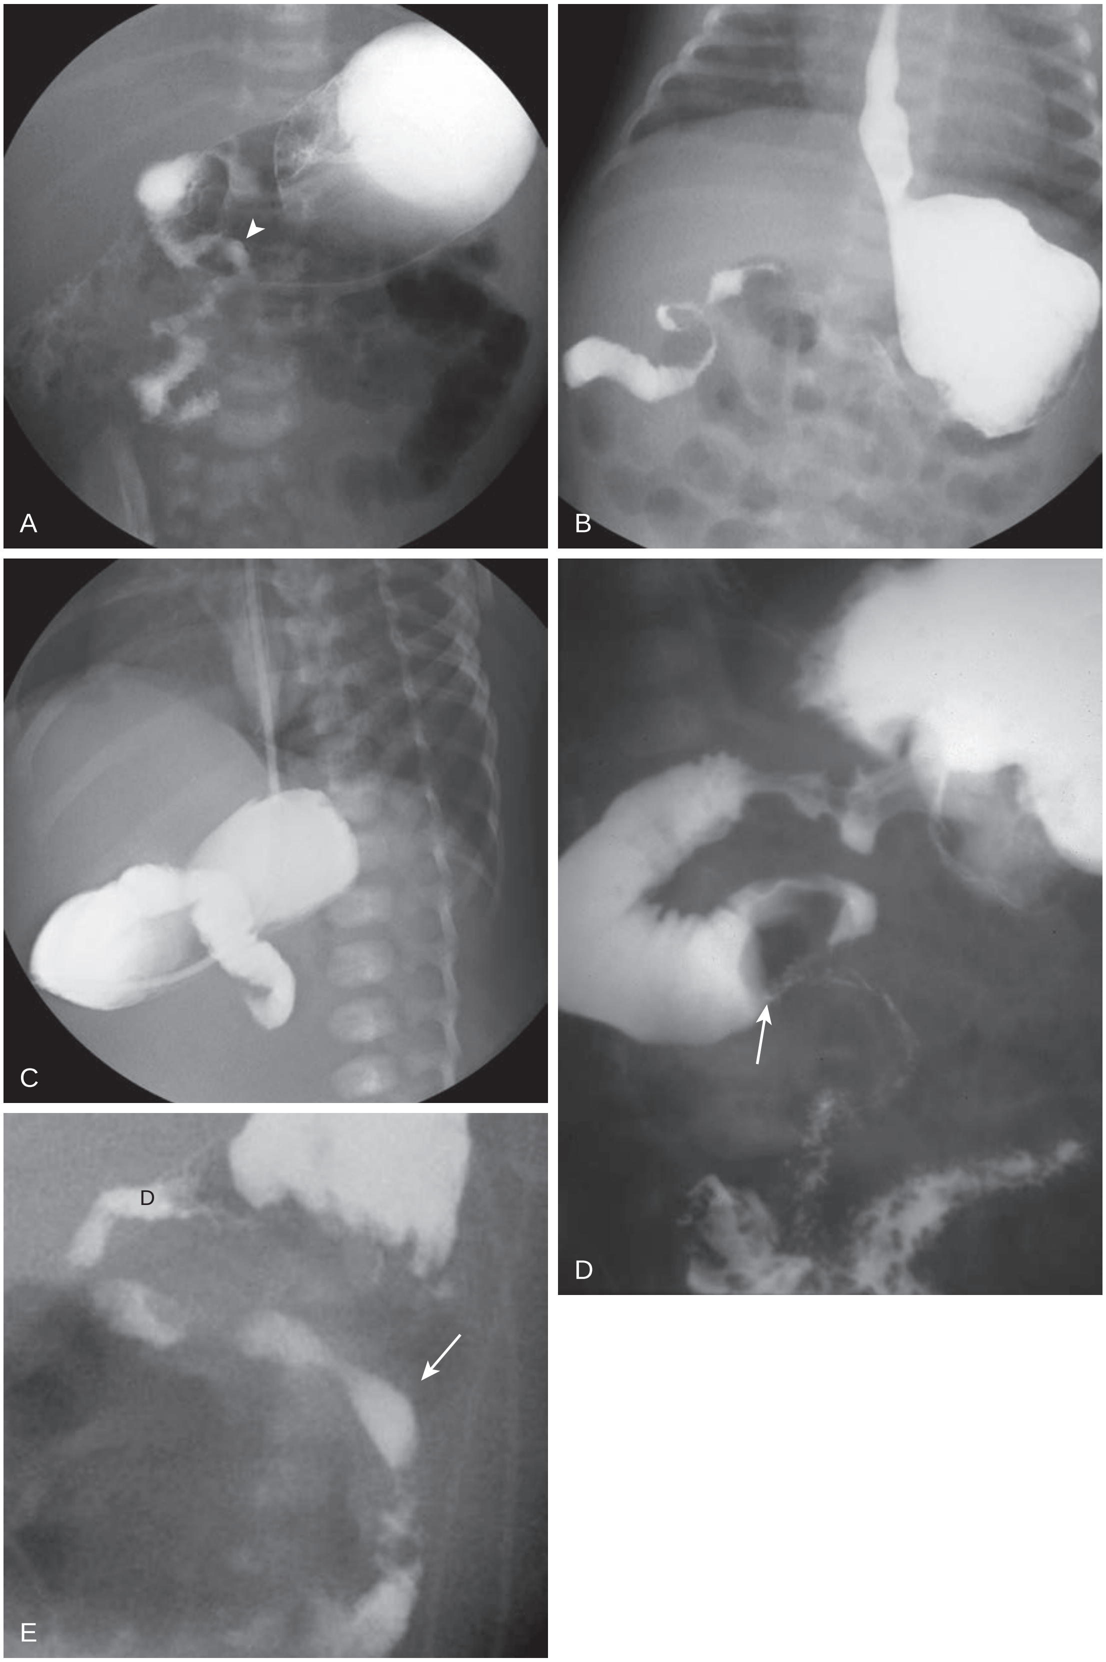


**Figure 102.19. Malrotation, volvulus, and Ladd bands on UGI.** (A) Malrotation in an infant without midgut volvulus. Frontal image demonstrates that the presumed duodenojejunal junction *(arrowhead)* is low and to the right of the midline. (B) Image obtained during UGI in infant with malrotation and midgut volvulus. Note the classic "corkscrew" configuration of the duodenum as it wraps around the mesenteric pedicle. There was significant reflux secondary to the obstruction. (C) Image from UGI on another infant with 1 day history of bilious vomiting, presenting to the ED with dehydration. There was complete obstruction of the duodenum, terminating in a configuration resembling a beak. (D) Ladd bands in 2-month-old girl with malrotation. Left posterior oblique spot image from an upper GI demonstrates the abnormal course of the duodenum, and dilatation of the proximal duodenum due to crossing bands at its third portion; note the kinking of the duodenum *(arrow)* and the resemblance to a corkscrew. This appearance does not exclude midgut volvulus. (E) Note the depression of the duodenojejunal junction *(arrow)* below the level of the duodenum (D) in this surgically confirmed normally rotated infant, secondary to the mass effect of dilated loops from a closed loop obstruction in the lower abdomen.

variants, such as the duodenum inversum previously discussed. Position of the proximal small bowel in the right upper quadrant, as an isolated finding, is not indicative of malrotation.[78,79,87] Displacement of a normal ligament of Treitz is another cause of false-positive results. We know that the neonatal duodenum is mobile[82] and can be displaced secondary to peritoneal masses; abnormal, dilated bowel loops[89] (Fig. 102.19E); or postoperatively.[90] A mobile or high position of the cecum, particularly in a neonate, can be a normal finding that overlaps with malrotation and renders evaluation for malrotation particularly challenging in individual patients.

Potential false-negative outcomes may result from suboptimal technique, such as failing to delineate the course of the duodenum on the first bolus of contrast from the stomach, or from failure to identify the subtle finding of malrotation, such as kinking of the duodenum along its course, or failing to appreciate an abnormally low location of the duodenojejunal junction, or one that is to the right of the left pedicle of the spine.[46,48,76,82,87] Limitations of the lateral view itself include the fact that the aorta and the superior mesenteric artery are not visualized, and therefore true retroperitoneal position of the duodenum cannot be ascertained unequivocally,[29] despite the parallel course of its ascending and descending portions anterior to the spine.

**Cross-Sectional Imaging.** Cross-sectional imaging is receiving further attention as a means of diagnosing malrotation and volvulus.[29,84,91–93] Even when cross-sectional imaging is not the first line examination, ultrasound may be the first examination performed in a child with vomiting in whom the presence or significance of bile in the vomitus has not been appreciated, or CT may be performed in an older child to assess atypical abdominal pain. Ultrasound can also be very helpful in patients with complete obstruction at the duodenum, in whom the rotation of the bowel or the presence of volvulus cannot be ascertained at UGI.

***Ultrasound.*** The normal retroperitoneal course of the duodenum is an indication of normal rotation of the bowel and has been underscored recently as an important finding on abdominal ultrasound.[29,84,91–94] That said, this is not an easy task, and as is true of the UGI, the ultrasound examination requires a knowledgeable and skilled operator, and utmost attention to detail. It is important to note that the peritoneal membrane is not visualized, and therefore the retroperitoneal location of the crossing duodenum is implied by the surrounding anatomy. It is easiest to find the duodenum as it courses beyond the pylorus and around the head of the pancreas, and follow its course between the aorta posteriorly and the superior mesenteric artery (SMA) and vein (SMV) anteriorly, noting the proximity of this crossing to the renal hila and to the origin of the SMA from the aorta (Fig. 102.20). Duodenal proximity to the origin of the SMA is important, as the duodenum crossing well below the renal hila does not document its retroperitoneal location.[93–96]

Alteration or inversion of the normal left-right relationship of the superior mesenteric artery and vein is often mentioned in the context of malrotation. Although the relationship can be abnormal in many patients with malrotation,[97] the finding is neither highly sensitive nor highly specific in the diagnosis of malrotation, with or without volvulus.[98]

The corkscrew findings of midgut volvulus have been termed the *whirlpool sign* at ultrasound,[99] where not just the duodenum, but also the SMV, can be seen turning clockwise about the axis of the SMA. As on UGI, the duodenum can be followed from the antrum and pylorus, around the head of the pancreas, and can be seen entering into the twist, indicating the presence of midgut volvulus (Fig. 102.21). As the transducer is moved craniocaudally, the clockwise twisting can be appreciated (Videos 102.2 and 102. 3). The relatively new advent of ultrasound in this emergent diagnosis begs the question of its sensitivity and specificity. Published data on smaller cohorts suggest that it is sensitive and specific for malrotation with volvulus,[100,101] with more recent presentations reporting sensitivity and specificity as high as 100%.[91] Despite these reports, experience with this modality is not widespread, and UGI remains the mainstay of diagnosis at most centers. On the other hand, if there is complete obstruction at UGI, consideration can be given to ultrasound to confirm the suspected diagnosis of volvulus. Ultrasound can further confirm flow within the SMA, within and distal to the volvulus (e-Fig. 102.22). In patients with bowel ischemia and gaseous distension of bowel, it is possible that the whirlpool sign may not be identified. Menten et al. propose that demonstration of a parallel orientation of the superior mesenteric artery and vein can exclude the presence of volvulus at the time of the examination.[102]

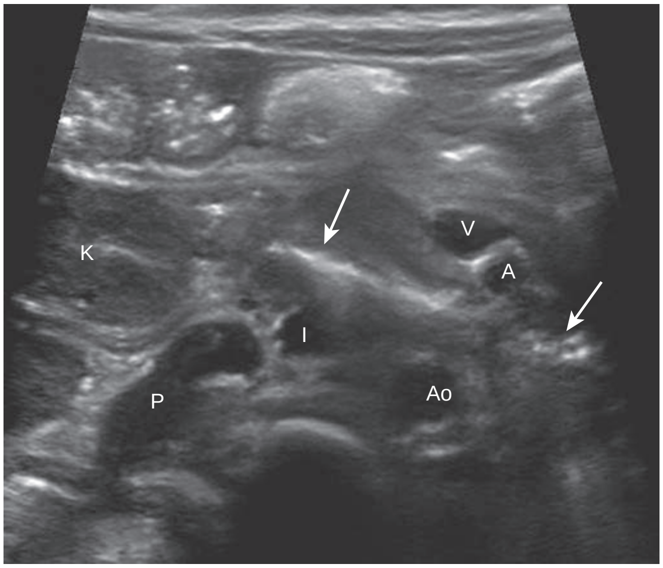

**Figure 102.20. Normal duodenum and rotation on ultrasound.** Normally rotated duodenum. Transverse ultrasound at the level of the renal hila, showing the gas-containing transverse duodenum (D3, *arrows*) crossing between the Aorta *(Ao)* and IVC *(I)* posteriorly, and the SMA *(A)* and SMV *(V)* anteriorly. *K*, Right kidney; *P*, right psoas.

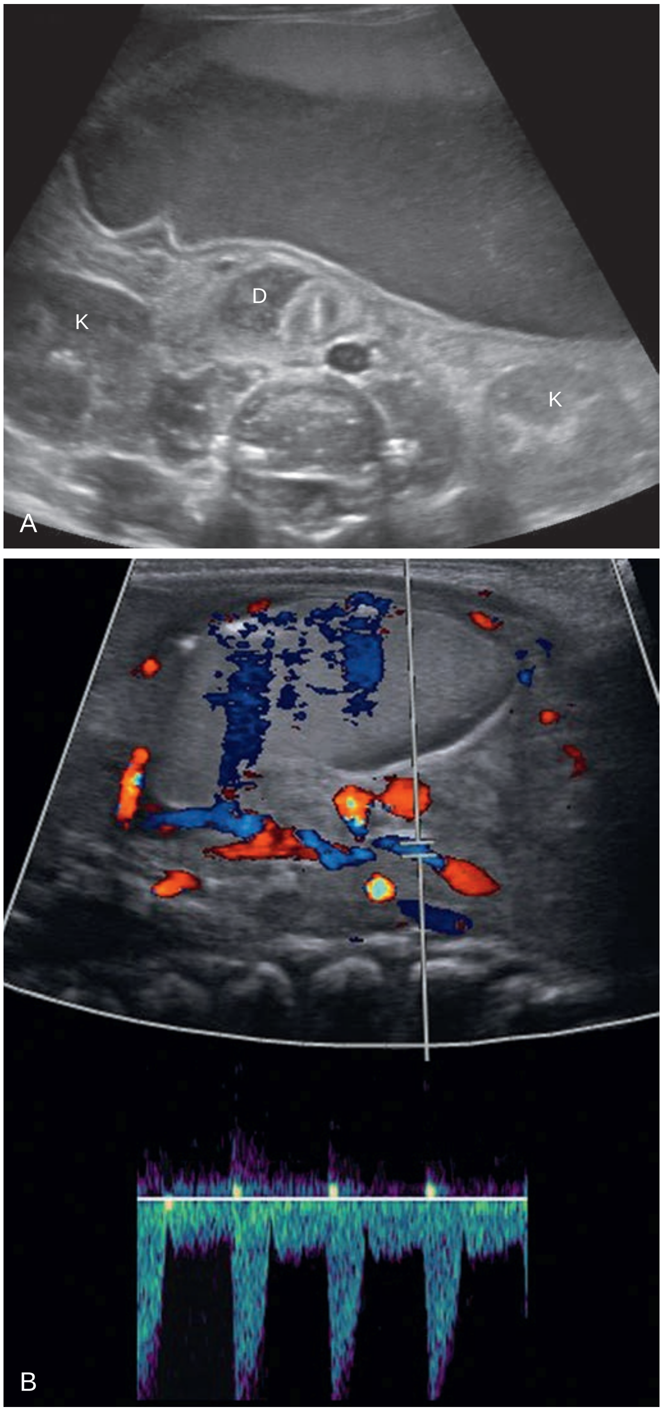
In older patients presenting with chronic volvulus, the sonographic findings are similar, although the duodenum may be considerably larger, as it has had time to become dilated, in contradistinction to the acute presentation (Fig. 102.23, Video 102.4).

***Other Cross-Sectional Imaging.*** CT demonstrates the retroperitoneal course of the normally rotated duodenum, as well as the position of the cecum, unencumbered by overlying bowel gas, and therefore is an excellent modality to document bowel rotation. Identification of midgut volvulus, with incorporation of the duodenum and the superior mesenteric vessels in the twist, is also possible (Fig. 102.24). Although CT currently is not considered a primary modality in the assessment of malrotation, the findings should be recognized if encountered on examinations performed for other reasons. With low dose and ultrafast scanners that do not require sedation, the role of CT may need to be re-examined.

***Treatment.*** The surgical Ladd procedure for treatment for malrotation with volvulus consists of surgical detorsion, identification and lysis of Ladd bands, straightening of the duodenum along the right abdomen, and placement of the cecum in the left lower quadrant, broadening the base of the mesentery and creating a separation between the duodenojejunal junction and the cecum resembling nonrotation, with incidental appendectomy.[30,103] When accompanied by volvulus, the surgery is emergent, and correction of existing metabolic and electrolyte derangements must be undertaken. Laparoscopic surgery is an alternative approach in older children,[104] and there may be fewer short- and long-term complications hopefully without increased risk of recurrent volvulus.[105]



**e-Figure 102.22. Midgut volvulus.** (A) Ultrasound in a 4-day-old neonate with bilious vomiting shows a markedly dilated stomach, and the duodenum *(D)* entering into the volvulus with a beaklike configuration. *K*, Right and left kidneys. Video 102.3 shows the distended duodenum and the superior mesenteric vessels within the clockwise rotation of the midgut volvulus complex. (B) Sagittal image demonstrating flow in the SMA distal to the midgut volvulus. At surgery, the midgut volvulus without bowel compromise was confirmed.

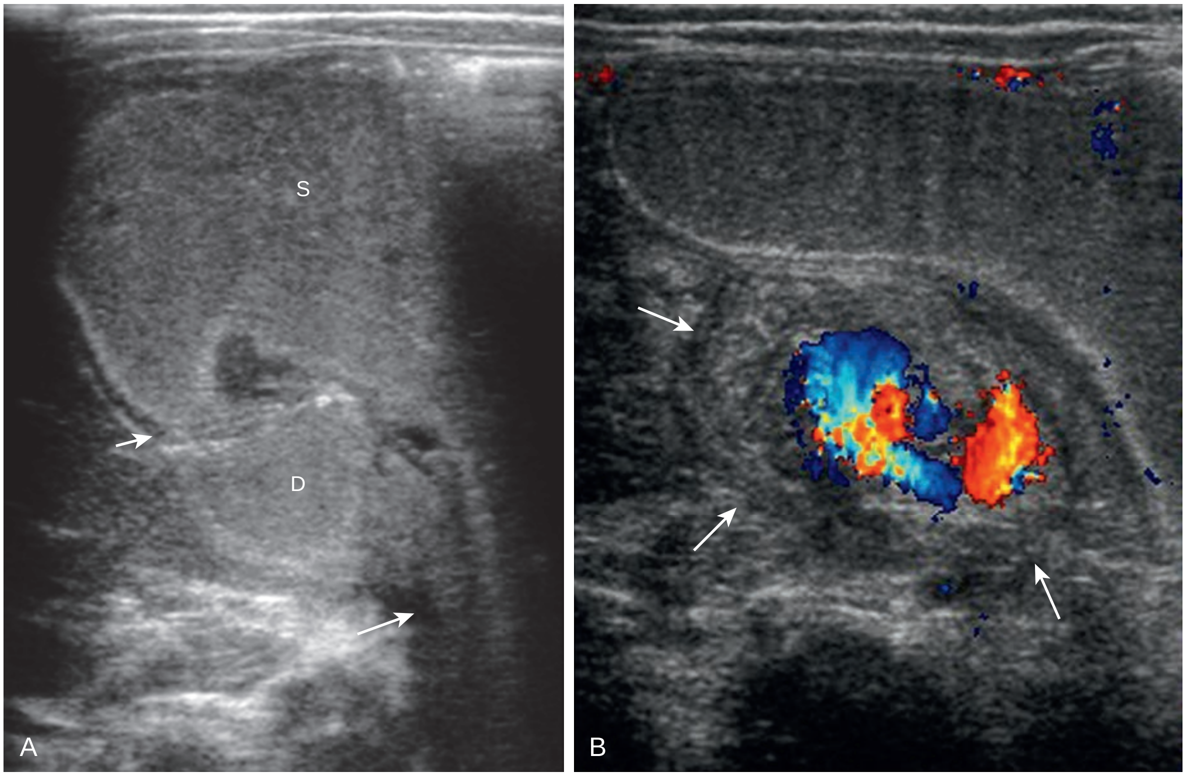


**Figure 102.21. Midgut volvulus on ultrasound.** (A) Ultrasound image of an 18-day-old boy with history of vomiting since birth, which had recently become "projectile" and was "occasionally yellow" shows a dilated stomach *(S)* and duodenum *(D)*, with the latter deviated medially as it enters into the midgut volvulus *(long arrow)*. The pylorus *(short arrow)* is widely open. (B) Color Doppler image shows the duodenum at the outer edge of the twist *(arrows)*, with the twisting superior mesenteric vein, and the centrally located superior mesenteric artery. Video 102.2 demonstrates the clockwise turning as the transducer moves in a cephalocaudal direction.

When malrotation in the absence of volvulus is found in the older child or adult, surgery is indicated if the patient is symptomatic. The role of surgery versus conservative management in the asymptomatic older patient with malrotation without volvulus, such as patients with heterotaxy,[106] remains controversial.[107] More recent literature suggests that observation, particularly in patients with heterotaxy, is preferable.[72,105,108–111]

### Preduodenal Portal Vein

***Overview.*** The portal vein forms at the junction of the superior mesenteric and splenic veins, and its normal course is retropancreatic and retroduodenal. The preduodenal portal vein courses anterior to the pancreas and duodenum; it is important because of its associated anomalies, but its major significance is surgical recognition.[112]

***Etiology.*** Preduodenal portal vein is the result of abnormal resorption of segments of the paired embryonic vitelline veins and their connections (e-Fig. 102.25). Normally there is persistence of the upper communicating branch between the left and right vitelline veins, resorption of the cephalad segment of the left vitelline vein, the caudal segment of the right, and of the lower communicating branch, resulting in the duodenum coursing ventral to the portal vein. The preduodenal portal vein results when the upper communicating branch is resorbed, with persistence of the lower communicating branch, which courses ventral to the duodenum; there is resorption of the left and persistence of the right vitelline veins.[113,114] It is often seen in disorders with failure of recognition of asymmetry, particularly heterotaxy, most often with left isomerism and polysplenia.[75,115]

***Clinical Presentation.*** The preduodenal portal vein is associated with conditions that cause duodenal obstruction, including duodenal web, annular pancreas, and malrotation. Therefore although often asymptomatic, the major presenting symptom is duodenal obstruction, believed to be secondary to the associated anomaly in most cases.[116,117] Preduodenal portal vein is highly associated with heterotaxy, particularly polysplenia.[75,118] The most important concern is inadvertent injury during surgery.[117,119,120] This anatomy should be identified before surgery whenever possible, particularly in presurgical candidates at risk for this anatomy.[73,75,121]

***Imaging.*** The preduodenal portal vein is well seen at cross-sectional anatomy. On sonography, the normal SMV is seen dorsal to the pancreas, where it is joined by the splenic vein to enter the liver. In the preduodenal arrangement, the SMV instead moves ventrally over the pancreas and hence, in a stepladder-like fashion, into the liver (e-Fig. 102.26).[75,122] On CT and MRI, the findings are similar (Fig. 102.27).[123]

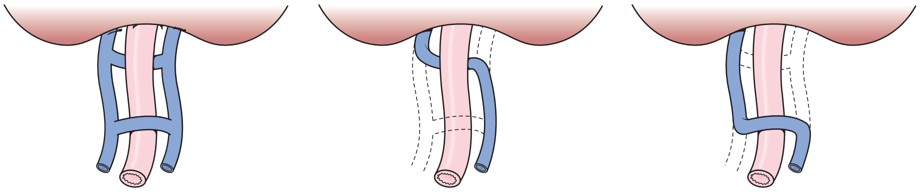
***Treatment.*** There is no treatment necessary for asymptomatic preduodenal portal vein. When associated with obstruction, bypass of the obstruction or correction of malrotation or Ladd bands is indicated.[120,124]

# PART II: SMALL BOWEL

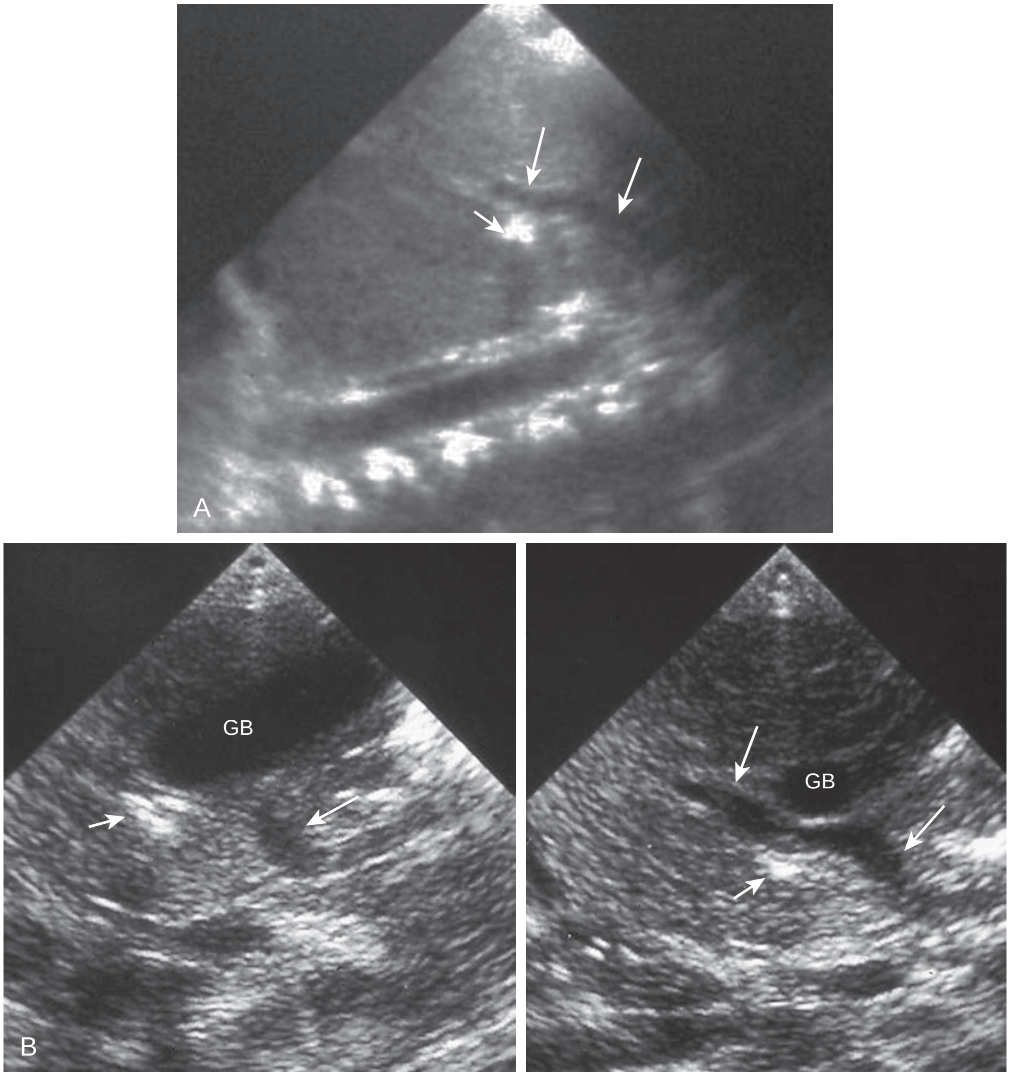
## Congenital/Neonatal Anomalies of the Small Bowel

### Small Bowel Atresia and Stenosis

***Overview.*** Atresia and stenosis affect the jejunum and ileum more commonly than any other portion of the abdominal GI



**e-Figure 102.25. Schematic illustration of formation of preduodenal portal vein.** Figure on *left* shows the paired vitelline veins with embryonic connections coursing dorsal (upper rung) and ventral (lower rung) to the duodenum. Normally (*middle* figure) there is persistence of the upper communicating branch, with resorption of the cephalad segment of the left vitelline vein, and the caudal segment of the right. The preduodenal portal vein (figure on the *right*) results from resorption of the upper communicating branch and persistence of the lower one, with resorption of the left vitelline vein and persistence of the right.



**e-Figure 102.26. Preduodenal portal vein.** (A) Sagittal sonogram in a child with asplenia shows the SMV/portal vein continuation into the liver *(long arrows)* passing anterior to the duodenum, outlined by a small amount of gas *(short arrow)*. (B) Sagittal sonogram in another child with polysplenia demonstrates the course of the SMV *(long arrows)* coursing over the pancreas and the duodenal bulb *(short arrows)* again outlined by a small amount of air. *GB* indicates a midline gallbladder.

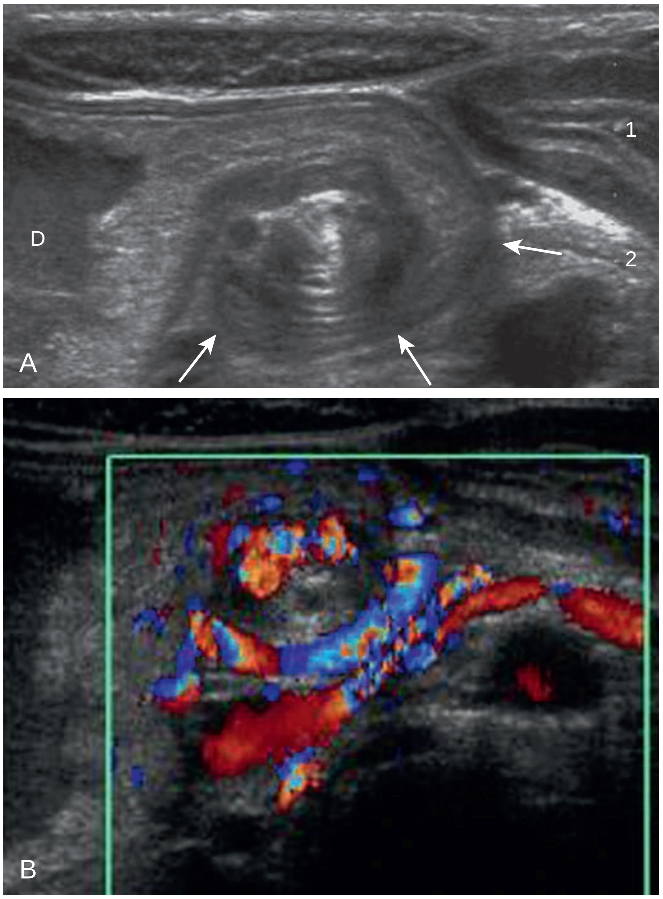


**Figure 102.23.** Video 102.4. **Chronic midgut volvulus.** A 5-year-old boy with a long history of vomiting, who weighed 15 kg at presentation to the ED, with a 14-pound weight loss over the previous 3 weeks, on a gluten-free diet for a recent diagnosis of gluten enteropathy. (See Video 102.4.) (A) Transverse sonogram of the upper abdomen shows a markedly dilated duodenum *(D)* narrowing as it enters into the midgut volvulus *(arrows)*. (B) Color Doppler at a similar level as (A) shows the mesenteric vein around the twist. Video 102.4 shows the clockwise twist, with distended distal mesenteric vasculature. Detorsion of a 720-degree twist and division of Ladd bands was accomplished at surgery.

tract: approximately 51% involve the jejunum and ileum, compared with the duodenum in 40% and the colon in approximately 9%.[125] Atresia is much more common than stenosis, which is seen in only 5% of cases. The incidence of jejunoileal atresia ranges between 1 and 3 cases per 10,000 live births, depending on geographic location, the incidence being greater in persons of European extraction and in African Americans, and lower in Latin Americans. Small bowel atresias affect the jejunum and ileum nearly equally; of those in the ileum, nearly two-thirds occur distally, while in the jejunum nearly two-thirds occur proximally.[126]

Jejunoileal atresias have been subdivided into five types and subtypes[125,127,128] (Fig. 102.28). Type I represents mucosal or membranous atresia, limited to luminal discontinuity. In type II, the blind ends of the bowel are connected by a fibrous cord, with continuity of the underlying mesentery. Type IIIa indicates discontinuity between the bowel ends, with an adjacent mesenteric defect, while IIIb is the specific long-segment atresia with wide mesenteric defect, typically described as “apple-peel,” “Christmas tree,” or “maypole” mesentery, due to the appearance of the residual distal small bowel, coiled around its tenuous vascular supply through retrograde flow via the ileocolic, right colic, or inferior mesenteric

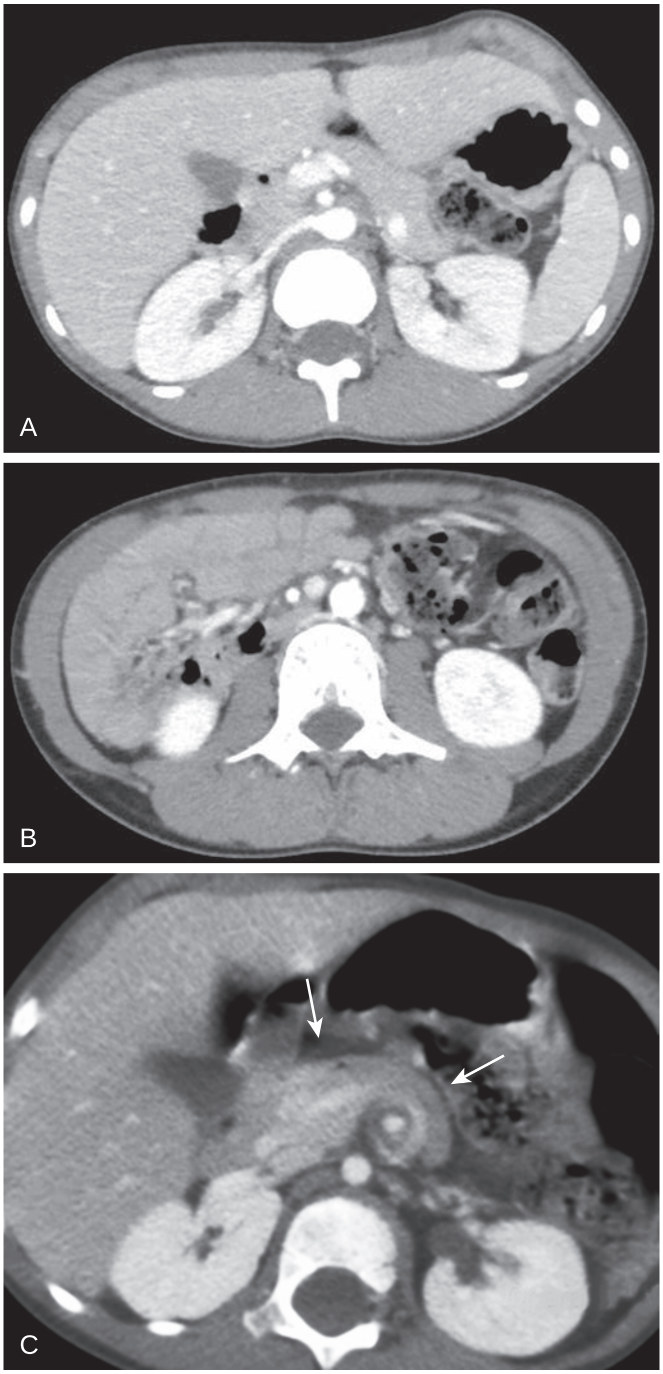

**Figure 102.24. Malrotation on CT.** (A and B) Two images from a contrast-enhanced CT scan in adolescent with abdominal pain (same patient as depicted in Fig. 102.15). (A) At the level of the renal hila, the duodenum does not cross the midline and remains intraperitoneal. (B) At the level of the inferior mesenteric artery, all the small bowel can be seen on the right side of the abdomen, and the colon on the left. (C) Contrast-enhanced CT scan in 2-year-old child with long history of intermittent abdominal pain and emesis. CT demonstrates a volvulus with duodenum *(arrows)*, which contains small bubbles of gas, entering into the twist.

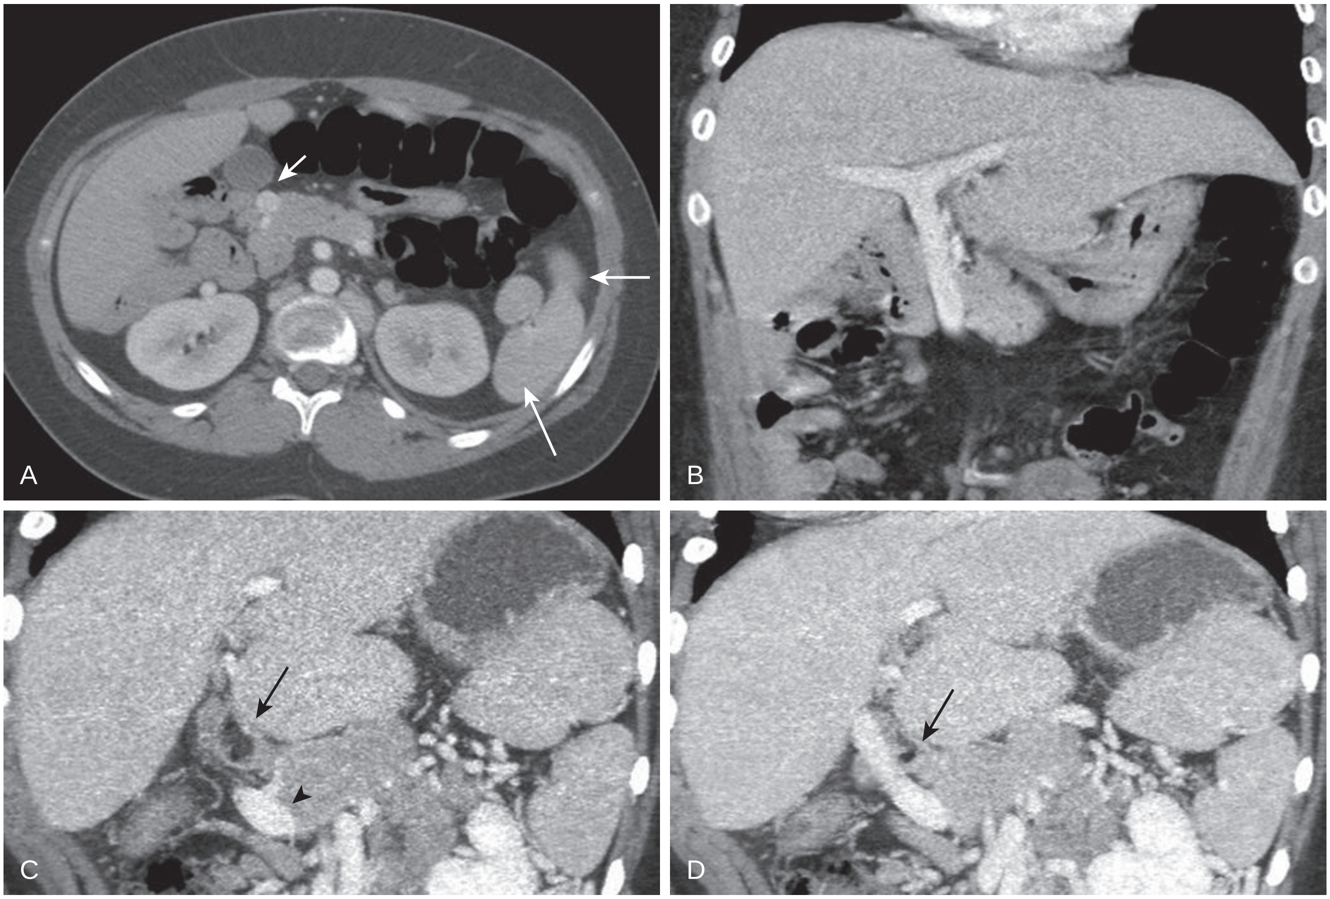

**Figure 102.27. Preduodenal portal vein.** (A) Axial contrast-enhanced CT image from a child with polysplenia *(long arrows)* shows a preduodenal portal vein *(short arrow)* ventral to the pancreas and duodenum. SMA is in normal position anterior to the aorta and dorsal to the pancreas. Note the congenitally short pancreas and the malrotation. (B) Coronal reformat shows the abnormal course of the portal vein as it extends into the liver. (C and D) Angled coronal reformats showing the anterior course of the portal vein. (C) The duodenum *(arrow)*, and the caudal portion of the portal vein, coursing anteriorly. (D) On the adjacent image, the portal vein is about to enter the liver directly ventral to the duodenum *(arrow)*. Note the similar anatomy displayed by ultrasound on another patient shown in Fig. 102.20.

arteries, further discussed later in this chapter.[129] Type IV refers to multiple atresias (Fig. 102.29).

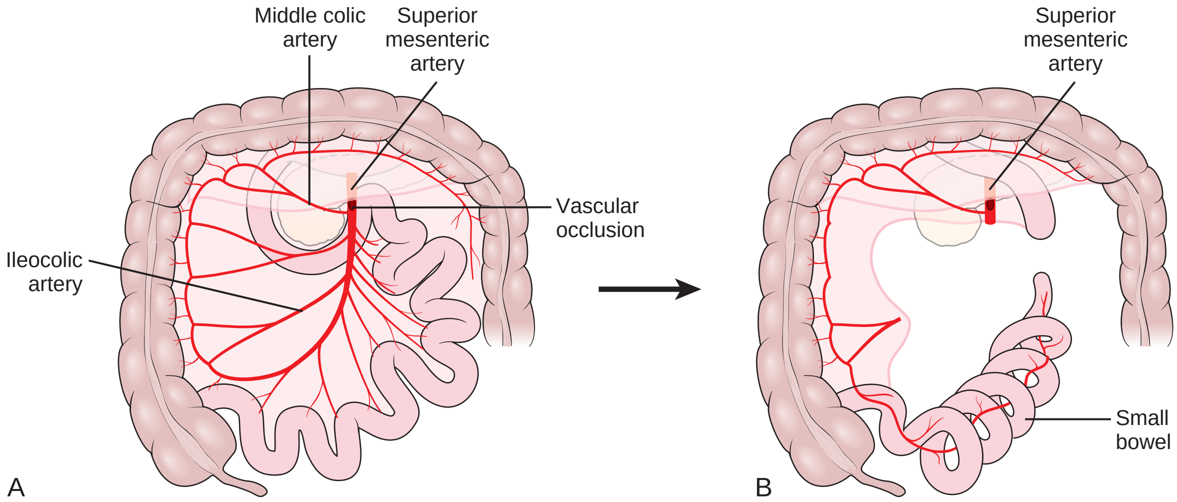
***Etiology.*** Unlike the duodenum, in which the etiology of atresia and stenosis is believed to be failure of recanalization, the most accepted etiology in the jejunum, ileum, and colon is a vascular accident, the location and extent of which governs the location and severity of the resultant defect.[126,128,130,131]

Conditions that can result in prenatal gut ischemia include gastroschisis, intrauterine volvulus, intussusception, and internal hernias.[132] Atresias are found in patients who have undergone significant compression of bowel segments, such as incarceration in omphalocele or in tight gastroschisis defects. Moreover, signs of peritonitis have been found in up to 48% of atresia patients.[126] Extensive apple-peel small bowel atresia is postulated to occur secondary to occlusion of the superior mesenteric artery distal to the origin of the right colic and ileocolic arteries (e-Fig. 102.30). Genetic abnormalities disrupting apicobasal polarity of gut epithelial cells and cellular apoptosis have been implicated in patients with the rare hereditary multiple intestinal atresias (HMIA), which may be associated with combined immunodeficiency and is characterized by multiple atresias with a very poor prognosis.[133–136]

***Clinical Presentation.*** Patients with intestinal atresia may present prenatally with polyhydramnios. Because there is increased bowel surface to absorb the swallowed amniotic fluid in more distal atresias, the percentage of infants with polyhydramnios increases with more proximal atresias; it is approximately 38% in jejunal atresia. Similarly, the percentage of patients presenting with bilious emesis postnatally also increases with more proximal atresia, approximately 84% in patients with jejunal atresia. Jaundice can also occur due to changes in the enterohepatic circulation and is seen in approximately 32% of infants with jejunal and 20% of infants with ileal atresia. The more distal the atresia, the greater the degree of clinical abdominal distension; patients with more proximal atresias may show some distension of the upper abdomen.

Other anomalies outside of the GI system may be present in nearly one-third of patients, but this is more common in patients with jejunal than with ileal atresia.[137] Although duodenal atresia shows a high association with trisomy 21, this is not the case with jejunoileal atresia, which is seen in approximately 0.5% to 3% of patients with Down syndrome. Multiple atresias and the apple-peel variant of intestinal atresia can show a genetic pattern, and patients with the apple-peel variant have been reported with a constellation of other anomalies, including ocular abnormalities and microcephaly. More than two-thirds of these patients are born prematurely, and more than half have malrotation.[126]

***Imaging.*** Radiographs in patients with bowel obstruction will demonstrate proximal dilatation and collapse of bowel distal to the obstruction, or to the most proximal level of obstruction in



**e-Figure 102.30. Type IIIB atresia apple-peel variant of intestinal atresia.** (A) Schematic drawing of normal distribution of superior mesenteric artery and its branches. If there is prenatal occlusion at the point indicated, part of the jejunum and the accompanying dorsal mesentery will involute. (B) Sequelae of (A) with collateral supply of the residual distal small bowel via ileocolic branches of the distal superior mesenteric artery that are supplied by connections to the inferior mesenteric artery. The residual distal ileal loops wrap around their collateral supply, resembling an apple peel; an arrangement that is also descriptively known as a *Christmas tree* or *maypole.*

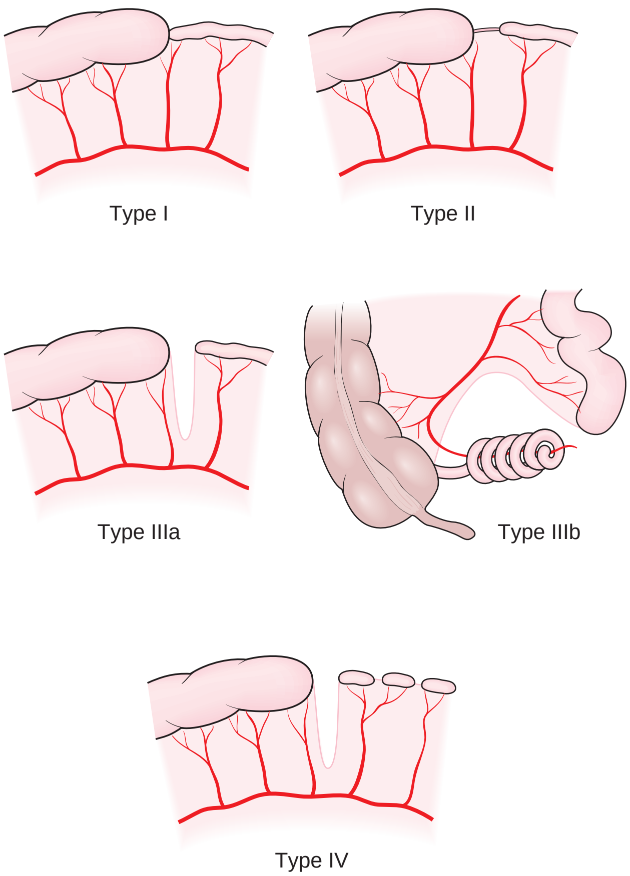


**Figure 102.28. Classification of jejunoileal atresias.** Type I is a mucosal or membranous atresia, in which only the lumen is atretic, with continuity of outer wall and mesentery. In type II atresia, the atretic segment is connected to the distal bowel by a fibrous cord, with an intact mesentery. Type IIIa indicates discontinuity between the atretic segment and the distal bowel, with an associated mesenteric defect, while in type IIIb, the mesenteric defect is large, with absence of a portion of the bowel; the remaining distal bowel is wrapped in "Christmas tree" or "apple-peel" fashion around a remnant arterial supply. Type IV refers to multiple atresias. *(Reproduced with permission of Grosfeld JL, Ballantine TV, and Shoemaker R. Operative mangement of intestinal atresia and stenosis based on pathologic findings.* J Pediatr Surg. *1979;14[3]:368–375.)*

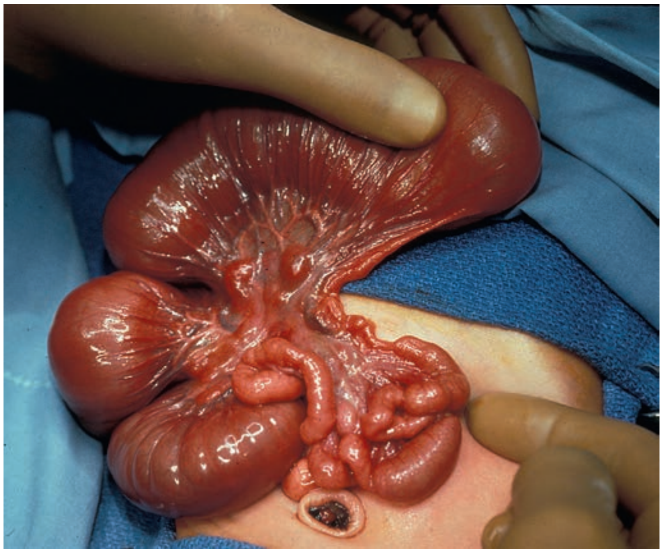

**Figure 102.29. Type IV atresia.** Intraoperative radiograph of an infant with multiple atresias. Note the dilatation of the bowel proximal to the first atresia, and the multiple, sausage-like distal atresias. *(Image courtesy of Dr. Wallace W. Neblett III, Nashville, TN.)*

patients with multiple atresias. Abdominal radiographs in patients with jejunal atresia will show dilatation of the stomach, duodenum and jejunum to the point of atresia, although the degree of dilatation may be much decreased if decompressed via enteric tube (Fig. 102.31A and B). In patients with proximal jejunal atresia, radiographs with the above findings are usually diagnostic. UGI will demonstrate the dilated stomach, duodenum, and small bowel to the point of first atresia (Fig. 102.31C).

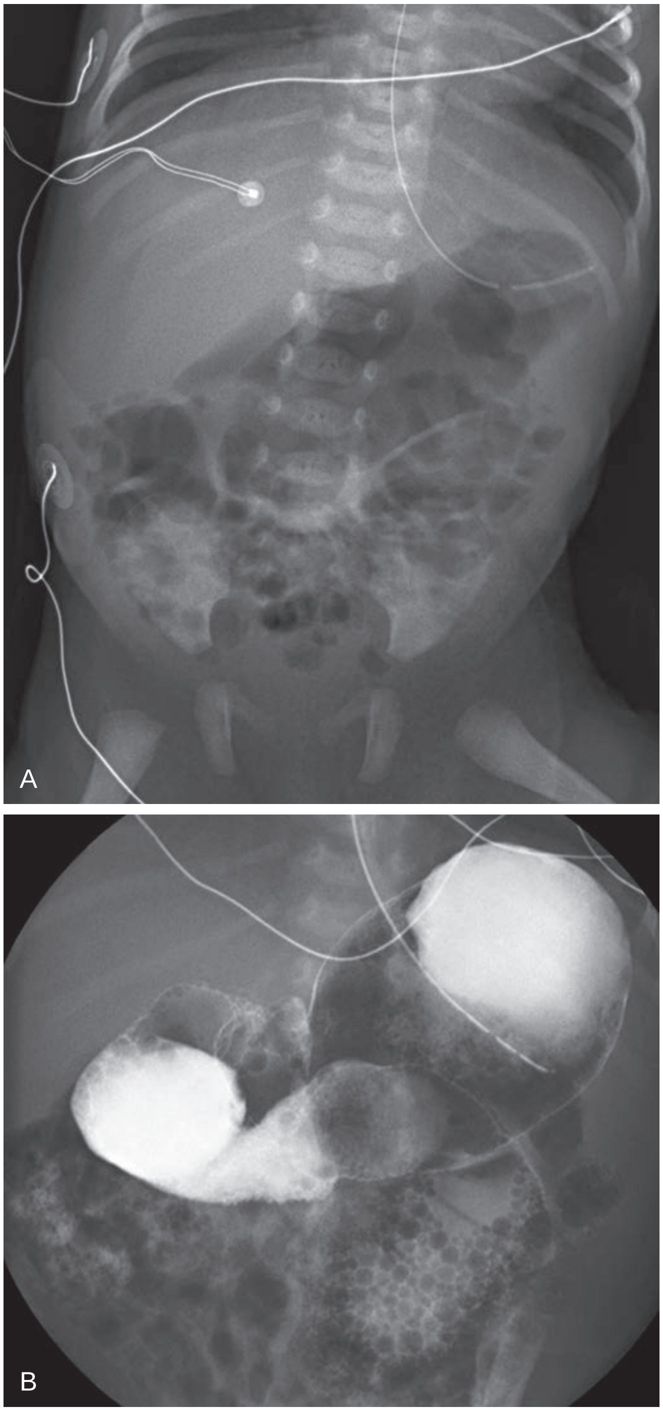
In patients with ileal atresia, abdominal radiographs will reveal dilatation of gas-filled loops of bowel, often with protuberance of the flanks and elevation of the hemidiaphragms (Fig. 102.32A). In neonates, it is not possible to distinguish small from large bowel, despite the degree of dilatation or location.[138] However, in distal small bowel obstruction, there will not be gas in the rectum, a finding that can be optimized by obtaining a prone cross-table lateral radiograph (Fig. 102.32B). In patients with radiographic findings of distal obstruction, the differential includes distal small bowel obstruction and colonic abnormalities; therefore in such patients a contrast enema is indicated for diagnosis. Water-soluble contrast material diluted to a near iso-osmolal concentration is preferred (see Chapter 84). In patients with ileal atresia, the contrast enema will reveal a very small, unused colon, known as a *microcolon*, whose lumen has not been distended by swallowed material or succus entericus (Fig. 102.32C). The differential diagnosis of microcolon is that of distal small bowel obstruction: ileal atresia, meconium ileus, or long segment Hirschsprung disease.

In patients with apple-peel atresia, in whom the atresia is at the jejunum, with a long gap to the residual distal small bowel, radiographs will reveal findings suggestive of proximal atresia. In patients with jejunal stenosis, there will be distal gas and proximal dilatation dependent upon the degree of stenosis (e-Fig. 102.33). Ileal stenosis is much less common.

***Treatment.*** The treatment and management of jejunal and ileal atresia or stenosis is surgical. Although considerable morbidity still plagues the survivors of these abnormalities,[132] the prognosis of these infants has undergone a revolutionary improvement. Survival has improved from approximately 1% to 10% in the first half of the 20th century, to 84% in the 1970s, to 95% currently, related to improvement in surgical techniques and in pre-, peri-, and postoperative care and nutritional support.[6,132] Surgical challenges arise in the caliber discrepancy between dilated proximal and collapsed distal bowel. In patients with multiple atresias or apple-peel lesion, modified surgical procedures are used to improve the prognosis in infants with residual short bowel, such as the serial transverse enteroplasty (STEP) procedure.[139–141]

## Meconium Ileus

***Overview.*** Meconium ileus denotes an obstruction in the terminal ileum secondary to inspissated meconium within the distal ileum and is responsible for approximately 20% of neonatal intestinal obstruction.[142] Meconium ileus is the initial presentation in approximately 15% to 20% of patients with cystic fibrosis (CF). Although most patients who present with meconium ileus will be diagnosed with CF, up to 25% to 50% of infants with meconium ileus might have other diagnoses such as pancreatic insufficiency due to partial pancreatic aplasia or pancreatic duct stenosis or very long segment Hirschsprung disease encompassing the small bowel. Very low birth weight premature infants, infants of diabetic mothers, and those born via cesarean section may also present with meconium ileus.[143–148]



**e-Figure 102.33. Jejunal stenosis.** (A) Abdominal radiograph on day 2 of life in an infant shows several dilated upper abdominal loops with normal distal bowel gas pattern. (B) UGI confirms dilatation of the proximal jejunum, with some passage of contrast into distal loops beyond the point of stenosis.

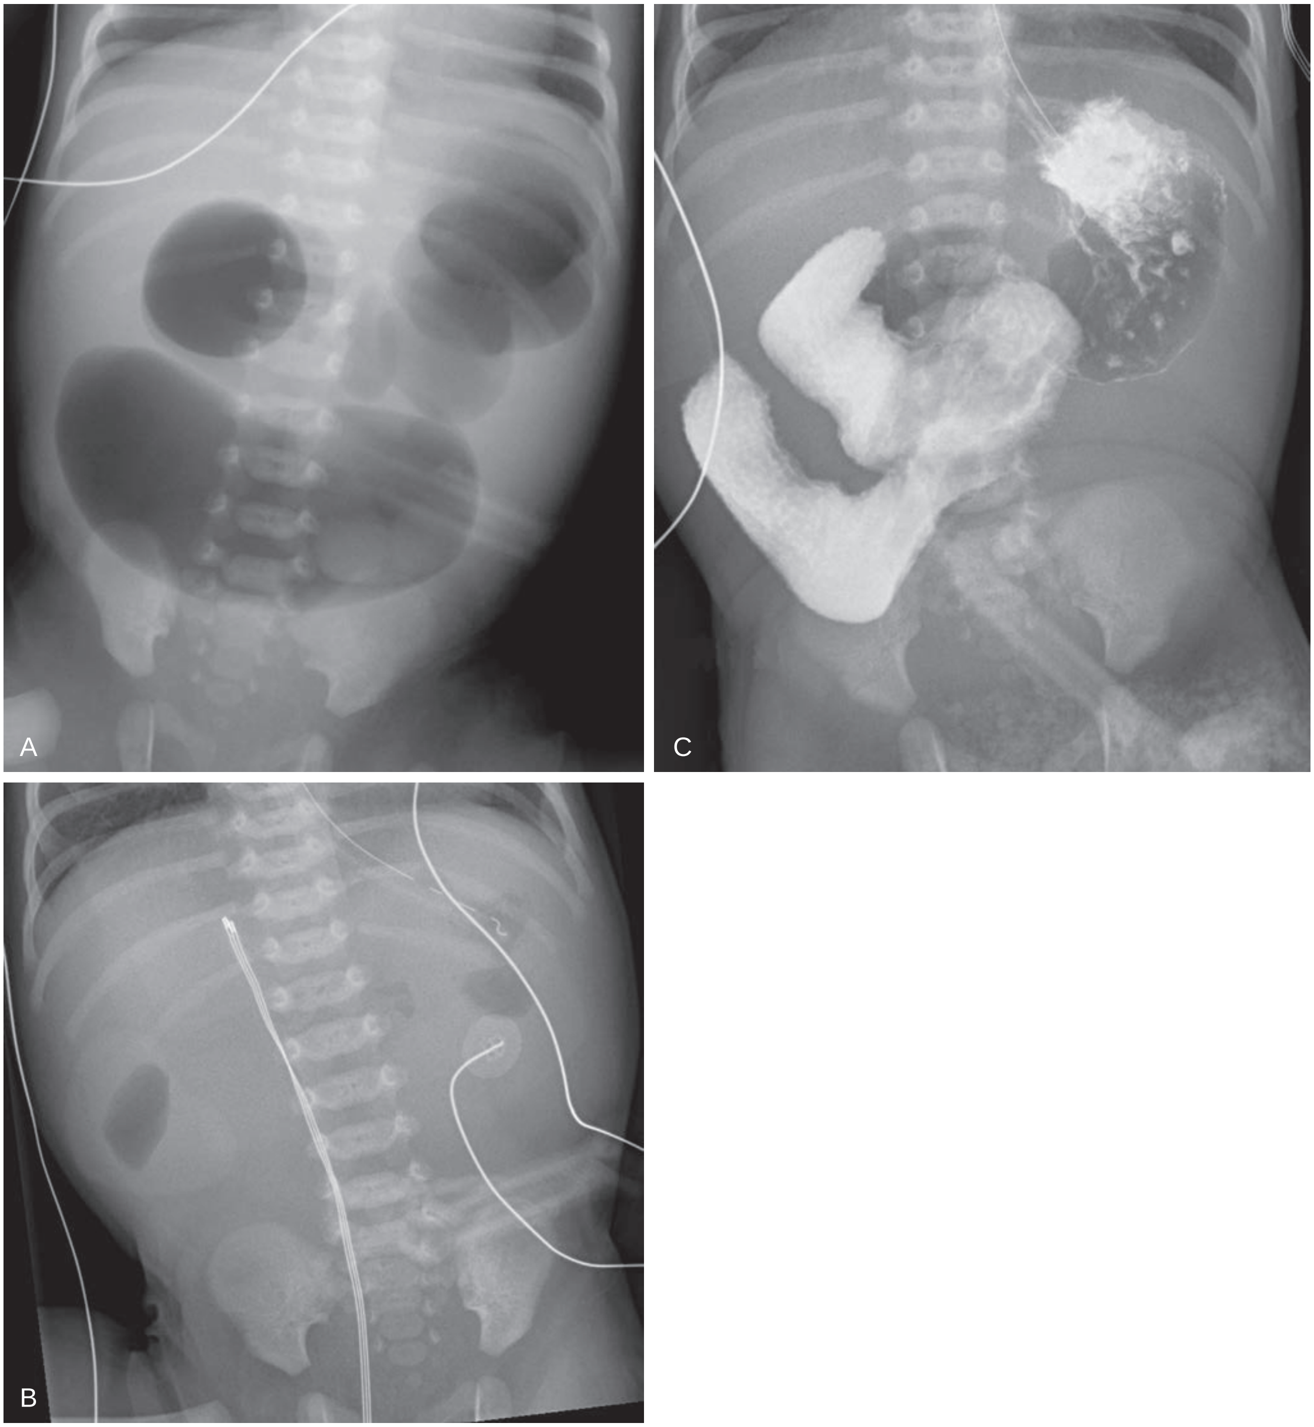


**Figure 102.31. Jejunal atresia.** (A) Abdominal radiograph on the first day of life in infant with jejunal atresia shows marked dilatation of proximal jejunal loops to the point of obstruction. Note that despite the very severe bowel dilatation, there is little distension of the flanks, and no elevation of the diaphragms, reflecting the fact that the more numerous distal bowel loops are collapsed. (B) After placement of orogastric tube, abdominal radiograph on the following day no longer demonstrates the dilated loops of bowel that were diagnostic on the initial radiograph. (C) UGI with iso-osmolal water-soluble contrast material shows close correlation with the gas-filled loops on the initial abdominal radiograph. This examination is not imperative to diagnosis but, if performed, will outline the dilated jejunal loops to the point of atresia.

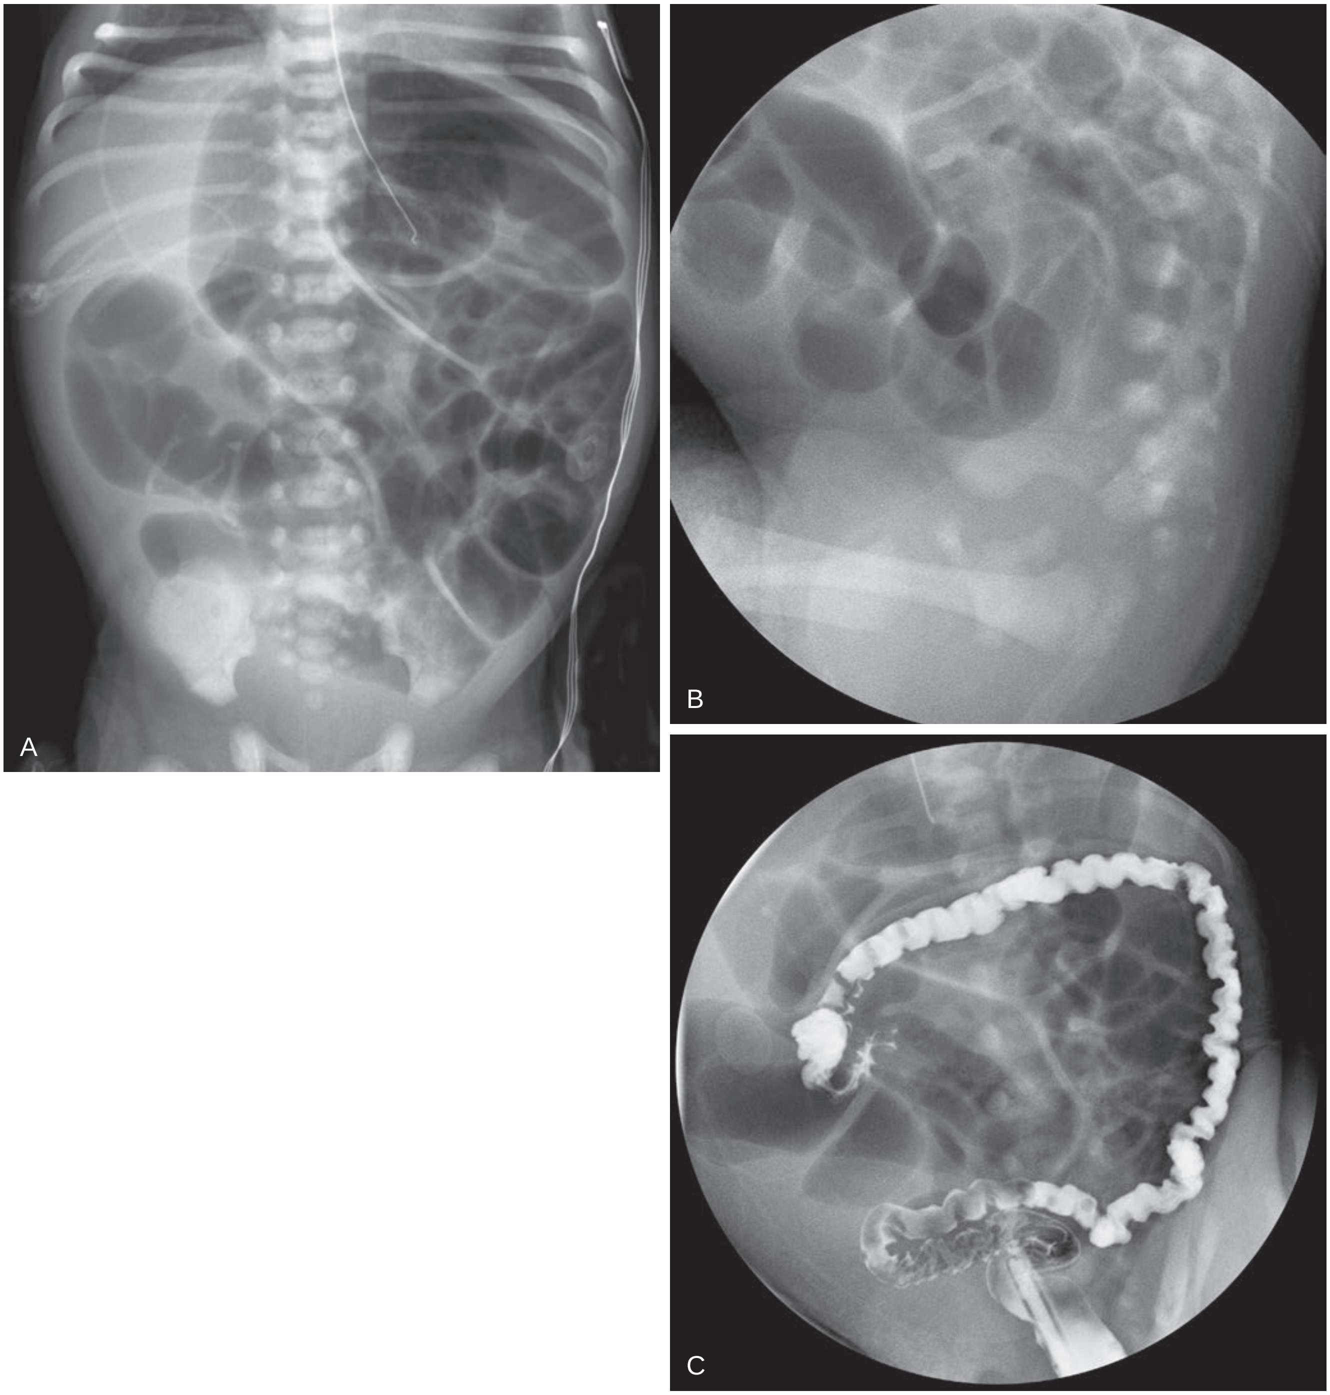

**Figure 102.32. Ileal atresia.** (A) Abdominal radiograph in infant boy demonstrates multiple dilated loops of bowel filling the abdomen. There is some distension of the flanks and elevation of the diaphragms, despite upper decompression via orogastric tube. Despite their large caliber, all of these loops represent small bowel. (B) Lateral radiograph before contrast enema demonstrates complete lack of distal gas, and none in the rectum. A catheter is present in the distal rectum. (C) Image from contrast enema demonstrates a microcolon. The colon is empty, without evidence of meconium pellets.

***Etiology.*** Patients with CF have a defect in the gene sited in locus q31.2 of chromosome 7, which encodes for the CF transmembrane conductance regulator (CFTR) protein and renders it ineffective in the regulation of chloride ion transport across the cell membranes in lungs, liver, pancreas, skin, digestive, and reproductive tracts. In the fetal gut, abnormal secretory products of the intestinal epithelial cells result in meconium with an abnormal electrolyte environment and increased concentration of protein (particularly albumin), which interact with other components of meconium, such as mucopolysaccharides. Degradation of this resultant material is impeded by abnormal concentration of pancreatic enzymes, also the result of the abnormal secretions produced by defective CFTR protein.[149,150] The meconium is markedly viscid and tenacious, and inspissates within the distal

**Figure 102.34. Meconium ileus.** (A) Schematic drawing of uncomplicated meconium ileus. Pellets of inspissated meconium fill the terminal ileum proximal to a microcolon. Several loops of more proximal ileum contain thick, tenacious meconium. (From Leonidas J.C., et al., Meconium ileus and its complications. A reappraisal of plain film roentgen diagnostic criteria. *Am J Roentgenol Radium Ther Nucl Med*. 1970;108[3]:598–609.) (B) Intraoperative radiograph shows an enterotomy of proximal bowel and the nature of the thick and tenacious meconium. Note the dilated proximal loops of bowel filled with meconium and the progressively small caliber of the distal bowel leading to the microcolon. *(Image courtesy of Dr. Wallace W. Neblett III, Nashville, TN.)*

small bowel lumen (Fig. 102.34), causing high-grade small bowel obstruction. More than 1,900 mutations of the CFTR gene have been reported with various genotype-phenotype correlations.[151]

***Clinical Presentation.*** The presentation of infants with meconium ileus is one of distal bowel obstruction, which may be complicated by in utero bowel perforation. Patients with uncomplicated or simple meconium ileus have been identified prenatally with abdominal distension, dilatation of bowel loops, and hyperechoic bowel.[152–154] Approximately 20% of the infants will have shown polyhydramnios in utero, more frequently in the subgroup with complicated meconium ileus discussed below. Postnatally the presentation will be similar to that of other infants with distal obstruction: abdominal distension, failure to pass meconium, and bilious vomiting.

Complicated meconium ileus occurs in approximately 40% to 50% of cases[143,155] and results from an in utero event secondary to the sheer volume and weight of the tenacious meconium; this can lead to a segmental volvulus, perforation with meconium peritonitis, and/or a small bowel atresia. Peritoneal meconium may be free in the peritoneal cavity or loculated into a persistent meconium cyst. Prenatal perforation might seal over in utero or may persist postnatally.

CF patients with the ΔF508 and G542X mutations have been reported to have a higher incidence of meconium ileus than patients with other mutations,[147] whereas complicated meconium ileus has been reported more frequently in patients homozygous for the ΔF508 mutation. Modifier genes located on chromosomes 4q35.1, 8p23.1, 11q25, and 19q13 have also been reported to affect the clinical presentation of infants with CF and the development of meconium ileus.[147,151] However, by the time the patients reach the age of 6 months, their prognosis is similar to those who did not present with meconium ileus.[155]

Meconium peritonitis is not specific to meconium ileus but occurs in patients in whom there has been intrauterine perforation for any reason. Occasionally a child is born with intraperitoneal calcifications in whom the perforation has sealed over and who is otherwise well, with no definable clinical sequelae (Fig. 102.35).

***Imaging.*** In infants without complicated meconium ileus, abdominal radiographs will show abdominal distension and multiple

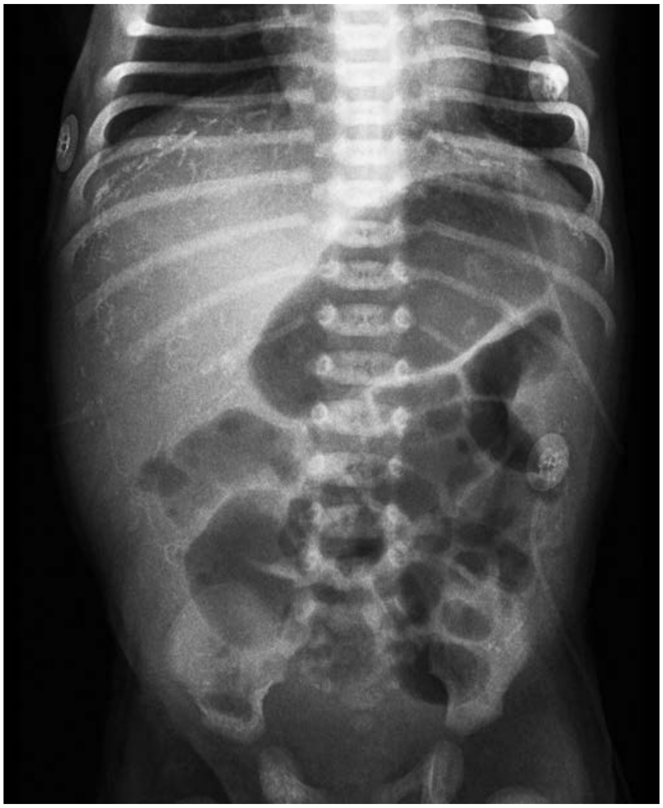

**Figure 102.35. Meconium peritonitis.** Abdominal radiograph of a 2-day-old infant with extensive intraperitoneal calcifications consistent with in utero perforation and meconium peritonitis. The child did well, without evidence of persistent perforation or obstruction, tolerated full feeds, and after appropriate observation, was discharged home.

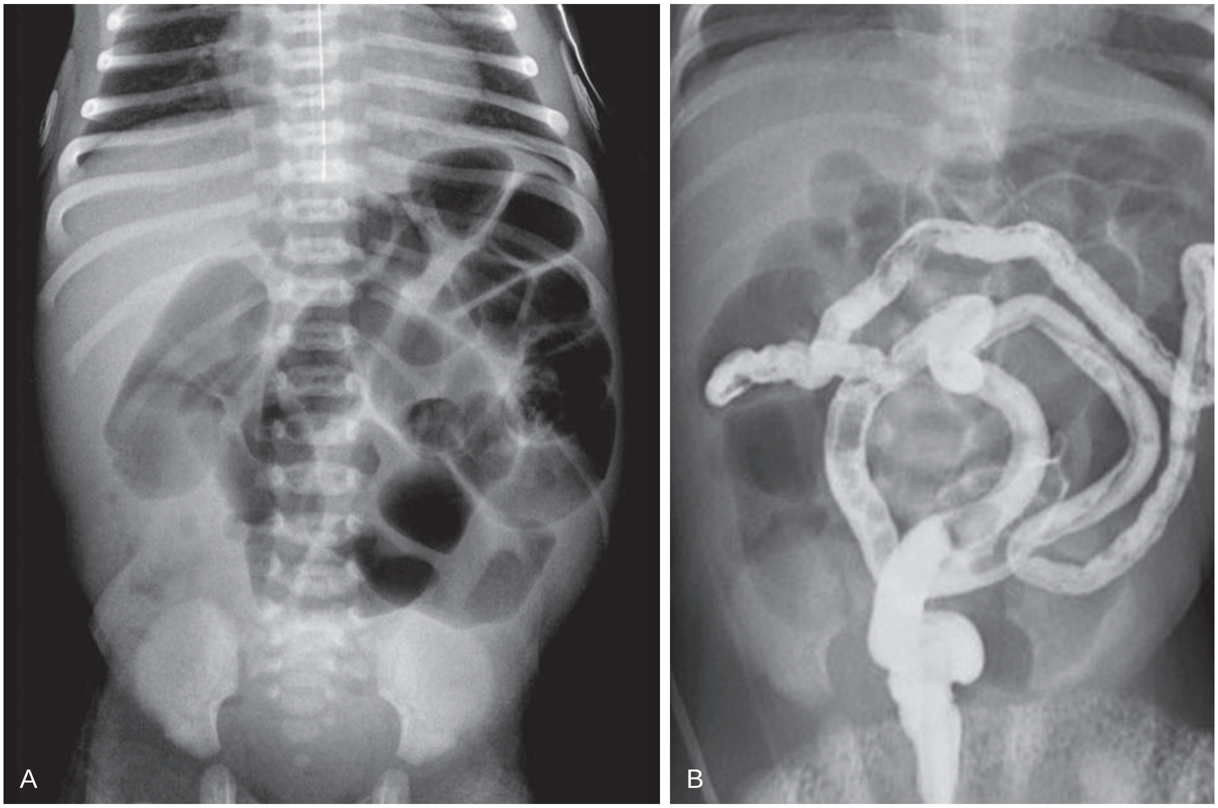

**Figure 102.36. Uncomplicated meconium ileus.** (A) Abdominal radiograph in 3-day-old infant with abdominal distension and bilious aspirates shows dilatation of multiple loops of bowel. No calcifications are seen on the radiograph to suggest complicated meconium ileus. There is an orogastric tube near the GE junction, which was subsequently advanced. (B) Contrast enema demonstrates a microcolon, with multiple meconium plugs, consistent with the diagnosis of meconium ileus. Compare with findings in Fig. 102.32C.

dilated loops of bowel, consistent with a distal obstruction (Fig. 102.36). In meconium ileus, the ileal loops are packed with meconium, which often renders a characteristic "soap bubble" appearance.[156] Air fluid levels are more typically described in patients with ileal atresia,[157] although their presence does not negate the diagnosis of meconium ileus, as loops proximal to the inspissated meconium may accumulate gas and fluid.

Radiographs of infants with complicated meconium ileus, in addition to signs of distal bowel obstruction, may show intraperitoneal calcifications consistent with meconium peritonitis and/or mass effect from a meconium cyst (Fig. 102.37A–E). Patients with such signs of complicated meconium ileus are operative candidates, not candidates for contrast fluoroscopic evaluation. Ultrasound is useful in some infants with complicated meconium ileus to document the location and size of a suspected meconium cyst (see Fig. 102.37B). Hyperechoic bowel loops, described in the fetus,[152–154] may also be seen postnatally (see Fig. 102.37C).

Similar to patients with ileal atresia, initial diagnostic imaging evaluation in the infant with simple meconium ileus is via contrast enema. As previously discussed, the diagnostic examination is with water-soluble contrast material diluted to a near iso-osmolal concentration. Barium is not recommended, as barium inspissated within the tarry meconium is unlikely to prove helpful, it is not necessary for diagnosis and can cause complications in case of perforation. Hyperosmolal material as the initial contrast medium may be harmful if the diagnosis proves to be a different abnormality, such as Hirschsprung disease. (See Chapter 84 for additional information on technique.) As is the case in patients with ileal atresia, the contrast enema in patients with meconium ileus will reveal an unused microcolon. However, in patients with meconium ileus in whom the distal ileum is impacted with tarry, tenacious meconium, small meconium pellets may be seen within the microcolon (see Fig. 102.36B). If contrast refluxes into the distal ileum, meconium pellets may be identified; if contrast reaches into the dilated loops of bowel, ileal atresia is excluded. However, contrast may not reflux readily into the dilated bowel loops in patients with meconium ileus due to inability to traverse the segments with inspissated meconium; in some cases, final diagnosis may rest on the surgical findings.

***Treatment.*** Patients with complicated meconium ileus are managed surgically; there is no role for an enema procedure in these patients.

Surgical removal of the obstructing meconium was the original treatment for simple meconium ileus,[158] but since Noblett's 1969 report, the Gastrograffin contrast enema is usually the initial treatment in patients with uncomplicated meconium ileus. Its success has been attributed to the hyperosmolarity of the contrast medium, as well as to the surfactant properties of polysorbate 80 (Tween 80).[159] Expected complications related to hyperosmolarity of the agent and subsequent fluid and electrolyte shifts can be managed with careful monitoring and replacement. Before the procedure, the patient should undergo adequate fluid and electrolyte replacement. Surgical consultation and stand-by are imperative.

Subsequent investigators have reported problems with bowel necrosis after administration of the Gastrografin enema[160] ascribed to the polysorbate component, which has been found to cause mucosal damage and necrosis in experimental animals.[161] For these reasons, many pediatric radiologists avoid Gastrografin during the therapeutic enema and utilize other moderately hyperosmolar media for relief of obstruction. A 1995 survey of pediatric radiologists in

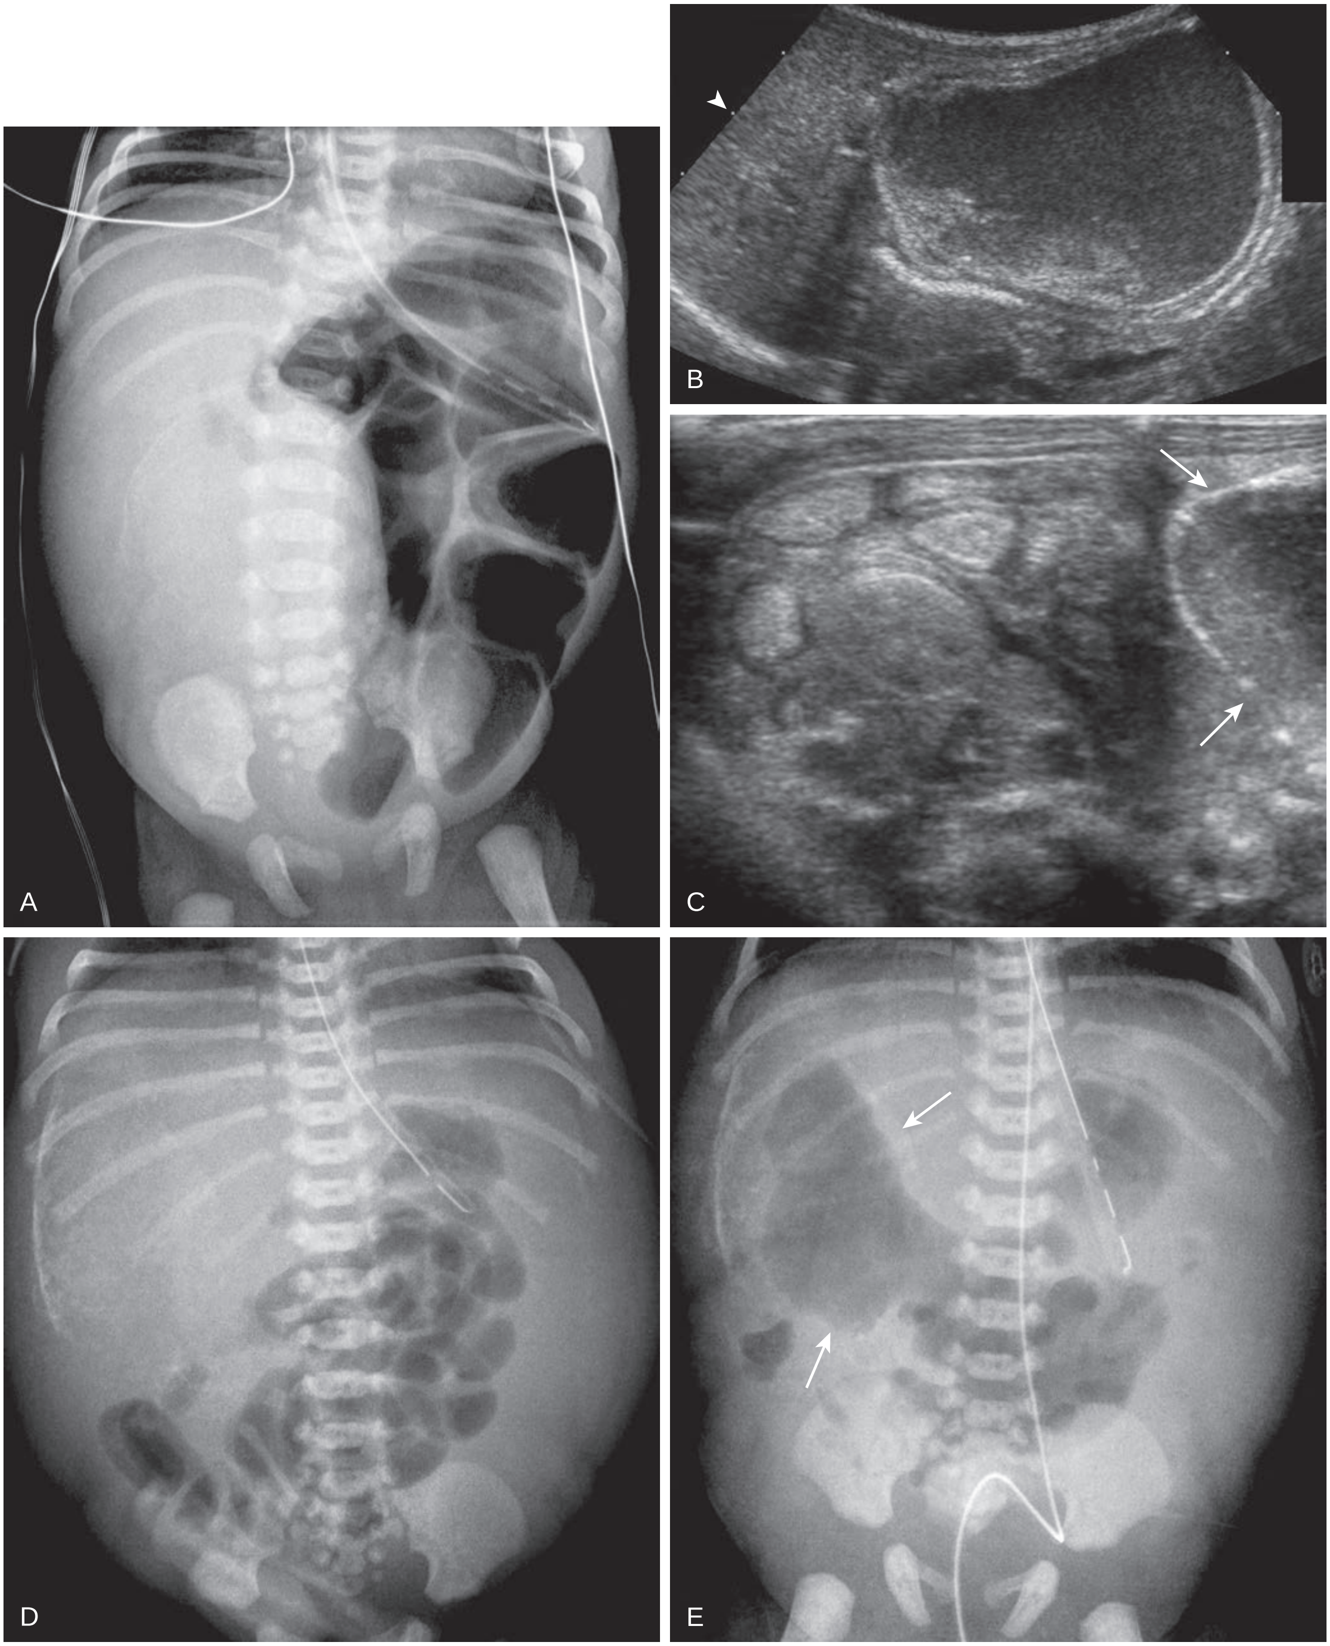

**Figure 102.37. Complicated meconium ileus.** (A) Abdominal radiograph in a 2-day-old girl with abdominal distension and bilious aspirates shows absence of bowel gas in the right abdomen with a partly calcified mass displacing gas-filled dilated loops of bowel to the left. (B) Ultrasound image demonstrates the subhepatic partly calcified mass with internal debris and fluid-fluid level. (C) Additional ultrasound image shows a portion of the cyst wall *(arrows)* and multiple, abnormal, hyperechoic loops of bowel. (D) Abdominal radiograph on a different 1-day-old infant shows a calcified mass in right upper quadrant, shown at sonography to represent a loculated complex meconium collection. (E) Radiograph a few hours later of the same infant shown in (D) shows a persistent perforation with gas entering into the right upper quadrant collection.

North America showed a higher success rate when an additive such as N-acetylcysteine (Mucomyst) was used but showed no correlation of success rate with contrast medium; reported perforation rate was 2.75%, with a higher risk of perforation in cases in which balloon occlusion of the rectum was used.[162]

Therapeutic enema may need to be repeated for definitive resolution of the obstruction; success may be at least partly dependent on perseverance of the operator, as the contrast material does not easily advance beyond the obstructing meconium into the dilated loops of bowel. The reported success rates vary but are most often quoted to be between 40% and 65%.[155,162,163] Close postprocedure monitoring of the infant is mandatory.

Surgery is indicated for patients in whom the therapeutic enema is unsuccessful.

## Meckel Diverticulum and Other Omphalomesenteric Duct Remnants

***Overview.*** Meckel diverticulum is found in approximately 1% to 4% of the population and is typically located within 100 cm from the ileocecal junction[164]; however, its location can be variable, being reported as up to 5 feet from the ileocecal valve.[165]

***Etiology.*** The Meckel diverticulum is a remnant of the vitelline or omphalomesenteric duct, the communication between the embryonic gut and the yolk sac that normally obliterates by the fifth to seventh week of gestation. Failure of obliteration of the duct leads to several results (e-Fig. 102.38). The ileal portion of the duct may remain as a Meckel diverticulum, located on the antimesenteric border, and containing all layers of the bowel wall. If the entire duct remains patent, the result is an umbilicoileal fistula. The lumen of the duct may obliterate, but the duct may remain as a fibrous cord, attaching the ileum or a Meckel to the anterior abdominal wall at the umbilicus. A focal, isolated part of the duct may remain open as a vitelline cyst.[165,166]

***Clinical Presentation.*** The vast majority of Meckel diverticula remain asymptomatic, with a complication rate estimated at 4% to 6%, decreasing with age.[166–168] Although the prevalence of diverticula is similar in both genders, symptoms are more likely to occur in males and in younger patients.[166–168] In a recent series encompassing more than four million admissions to children's hospitals, symptomatic Meckel were found to be more prevalent in whites and less frequent in African Americans.[167] The most common clinical presentation is that of painless rectal bleeding; Meckel diverticulum accounts for approximately 50% of lower GI bleeding in infants and toddlers, typically occurring as a complication of gastric mucosa within the diverticulum. The incidence of gastric mucosa within bleeding Meckel diverticula is estimated at approximately 23% to 80%.[165,166] Heterotopic pancreatic tissue, consisting of acini, ducts, and islets, is found in 5% to 16% of cases.[166] In addition to bleeding, gastric and pancreatic mucosa can lead to inflammation of the diverticulum, with abdominal pain mimicking appendicitis that can similarly evolve into perforation and/or obstruction.[165,169,170] Meckel diverticula can also torse,[171] particularly when very large (so called "giant diverticula").

Meckel diverticulum can present as distal small bowel obstruction through a variety of other mechanisms. The diverticulum may invert into the ileal lumen and serve as a lead point for intussusception. If there is a persistent attachment of the ileum or of the diverticulum to the umbilicus, this anchor can serve as a pivot point for a segmental volvulus, or the umbilical attachment can act as an adhesion to cause simple or closed loop obstruction. The Meckel diverticulum can become incarcerated in an inguinal hernia, known as a *Littre hernia*.[166] Patients with obstruction present with abdominal pain and vomiting, which can be complicated by bleeding in cases of intussusception.

Meckel can also present with neoplasia, typically in adult patients; the tumors are most commonly carcinoids, and complications include luminal obstruction and intussusception. Meckel diverticula may contain enteroliths and may also present with parasitic infections and lodged ingested foreign bodies.[165] Ulceration of the diverticulum can result in perforation, and this has been reported in preterm neonates[172]; ulceration is associated with gastric mucosa but not with *Helicobacter pylori* infection.[165,173]

***Imaging.*** Radiographs are not particularly helpful in the diagnosis of Meckel diverticula except as indicators of some of its complications. Fluoroscopic examination such as small bowel follow-through requires very careful technique and may be able to demonstrate the antimesenteric saccular outpouch from the distal ileum, particularly when enteroclysis is performed, or when the diverticula are larger, such as the "giant" diverticula that measure greater than 5 to 6 cm in diameter and up to 15 cm in length.[166] However, small diverticula may be inconspicuous and difficult to detect among multiple bowel loops.

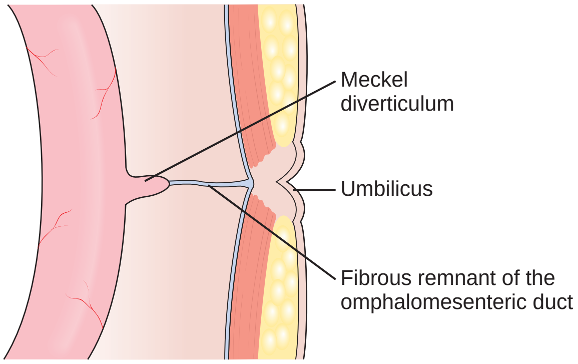
The most well-known imaging examination for detection of Meckel diverticula is the technetium pertechnetate abdominal scintigram (see Chapter 84).[174] This examination is dependent upon the presence of gastric mucosa, with a reported sensitivity of 80% to 90%, specificity of 95%, and accuracy of 90% in pediatric patients[175]; accuracy may be lower in patients with bleeding who present with a hemoglobin less than 11g/dL.[174] Use of single photon emission computed tomography (SPECT) has been reported to improve detection over conventional planar imaging.[166,176] Duplication cysts with gastric mucosa are part of the differential diagnosis in a positive scan but often can be differentiated clinically or with other cross-sectional imaging modalities.

In patients with inflamed diverticula, sonography can detect the inflamed diverticulum, which appears as a blind-ending structure, surrounded by inflammation (Fig. 102.39A).[177,178] On cross-sectional imaging, the findings may be very difficult to distinguish from appendicitis (Fig. 102.39B); however, in other cases, a larger size and periumbilical location may indicate the correct diagnosis preoperatively (Fig. 102.39C). In patients in whom there is intussusception, the diagnosis can be made with cross-sectional imaging (e-Fig. 102.40).[166,179,180] Inverted diverticulum can also act as a lead point in ileo-ileo-colic intussusception (Fig. 102.41). On MRI, the inflamed Meckel may be visible, and differentiation from appendicitis may be aided by the identification of blood products within some diverticula.[181]

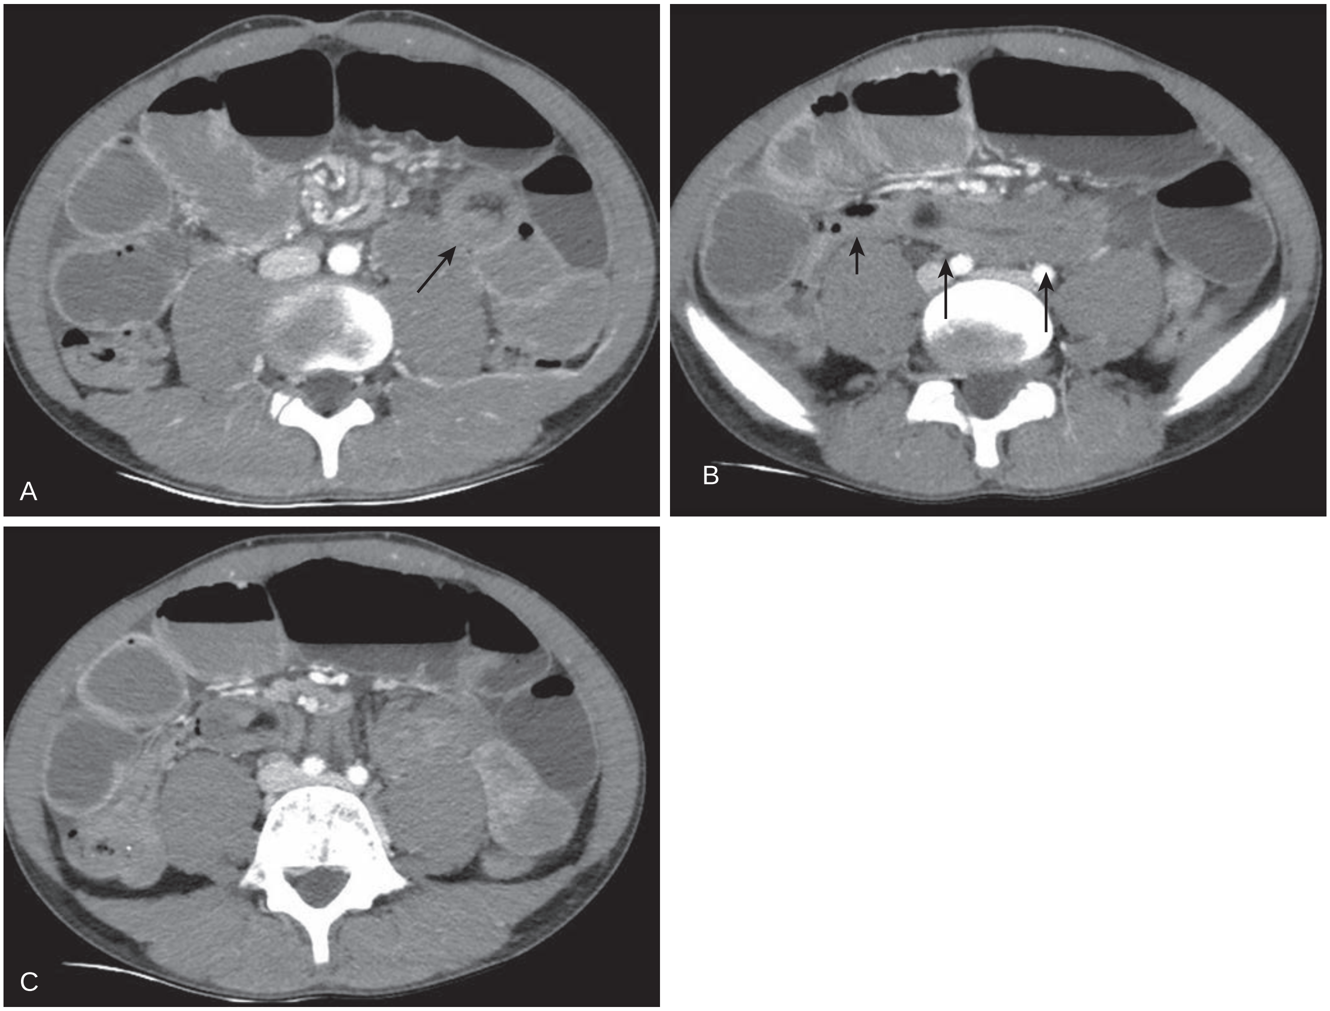
***Treatment.*** The treatment of complicated Meckel diverticula is surgical resection, including the adjacent base to ensure removal of all ectopic mucosa. However, the treatment of diverticula that are asymptomatic and incidentally discovered during surgery for another reason is less clear. The potential for the development of complications needs to be weighed against the potential for postsurgical complications, reported as 1% to 2% for patients with incidental resection, with a mortality rate of 0.001%.[165] Considerations include higher risk factors for complications existing at the time of incidental discovery, such as younger age and male gender,[182] and the increased risk of neoplasia in older age groups.[183] Laparoscopic or laparoscopically assisted removal is advocated,[184,185] and some investigators suggest that laparoscopy can replace the Meckel technetium scan in patients with a high clinical suspicion.[165,184]

## Duplication Cysts

***Overview.*** Duplication cysts of the GI tract are characterized by contiguity with and adherence to a segment of the alimentary tract by a smooth muscle coat, mucosal lining including one or more types of cells found within any portion of the alimentary canal, and a shared blood supply with native GI structures.[186] They can occur anywhere along the length of the GI tract from the mouth to the anus. In the abdomen, they are most common in the terminal ileum and ileocecal valve[187]; duodenal duplications account for approximately 6% of the total and are therefore



**e-Figure 102.38.** Diagrammatic representation of omphalomesenteric duct remnants. Meckel diverticulum is a true diverticulum containing all layers of the bowel wall, arising from the antimesenteric wall of the ileum. It may be free in the peritoneal cavity, or may remain attached to the abdominal wall at the umbilicus via a fibrous remnant of the omphalomesenteric duct, as depicted here. The omphalomesenteric duct can exist without a Meckel, either patent as an umbilicoileal fistula, as a fibrous cord, or a portion may be patent as a vitelline cyst.



**e-Figure 102.40. Meckel diverticula with intussusception.** (A–C) Small bowel intussusception with Meckel diverticulum lead point. More proximal CT image (A) shows a small bowel obstruction, with multiple dilated small bowel loops and collapsed right and left colon. *Arrow* points to the beginning of a small bowel intussusception. More distal CT image (B) shows the small bowel intussusception with a fat density lead point *(arrows)*, which at surgery and pathology proved to be a lipoma at the base of a Meckel diverticulum. Additional image (C) below the level of the long intussuscepted loop shows the diverticulum to better advantage.

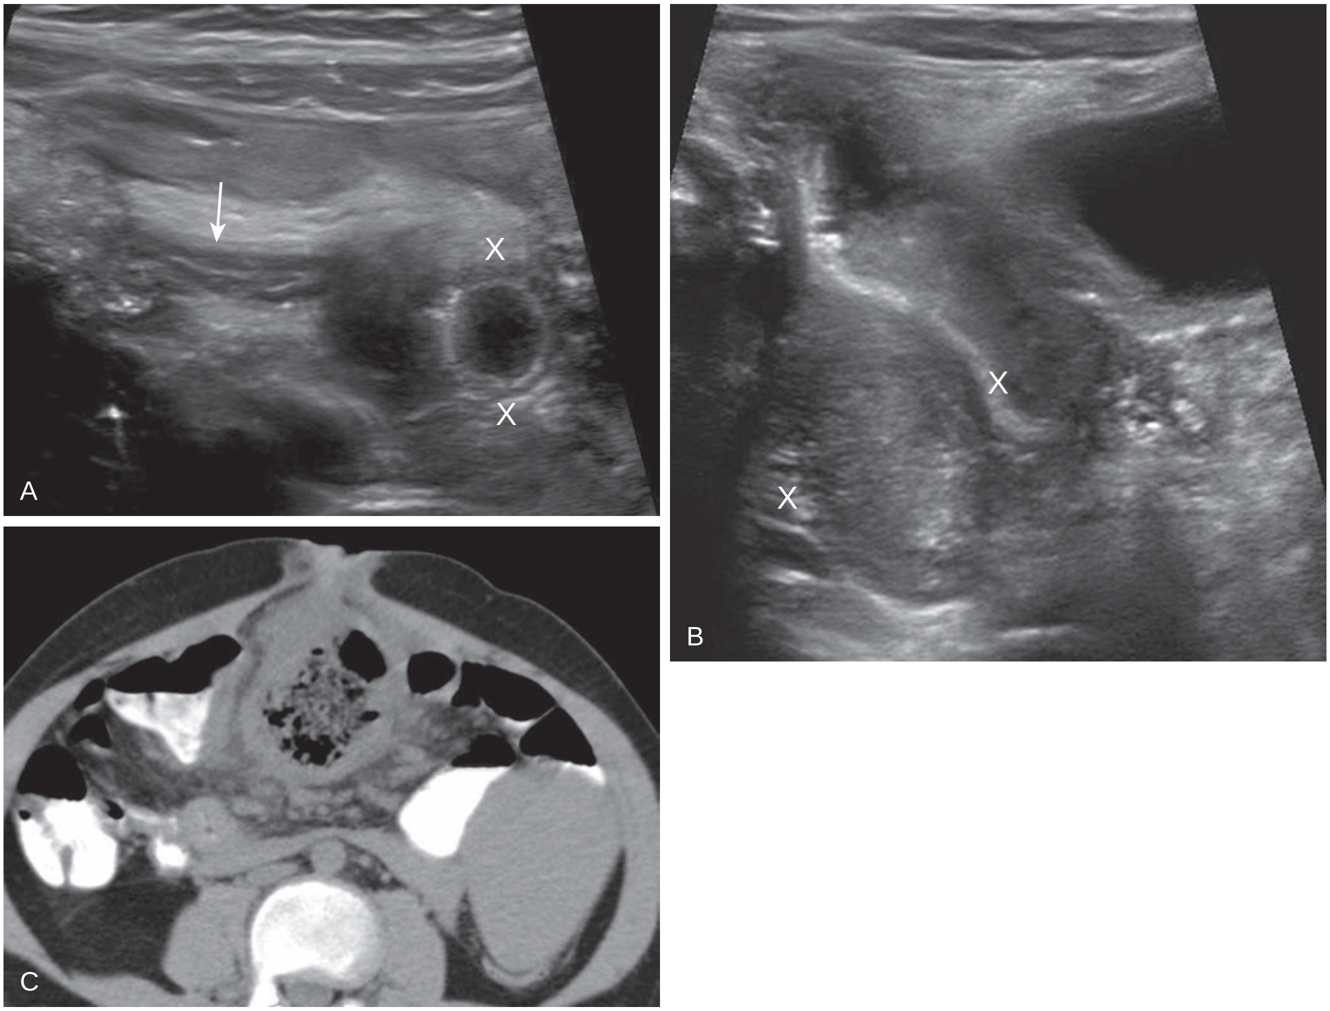


**Figure 102.39. Meckel diverticulum.** (A) Sonogram in a 4-year-old girl with abdominal pain and concern for appendicitis shows a normal appendix *(arrow)* with surrounding inflammation. There is a blind ending structure (between *X calipers*) measuring approximately 10 mm in diameter, which at surgery was a perforated Meckel diverticulum. (B) Sonogram in a 2-year-old girl with abdominal pain and concern for appendicitis. A normal appendix was seen on other images. There is a 12-mm thick-walled structure (between *X calipers*) that at surgery was an inflamed Meckel diverticulum with tip perforation. (C) CT image of an adolescent boy with abdominal pain demonstrates a large, inflamed loop of bowel with fecalized contents in close association with the umbilicus, representing an inflamed Meckel diverticulum.

uncommon.[188] Unlike the Meckel diverticulum, which is located on the antimesenteric border of the intestine, duplication cysts occur along the mesenteric border of the involved bowel loop and, in the duodenum, are found medial to the descending limb or along its third portion. Most of the cysts do not communicate with the intestinal lumen; a communication may be present in some of the tubular duplications.

***Etiology.*** The exact etiology of alimentary tract duplications remains unknown, although there are several theories that attempt to explain their origin. One theory is that duplication cysts result from incomplete attempts at twinning, a theory that also suggests an explanation for duplications of other organs, such as the bladder and urethra, which at times can accompany GI duplications. Duplications associated with anomalies of the spine (neurenteric cysts, found more commonly in the chest) may result from a split notochord with herniation of a foregut diverticulum. A third theory is that these anomalies are the result of diverticula that form during the recanalization stage of the bowel. A fourth hypothesis suggests that environmental factors, such as trauma or hypoxia, can induce events that can result in an enteric duplication.[188] No single theory explains all the instances of duplication anomalies, and it may be that more than one theory may be pertinent to the various types of anomalies.

***Clinical Presentation.*** The presentation of duplication cysts is usually related to their size, to their location, to the type of mucosal lining, to whether they are cystic or tubular, and to whether they are associated with other anomalies. Large cysts can present with mass effect or as a palpable mass. Duodenal duplication cysts can present as gastric outlet obstruction, failure to thrive, or pancreatitis possibly related to compression of the pancreatic duct,[189] and have also been reported to cause a fluid collection within the lesser sac.[190] Cysts containing gastric mucosa can ulcerate, bleed, and lead to inflammatory changes, presenting with abdominal pain and vomiting. Duplication cysts may act as a fulcrum for segmental volvulus[187]; those located in the terminal ileum and ileocecal valve may act as a lead point in intussusception and should be suspected when intussusception occurs in infants within the first 3 months of life (see chapter 107). Duplications may be multiple in as many

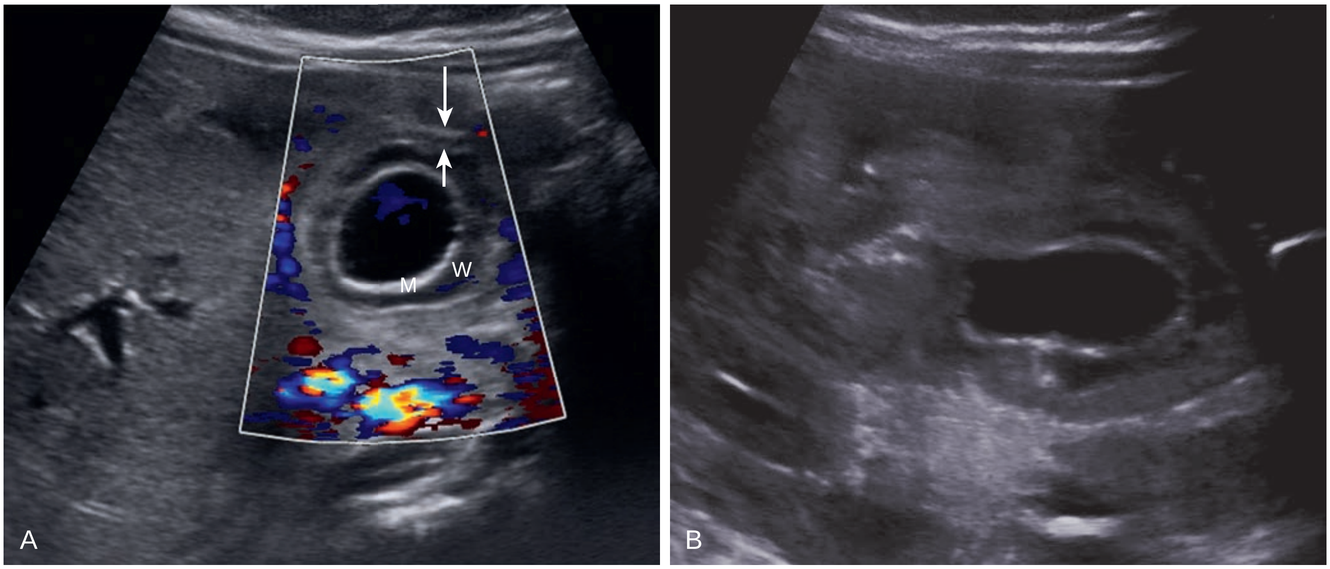

**Figure 102.41. Inverted Meckel diverticulum with ileo-ileo-colic intussusception in a 2-month-old infant.** (A) Transverse color Doppler sonogram of the distal tip of the intussusceptum complex shows a cystic lead point. *Arrows* outline the wall of the intussuscipiens; *W*, Diverticular wall; *M*, hyperechoic mucosal lining. (B) Longitudinal sonogram shows the diverticulum at the leading edge of the intussusception.

as 10% to 20% of patients, vertebral anomalies may be present, particularly in lesions that are supplied by vessels on both sides of the mesentery,[191] and there may be urinary tract anomalies.[192]

***Imaging.*** In duodenal duplication cysts, plain radiographs may demonstrate a soft-tissue mass or obstruction, with the mass effect seen along the distal aspect of the stomach or the duodenum.

Upper GI series could be the first study obtained in a child presenting with vomiting; in cases of duplication cysts of the duodenum, the examination reveals a filling defect along the mesenteric wall of the duodenum or extrinsic compression (Fig. 102.42A). Compression of the gastric outlet or of the first portion of the duodenum by the cyst has been described as a “beak” sign.[193] If there is focal communication between the cyst and the duodenum, contrast will enter the duplication. On CT and ultrasound (Fig. 102.42B–D), duodenal duplication cysts will be seen as cystic structures along the mesenteric border of the duodenum, with the characteristic hypo/hyperechoic wall typical of gut signature.

In large duplications of the small bowel, abdominal radiographs may demonstrate a mass (e-Fig. 102.43A and B). Cross-sectional imaging will demonstrate the cystic structure of the lesion, and the specific segment of bowel involved should be identified (e-Fig. 102.43C).

Small bowel duplication cysts may also present with obstruction, inflammation, intussusception, or a combination. As noted earlier, ultrasound typically reveals an anechoic cyst, but the fluid may contain debris if there has been infection or hemorrhage from associated ectopic gastric mucosa and ulceration (e-Fig. 102.43D). Typical “bowel wall signature” of an enteric duplication cyst is usually present.[194–196] The presence of bowel wall signature may help to differentiate a duplication cyst from a pancreatic pseudocyst in a patient presenting with pancreatitis, if the cyst is located within the pancreatic head. However, the gut signature is not fully sensitive or specific to duplication cysts; the gut signature may be obliterated by superimposed inflammatory changes and may be mimicked in other conditions, such as mesenteric cyst, cystic teratoma,[197] and ovarian cysts.

CT demonstrates a discrete fluid-filled cyst on the mesenteric border of the involved bowel segment often with bright enhancement of the cyst wall if there is inflammation (e-Fig. 102.43E). On MRI, as is the case with ultrasonography, hemorrhage or infection can alter the signal characteristics of the cyst contents. MRI is particularly helpful in cases of duodenal duplication cyst, when accompanied by MRCP, which can demonstrate the relationship of the cyst to the duodenal wall, as well as to the pancreatic head and the pancreatic and biliary ductal systems, which is important preoperative information.[188]

***Treatment.*** The most common treatment for duplication cysts is resection, although marsupialization with internal drainage may also be utilized in appropriate cases. Cysts with gastric mucosa should be excised or stripped of the mucosal lining; complex cases may require more extensive surgical excision.[188]

## Heterotopic Gastric Mucosa

***Overview.*** Although heterotopic gastric mucosa is most commonly associated with Meckel diverticula and with duplication cysts, it can also be found as an isolated anomaly anywhere along the intestinal tract.[198,199]

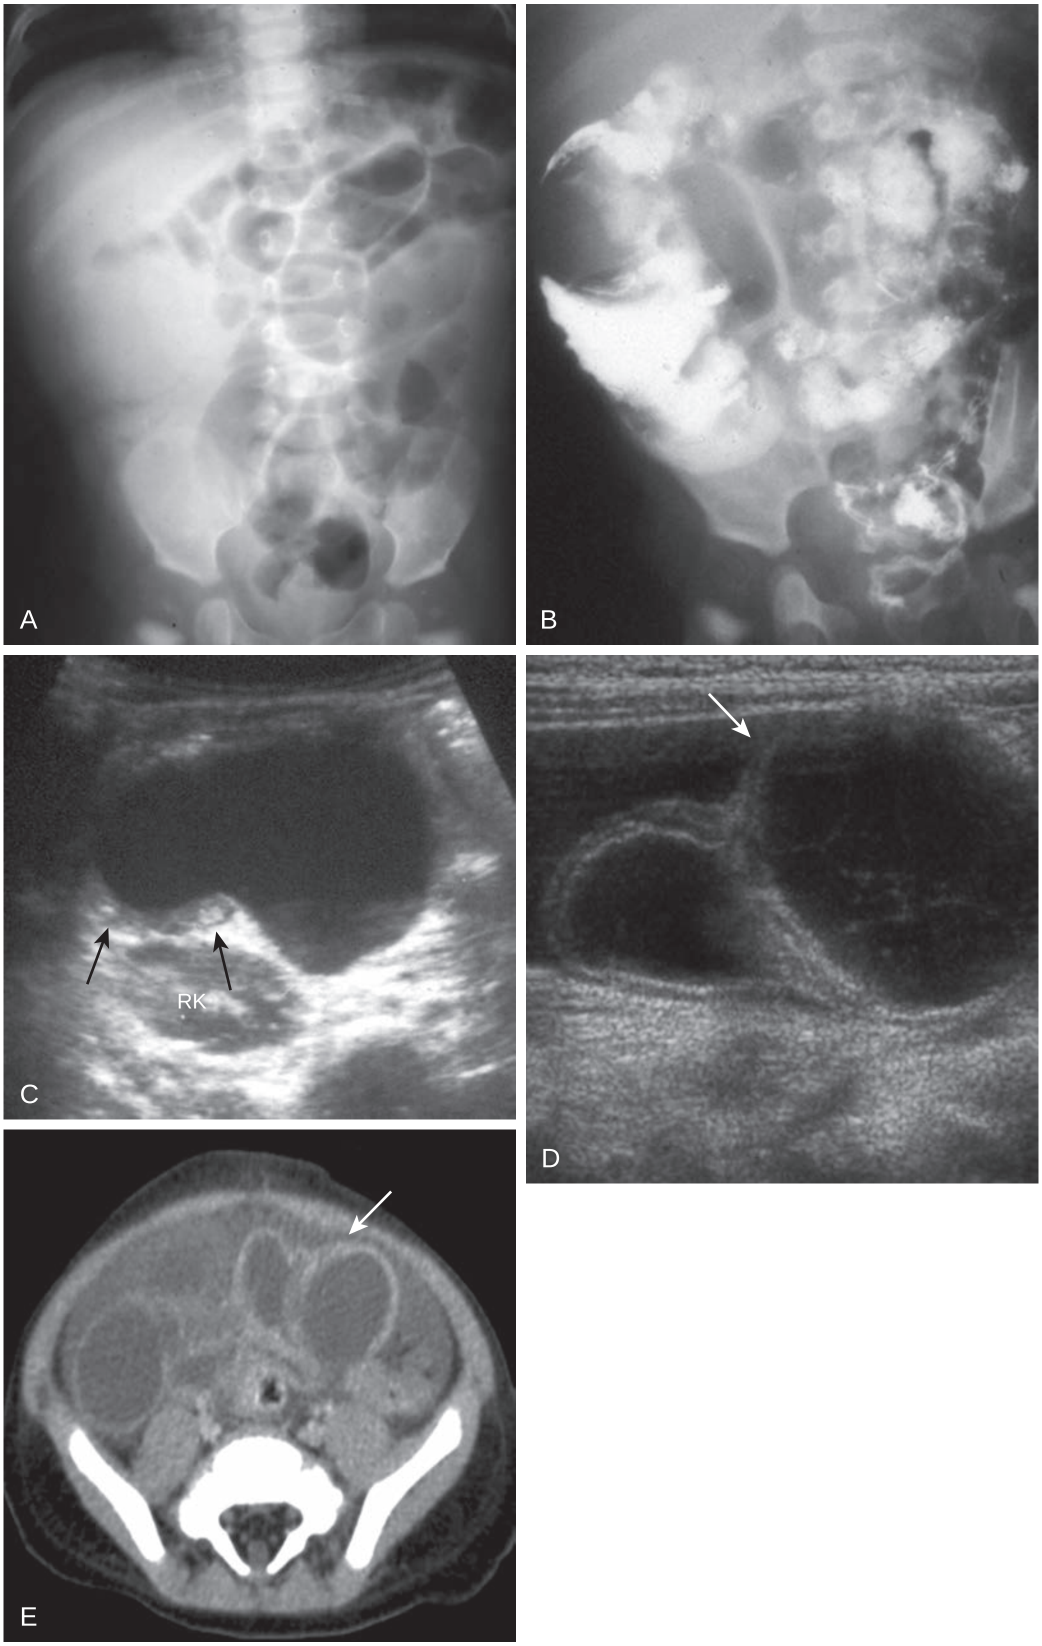
***Clinical Presentation.*** Patients can present with bleeding which can be life-threatening.

***Imaging.*** In the jejunum, heterotopic gastric mucosa often has an appearance of polypoid masses that extend into the bowel lumen. Because by definition these rests contain gastric mucosa, the diagnosis is best made with a technetium pertechnetate scan, although this rare lesion can be confused with the more common Meckel diverticulum. The diagnosis can also be made on contrast-enhanced CT with negative oral contrast material, in which the lesions may appear as hyperenhancing polypoid intraluminal lesions (Fig. 102.44).

***Treatment.*** As with Meckel diverticula and duplication cysts, the treatment is lesional excision.

## Lymphatic Malformations, Mesenteric and Omental Cysts

***Overview.*** Abdominal lymphatic malformations can be located in the mesentery or omentum as mesenteric or omental cysts. Lymphatic malformations have only an endothelial lining and contain lymphoid tissue within their walls, are usually multiloculated,



**e-Figure 102.43. Ileal duplication cysts.** (A) Plain abdominal radiograph on a 4-month-old infant presenting with vomiting at an outside institution demonstrates dilated loops of small bowel and mass effect along the right flank. (B) UGI was followed through to the ascending colon. The mass effect upon the ascending colon was mistaken for an intussusception, and the child was referred to a pediatric institution for further evaluation and reduction. (C) Axial sonogram demonstrates a large cystic mass in the right flank, with mass effect upon the adjacent, empty colon *(arrows)*. At surgery, a duplication cyst attached to the terminal ileum was identified and resected. *RK*, Right kidney. (D) Ultrasound of lower abdomen in a 3-year-old girl presenting with vomiting, abdominal pain, and abdominal distension reveals duplication cyst *(arrow)* containing echogenic debris, sharing a common wall with the distal ileum. Note that the distal ileum retains the gut signature, but this is partly absent within the duplication cyst. There is surrounding ascites. (E) Contrast-enhanced CT scan demonstrates enhancement of both the duplication cyst *(arrow)* and the adjacent ileal loop with which it shares a common wall. Ascites and findings of bowel obstruction with dilated loops of proximal bowel are seen. At surgery, an ileal duplication cyst was resected.

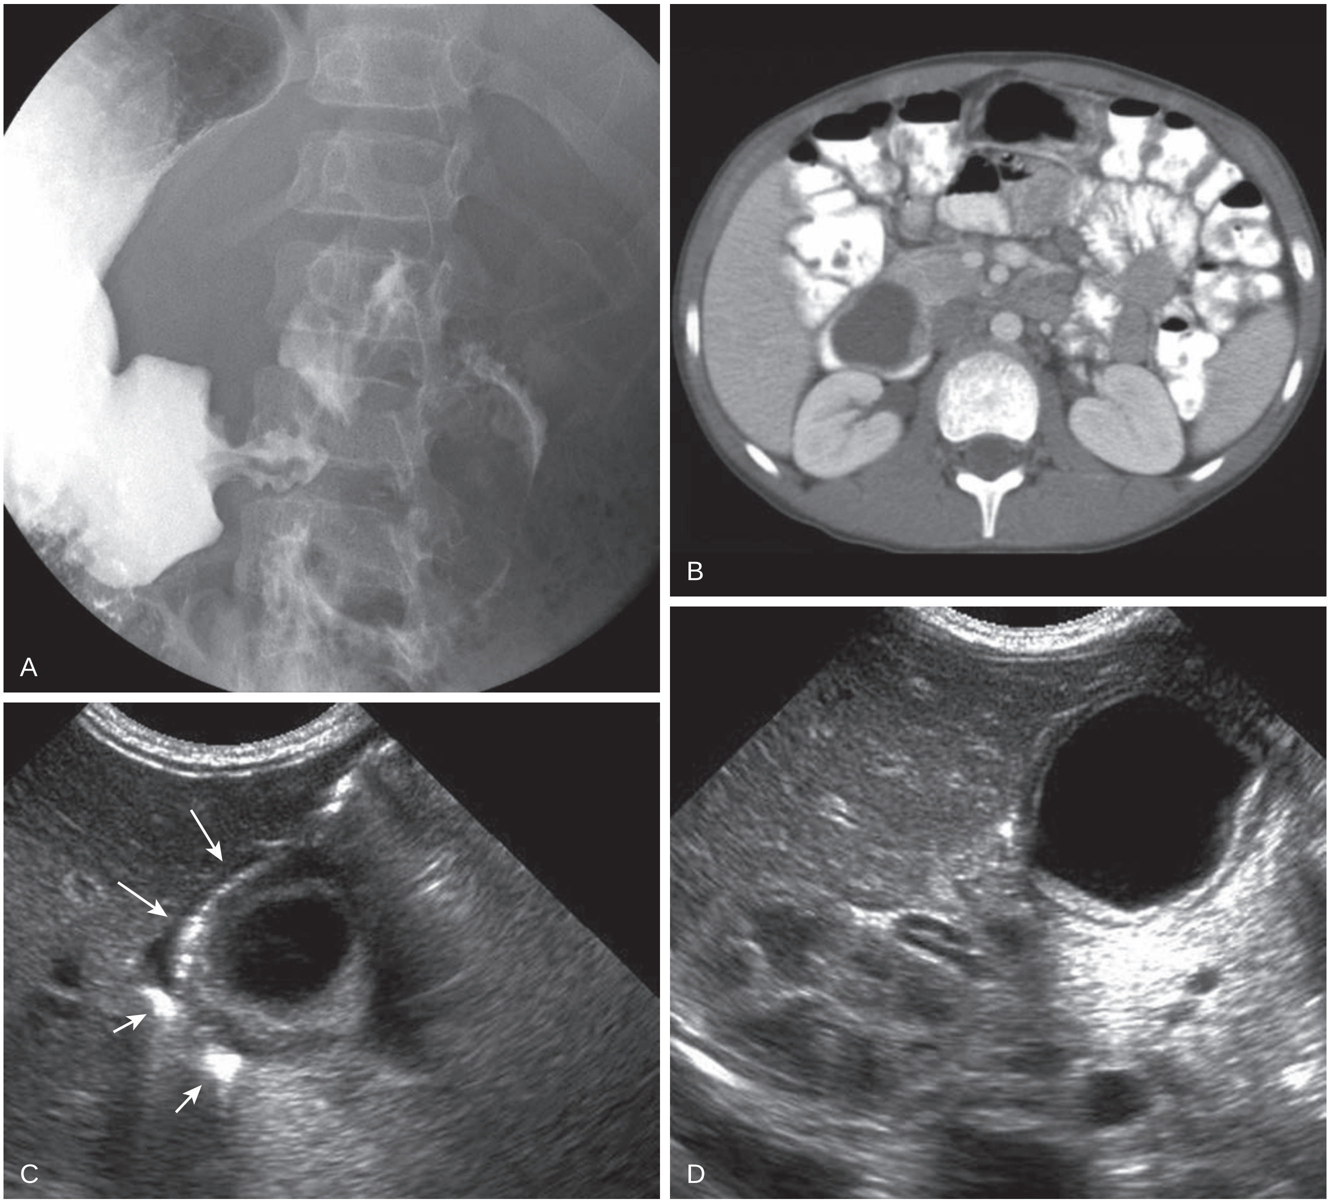


**Figure 102.42. Duodenal duplication cysts.** (A) UGI image in an 11-year-old boy demonstrates intramural mass effect upon the mesenteric border of the duodenum. (B) CT with oral and intravenous contrast on same patient in (A) again shows the location of the cystic mass along the mesenteric border of the duodenum encroaching upon its lumen. (C and D) 1-day-old infant with vomiting and prenatal diagnosis of abdominal cyst. (C) Sonogram shows the cyst to be intimately related to the distal antrum *(long arrows)* and the descending duodenum *(short arrows)*. (D) Additional image on same patient demonstrates the typical hypo/hyperechoic double layer of a duplication cyst, typical of gut signature.

and may contain chyle. The most common type of mesenteric or omental cyst is the lymphatic malformation, and most of these tend to occur in the mesentery rather than the omentum, because of its richer lymphatic content, most commonly in the ileal mesentery.[200,201]

Mesothelial cysts, on the other hand, occur in the small bowel, the mesentery, and the mesocolon, and are the result of accumulation of fluid between mesothelial layers. These cysts are therefore lined by mesothelium, without mural muscle fibers or lymphatic structures.[202] Nonpancreatic pseudocysts may also occur in the mesentery, or more often, in the omentum, and are believed to result from prior trauma or infection, with no inner cellular lining on histology.

***Etiology.*** The etiology of lymphatic mesenteric and omental cysts is not known; hypotheses include failure of embryonic lymphatic spaces to develop normal connections and drainage into the venous system, and benign proliferation of ectopic lymphatics sequestered from the venous system.[200] Mesothelial cysts and nonpancreatic pseudocysts are previously discussed.

***Clinical Presentation.*** Abdominal lymphatic malformations are rare, representing approximately 5% of lymphatic malformations occurring in all other areas, and with a prevalence of approximately 1 per 20,000 admissions, with a lower incidence in African Americans.[200,203] In the pediatric population, presentation is more common in males, although in adults the presentation is more common in females, through a putative estrogenic effect.[204] These

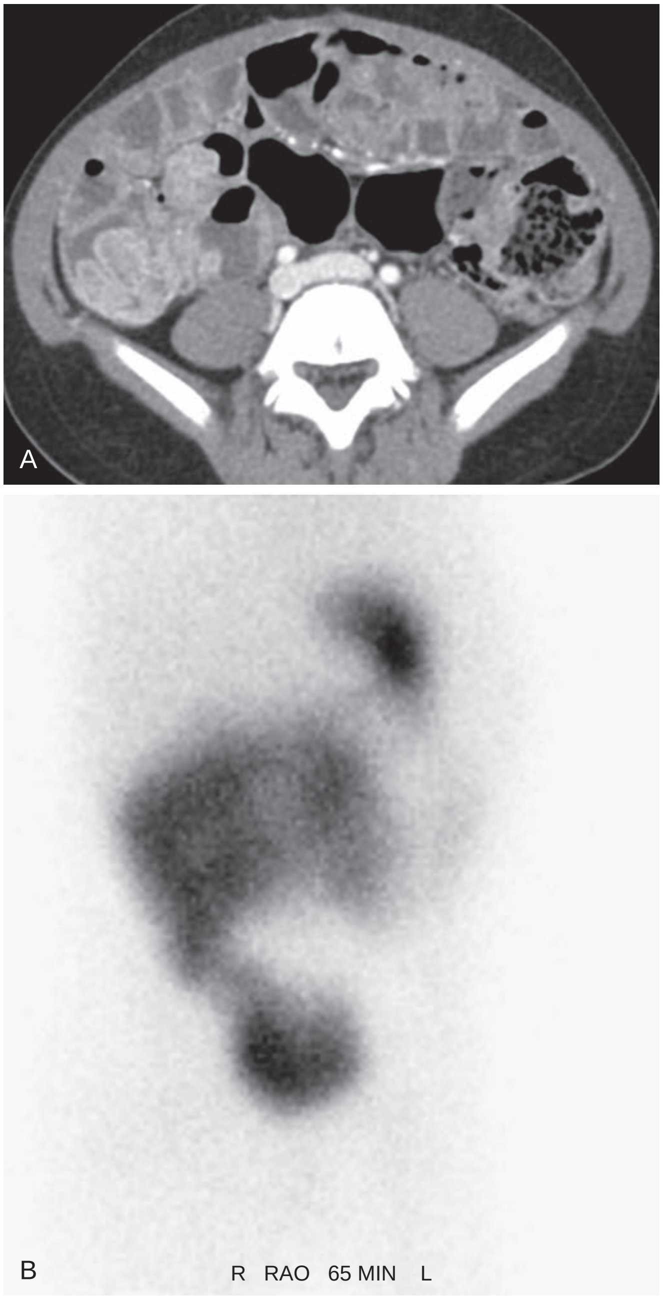

**Figure 102.44. Heterotopic gastric mucosa.** (A) Contrast-enhanced CT enterography in 12-year-old boy with heterotopic gastric mucosa shows multiple hyperenhancing nodular lesions encroaching upon the bowel lumen. (B) Technetium pertechnetate scan on the same patient several years earlier shows diffuse uptake throughout the bowel. *(Images courtesy of Andrew Trout, Cincinnati, OH.)*

lesions may be asymptomatic and discovered incidentally, or they may present as a result of size or complications of the lesion. Mass effect can result in partial obstruction developing over time or acutely due to acute enlargement of the cyst secondary to acute event such as hemorrhage.[205,206] Abdominal pain can occur through torsion of the cyst or one of its components (e-Fig. 102.45) or of adjacent bowel loops with the cyst acting as a fulcrum. The cysts can become infected, producing fever, abdominal pain, or sepsis.[200,201]

***Imaging.*** Radiographs show a large mass displacing intestinal loops. Dilated loops may be seen in patients with obstruction. GI contrast studies show displacement of bowel. Ultrasound demonstrates the multilocular nature of the mass with fine septations. The masses are usually anechoic, but some of the loculated spaces may be hypoechoic or even hyperechoic, depending on the chyle or blood content.[207] If the malformation is composed of microscopic cysts, it may simulate a solid lesion.[208] In case of omental cysts, it is important to recognize the blanket-like distribution of the fluid to differentiate it from ascites (Fig. 102.46). On CT, the attenuation values of the fluid range from near-fat to near-water, depending on its composition. On CT, septa and loculations are usually demonstrated, unless their attenuation value merges with that of the surrounding fluid. Fine calcifications may be present in some cases.[200] MRI studies of patients with lymphatic malformations show characteristics of the cyst ranging from fluid with low-intensity signal on T1-weighted images to fat with high-intensity signal.[209] Mesothelial cysts typically do not contain internal septations.[210]

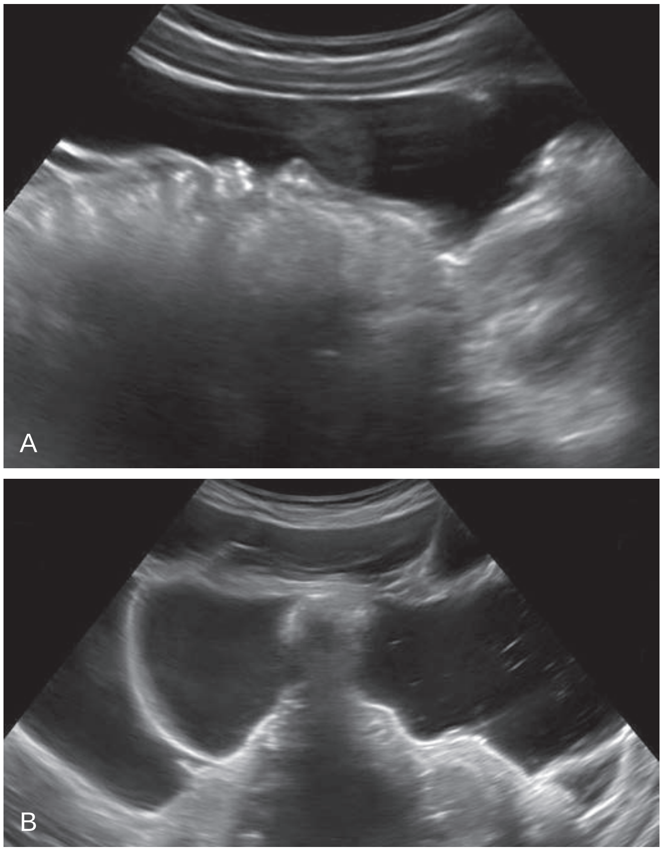

**Figure 102.46. Omental cyst.** (A) Transverse sonogram just below the liver in a 9-month-old infant thought to have ascites shows a cystic fluid-filled lesion, blanketed over the gas-containing bowel. (B) Transverse sonogram through the lower abdomen shows the large size of the lesion, containing septa, covering the bowel. At surgery, a large omental cyst was removed.

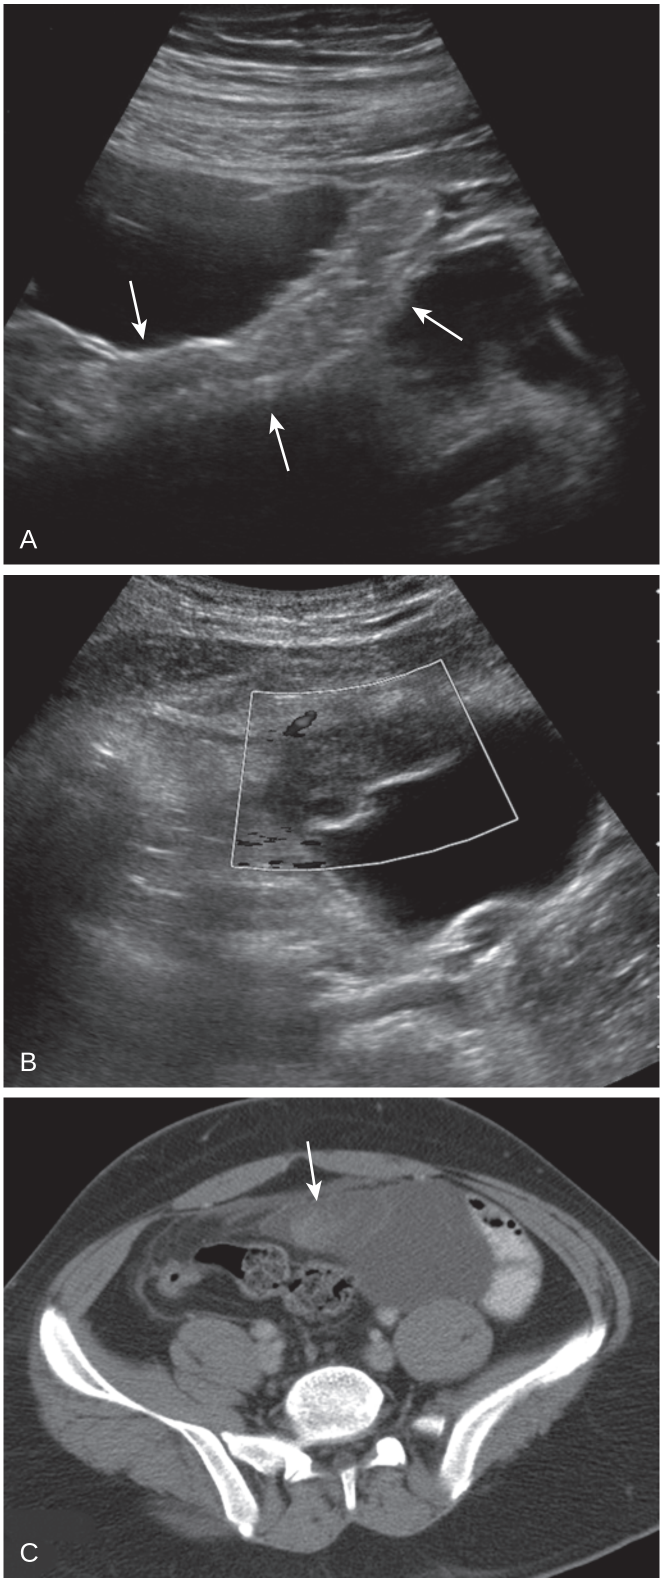
***Treatment.*** Traditional treatment is surgical resection with complete extirpation of the cyst. In children with mesenteric cysts, this is more likely to require segmental bowel resection than in adults (50%–60% vs. 33%).[200] If complete resection is not possible, marsupialization of the cyst with sclerosis of the lining can be performed. A surgical classification of mesenteric cysts, based on operative management, includes four types: type 1 is on a pedicle, and easily removed. Type 2 is sessile, restricted to the mesenteric boundaries, whereas type 3 has retroperitoneal extension and may involve the aorta, inferior vena cava, and other retroperitoneal



**e-Figure 102.45. Mesenteric cyst.** (A) A 14-year-old boy presented with abdominal pain and dysuria. Ultrasound of left midabdomen reveals multiseptated cystic mass, with intervening loop of small bowel *(arrows)*. (B) Color Doppler image obtained more inferiorly in the supravesical area shows an avascular solid-appearing component to the cystic lesions, with surrounding hyperechogenicity consistent with inflammation and edema. (C) Contrast-enhanced CT scan which had been done earlier at another institution shows the solid-appearing component *(arrow)* corresponding to the avascular structure noted on sonography in (B), and surrounding inflammation with fat stranding in the supravesical area. At surgery, a loculated mesenteric cyst was removed, with volvulus and infarction of a supravesical component, leading to the presenting symptoms and imaging findings.

structures, representing a severe surgical challenge. Type 4 refers to multicentric cysts.[203,211]

Laparoscopic resection is possible; however, this is best approached with caution if the diagnosis is not certain preoperatively or if the procedure will necessitate segmental bowel resection.[212–214]

Alternatively, lymphatic malformations may be treated via image-guided sclerotherapy with a variety of sclerosants. Multiple procedures may be required for complete resolution.

## KEY POINTS

- The finding of a double bubble on plain film is diagnostic of duodenal atresia/stenosis and does not need contrast studies for confirmation.
- Air can rarely be seen distal to the site of complete duodenal atresia in patients in whom an anomalous bifid biliary duct straddles and bypasses the point of obstruction.
- Polyhydramnios occurs in 30% to 50% of patients with duodenal atresia, and approximately half of these may be born prematurely.
- Associated anomalies in patients with duodenal atresia/stenosis include trisomy 21, Hirschsprung disease, esophageal atresia, and heterotaxy.
- In many patients with annular pancreas with obstruction, the obstruction is intrinsic and not secondary to the annular pancreas itself.
- Malrotation is the overarching term for incomplete rotation of the gut, before completion of the 270 degrees of counterclockwise rotation and normal fixation of duodenojejunal junction and cecum.
- Malrotation can lead to midgut volvulus due to the lack of normal fixation of the bowel and the short mesenteric pedicle that results from failure of completion of the normal rotation.
- Preduodenal portal vein is often found in patients with intrinsic duodenal obstruction, such as a duodenal membrane. The vein itself is not believed to be the primary cause of obstruction in most cases.
- Conditions that can result in prenatal gut ischemia and atresia include gastroschisis, intrauterine volvulus, intussusception, and internal hernias.
- Meconium ileus is the result of tarry, tenacious meconium impacted in the distal small bowel, causing distal small bowel obstruction.
- Calcifications in abdominal radiographs of infants with meconium ileus are a sign of meconium peritonitis and complicated meconium ileus. Such patients are operative candidates without further imaging or attempts at nonoperative treatment.
- Painless rectal bleeding is the most common presentation of Meckel diverticulum.
- Gut signature is a suggestive diagnostic finding of duplication cyst on sonography, but it is not completely specific.
- Duplication cysts are most common in the ileum, where they can act as lead points for intussusception.
- Lymphatic cysts are lined by endothelial cells and contain lymphoid tissue in their walls. Mesothelial cysts are the result of accumulation of fluid between mesothelial layers and are lined by mesothelium.

# 103 Acquired Abnormalities

Marta Hernanz-Schulman

Acquired duodenal abnormalities can be generalized into conditions that cause obstruction, inflammation, and neoplasia.

## ABNORMALITIES THAT RESULT IN DUODENAL OBSTRUCTION

### Superior Mesenteric Artery Syndrome

***Overview.*** First described at autopsy by von Rokitansky in 1861,[1] the term *superior mesenteric artery* or *SMA syndrome* refers to obstruction to the third portion of the duodenum at its crossing between the aorta and the superior mesenteric artery. It is also known by other terms, including cast syndrome and Wilkie syndrome.[2] The overall prevalence is cited to be between 0.013% and 0.3% of patients undergoing upper gastrointestinal (UGI) examinations;[3–5] a 20-year series confined to pediatric patients reports approximately one child per year diagnosed with this condition in the authors' pediatric hospital.[6]

***Etiology.*** The normal angle between the aorta and the SMA is between 25 and 60 degrees, and the normal aorto-SMA distance is 10 to 28 mm,[3] parameters that have been found to be significantly correlated to adult body mass index (BMI), particularly in females.[7] The etiology of SMA syndrome has been ascribed to an abnormally low angle between the aorta and the superior mesenteric artery, bringing them in close apposition at the crossing of the third portion of the duodenum. The low angle and decreased distance between the aorta and the SMA is thought to occur due to an abnormally low origin of the SMA, or an abnormally high position of the duodenojejunal junction at the ligament of Treitz, or "hypertrophy" of the ligament of Treitz.[1,7–9]

Although asthenic individuals, particularly after acute weight loss, are most susceptible to the development of SMA syndrome, Biank et al. found that this was not true in approximately 50% of their pediatric patients, who had a mean BMI at the 39th percentile. Premorbid conditions include Nissen fundoplication, cerebral palsy, traumatic brain injury, and posterior spinal fusion.[6] Other predisposed individuals include burn victims, and patients with lumbar hyperlordosis or in spinal traction/cast.[10] SMA syndrome may occur in families, raising the question of genetic predisposition.[11]

***Clinical Presentation.*** The clinical syndrome occurs more commonly in females between the ages of 10 and 39 years,[12] although it has been reported rarely in neonates and questionably prenatally.[12–14] The most common clinical presentation includes abdominal pain, vomiting, nausea, early satiety and anorexia;[6,15] acute presentation may follow one of the premorbid conditions previously described.[16]

***Imaging.*** Plain radiographs may show gastric dilatation, but the stomach may be decompressed by vomiting or via enteric tube. Contrast UGI study shows dilatation and partial obstruction of the third portion of the duodenum, terminating in a straight line at the expected location of the crossing of the SMA, with active but poorly effective peristalsis across the point of obstruction.

Ultrasound has been used to measure both the angle and the distance between the aorta and the SMA but may have difficulty outlining their relationship to the duodenum unless the latter is fluid-filled. As in the UGI, magnetic resonance imaging (MRI) and computed tomography (CT) (Fig. 103.1) are able to assess the dilatation of the duodenum and additionally can determine its relationship to the SMA, as well as the aorto-mesenteric angle and the aorto-mesenteric distance; angles less than 25 degrees and distances less than 8 mm are correlated with the clinical syndrome.[16]

***Treatment.*** Nonoperative medical treatment consists of measures for weight gain with high calorie enteral nutrition either by mouth, with transpyloric tube feedings beyond the point of obstruction, or with hyperalimentation. In one pediatric series, this was successful in 86% of patients, with a mean length of treatment of 65 days.[6] Medical treatment is most likely to be successful when the syndrome is of acute onset.[17]

Operative treatment is reserved for those who fail medical management and typically consists of duodenojejunostomy, with laparoscopic procedures resulting in a decreased length of hospital stay.[18,19]

### Duodenal Hematoma

***Overview.*** Duodenal hematoma is an infrequent injury in pediatric patients, occurring in less than 2% to 3% of children with abdominal injuries, usually associated with blunt abdominal trauma, both accidental and nonaccidental. The hematoma may extend beyond the ligament of Treitz into the proximal jejunum as a duodenojejunal hematoma.[20] Duodenal hematomas are graded as I or II, depending on whether a single portion or more than one portion of the duodenum is involved, according to The American Association for the Surgery of Trauma (AAST).[21]

***Etiology.*** The retroperitoneal duodenum contains a vascular submucosal and subserosal plexus and lies relatively fixed against the rigid spine, thus facilitating injury after blunt abdominal trauma. Bleeding is contained within the submucosa and subserosa and, as it increases in volume, it encroaches into the duodenal lumen. In children, this injury typically occurs after blunt trauma such as a direct punch or kick to the epigastrium, or handlebar injuries. Motor vehicle injuries involving sudden deceleration forces can also produce a shearing injury and result in intramural hematoma.[20] In a series of 33 children with blunt duodenal injury, nonaccidental trauma was the most common cause of duodenal injury (24%), followed by motor vehicle crashes, handlebar injuries, sports injuries, and other forms of direct trauma.[23] Duodenal hematoma has also been reported after endoscopic duodenal biopsy,[22,24–27] in patients with coagulation abnormalities after relatively minor trauma, or patients with pancreatitis, the latter postulated to be secondary to disruption of intramural vasculature by pancreatic enzymes.[28,29]

***Clinical Presentation.*** The clinical presentation includes abdominal pain and vomiting, typically bilious. When occurring after blunt trauma, there may be an associated pancreatic injury. Luminal obstruction sufficient to produce symptoms may not occur immediately after injury, and children may not present until several days after the traumatic event. When occurring after significant trauma such as a motor vehicle accident, the injury may be identified at CT evaluation. In the appropriate clinical setting, this injury should raise the concern for nonaccidental, inflicted trauma.[20,24,30] Rarely, the hematoma can act as a lead point of an intussusception into the adjacent jejunum.[31]

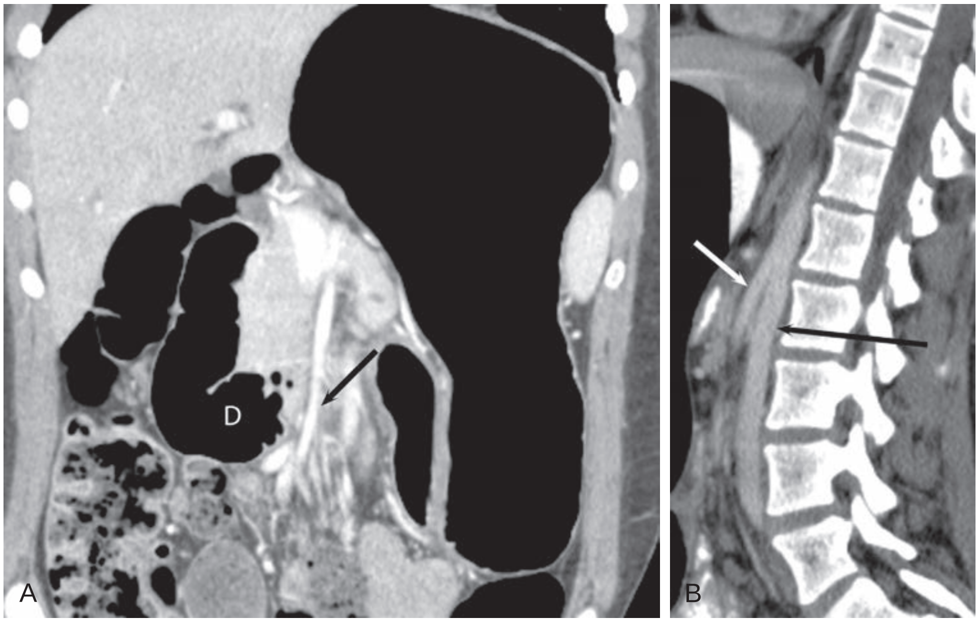

**Figure 103.1. Superior mesenteric artery syndrome.** Adolescent boy with cerebral palsy and vomiting. (A) Coronal reformatted contrast-enhanced CT image shows a dilated duodenum *(D)* to the crossing of the SMA *(black arrow)*. (B) Sagittal image on the same patient shows the narrow angle between the aorta *(black arrow)* and the SMA *(white arrow)*, which measured less than 12 degrees.

***Imaging.*** Plain films may be the initial modality in a child presenting with epigastric abdominal pain, tenderness, and vomiting. Depending upon the degree of obstruction and the severity of vomiting, the radiographs may show distension of the stomach and duodenum, with paucity of distal bowel contents; rarely, the outline of the hematoma may be visible against the gas in an adjacent viscus (Fig. 103.2A).

The findings on UGI depend on the ability of some of the contrast to traverse the obstructed portion of the duodenum. If very little contrast passes, the luminal border of the distended duodenum may show a lobulated contour. As contrast passes through the obstruction, it will outline the contour of the hematoma as a lobulated filling defect (Fig. 103.2B). Smaller hematomas may demonstrate more subtle findings, such as duodenal fold thickening.[20]

Ultrasound typically shows a distended proximal duodenum, with a mass of variable echogenicity encroaching upon and obliterating the more distal lumen (Fig. 103.2C).[32,33] The echogenicity of the mass is variable, depending on the status of the clot; the clue to the diagnosis is that the mass follows the course of the duodenum. On Doppler interrogation, there is no internal flow.

CT demonstrates similar findings, with dilatation of the more proximal duodenum, and a nonenhancing mass that follows the course of the duodenum obliterating its more distal lumen (Fig. 103.2D and E). (See also Fig. 109.11.)

MR is not often performed in children with duodenal hematomas. If performed, it will again show a mass following the course of the duodenum, obliterating its lumen, with signal characteristics consistent with evolving hematoma.

***Treatment.*** Patients with duodenal perforation need emergent surgery, but the treatment for duodenal hematoma generally consists of decompression of the stomach and duodenum via nasogastric tube, and maintenance of hydration and parenteral nutrition until resolution of the hematoma. In one series, the mean time to resolution of symptoms ranged between 12 and 16 days.[23,34] More severe grade II injuries are associated with longer intervals to resolution and discharge but typically also respond to expectant and supportive management.[35] If there is complete obstruction without improvement, it may be necessary to evacuate the hematoma surgically or via percutaneous drainage.[23,35]

## Duodenal Intussusception

***Overview.*** Duodenal intussusception may be seen in both antegrade and retrograde direction, typically around a gastrojejunostomy (GJ) tube.

***Etiology.*** Antegrade duodenojejunal intussusception is a relatively common complication of postpyloric GJ tubes, as the tube acts as a lead point for the intussusception. In large series, the rate of intussusception ranges from 16% to nearly 50%.[36,37] Intussusceptions are more likely in boys, in younger patients, with larger bore tubes and tubes with a distal pigtail that may act as a lead point, and administration of prokinetic agents.[37,38] Intussusception can also occur around a weighted nasojejunal tube.[39] Retrograde intussusception, on the other hand, is much less common and is believed to occur as a tube with an inflated terminal balloon, which has migrated distally due to peristalsis, is pulled back toward the stomach.[40,41]

***Clinical Presentation.*** The presentation is typically the onset of vomiting, bilious in approximately half the cases,[36] which may be accompanied by abdominal pain/irritability. However, these intussusceptions may be discovered incidentally at the time of routine tube check,[42] and therefore may be asymptomatic and transient in some cases. Uncommonly, intussusceptions lead to bowel necrosis requiring resection.[38] Hematemesis or bloody gastric aspirates are described in patients with retrograde intussusceptions.[40,41] Retrograde intussusception also occurs after gastric surgery, such as gastrojejunostomy, although in those cases the duodenum is bypassed. The intussuscepted jejunum may be gangrenous; obstruction and hematemesis are typical in acute presentation.[43]

***Imaging.*** Abdominal radiographs and ultrasound are helpful in diagnosis. Radiographs may reveal gastric outlet obstruction, and in retrograde intussusception, gas within the stomach will demonstrate the distal mass protruding into the gastric antrum

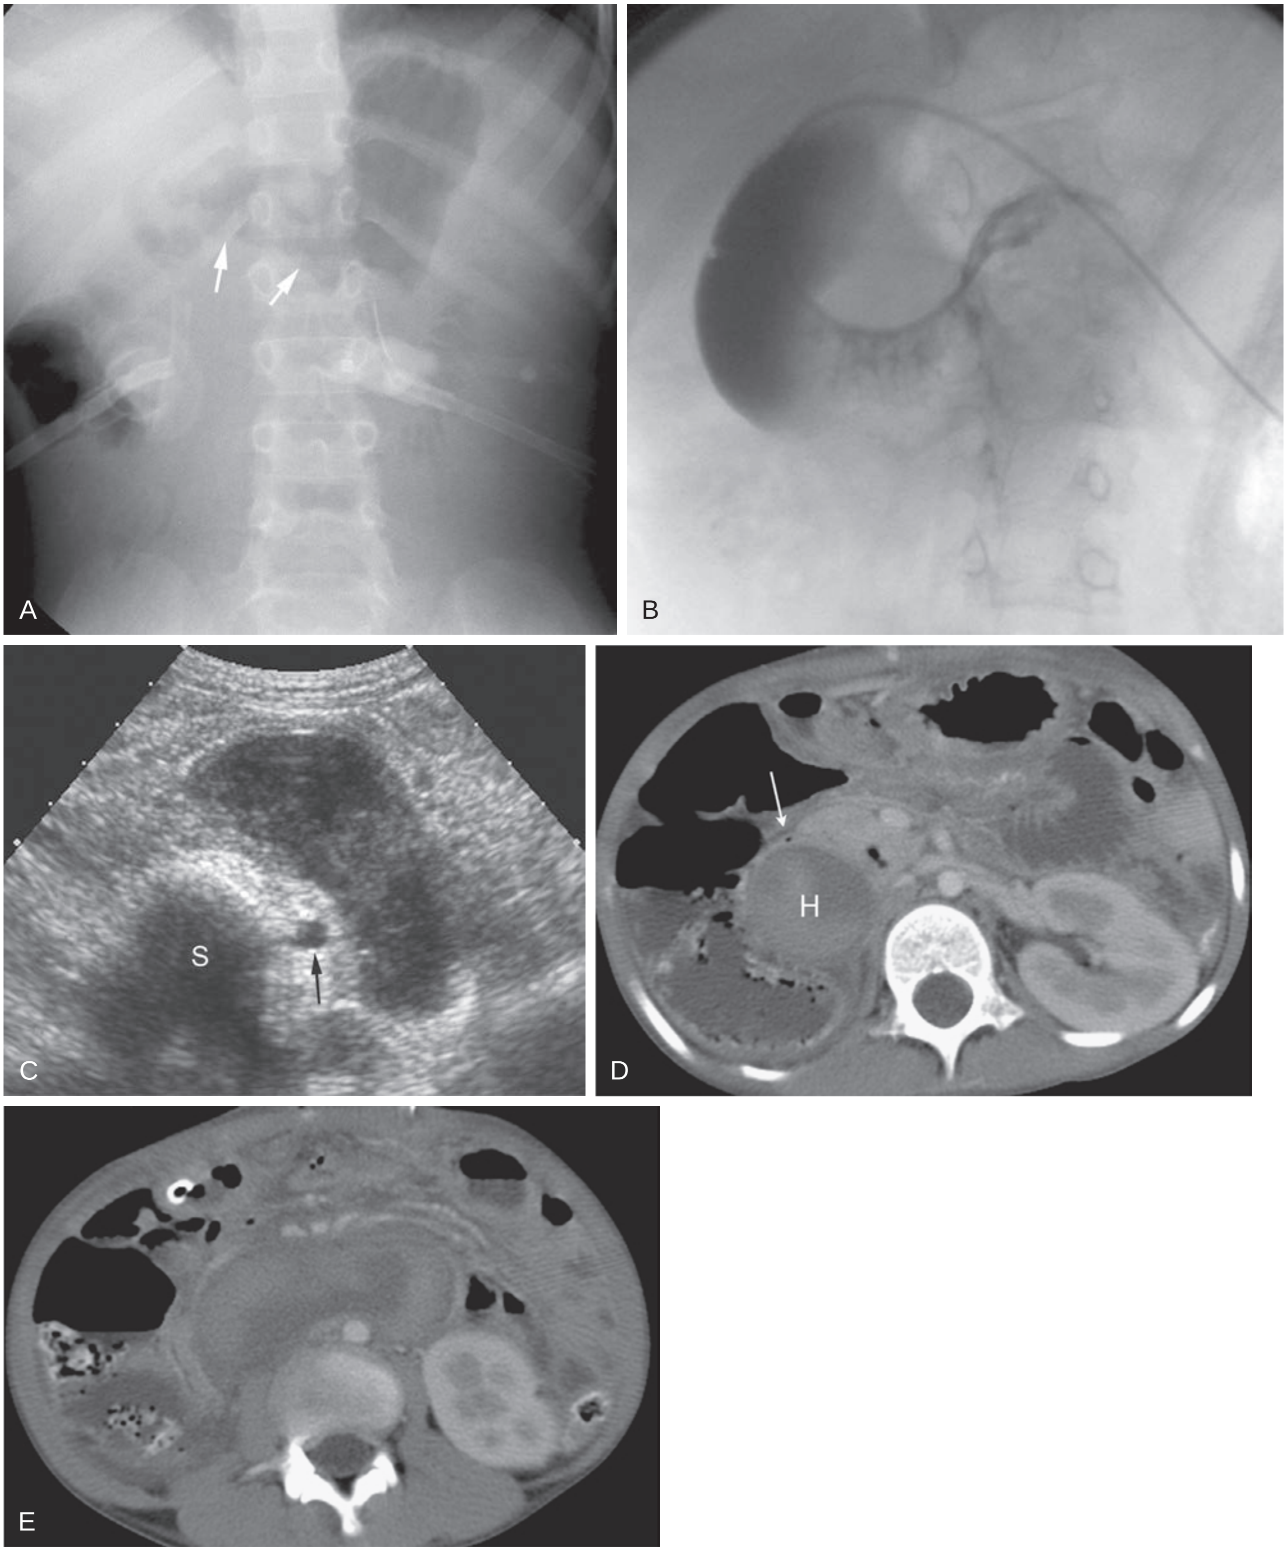

**Figure 103.2. Duodenal hematomas.** (A) An 8-year-old who had undergone an upper endoscopy with duodenal biopsy, and developed persistent bilious vomiting. Radiograph shows a polypoid density *(arrows)* encroaching upon the gas along the inferior border of the antrum. There is gaseous distension of the more proximal duodenum, with very little gas distally. (B) Fluoroscopic UGI image of a 10-year-old boy with cerebral palsy and mental retardation who presented to the ED with dehydration and inability to tolerate feedings. Introduction of contrast during unsuccessful GJ tube placement shows an obstructing duodenal hematoma as a filling defect upon the third and distal second portions of the duodenum. (C) Transverse sonogram on same patient as shown in (A), demonstrates the heterogeneous duodenal hematoma, following the course of the third portion of the duodenum. *S*, Spine. *Arrow* points to the aorta. (D) Contrast-enhanced CT at the level of the junction of the second and third portions of the duodenum, same patient as illustrated in (A) and (C), shows the large heterogeneous hematoma *(H)* obliterating the duodenal lumen. *Arrow* points to the duodenal wall and gas bubble in residual obliterated lumen. (E) More distal CT section through the third portion of the duodenum shows the heterogeneous hematoma, obliterating the lumen of the third portion of the duodenum.

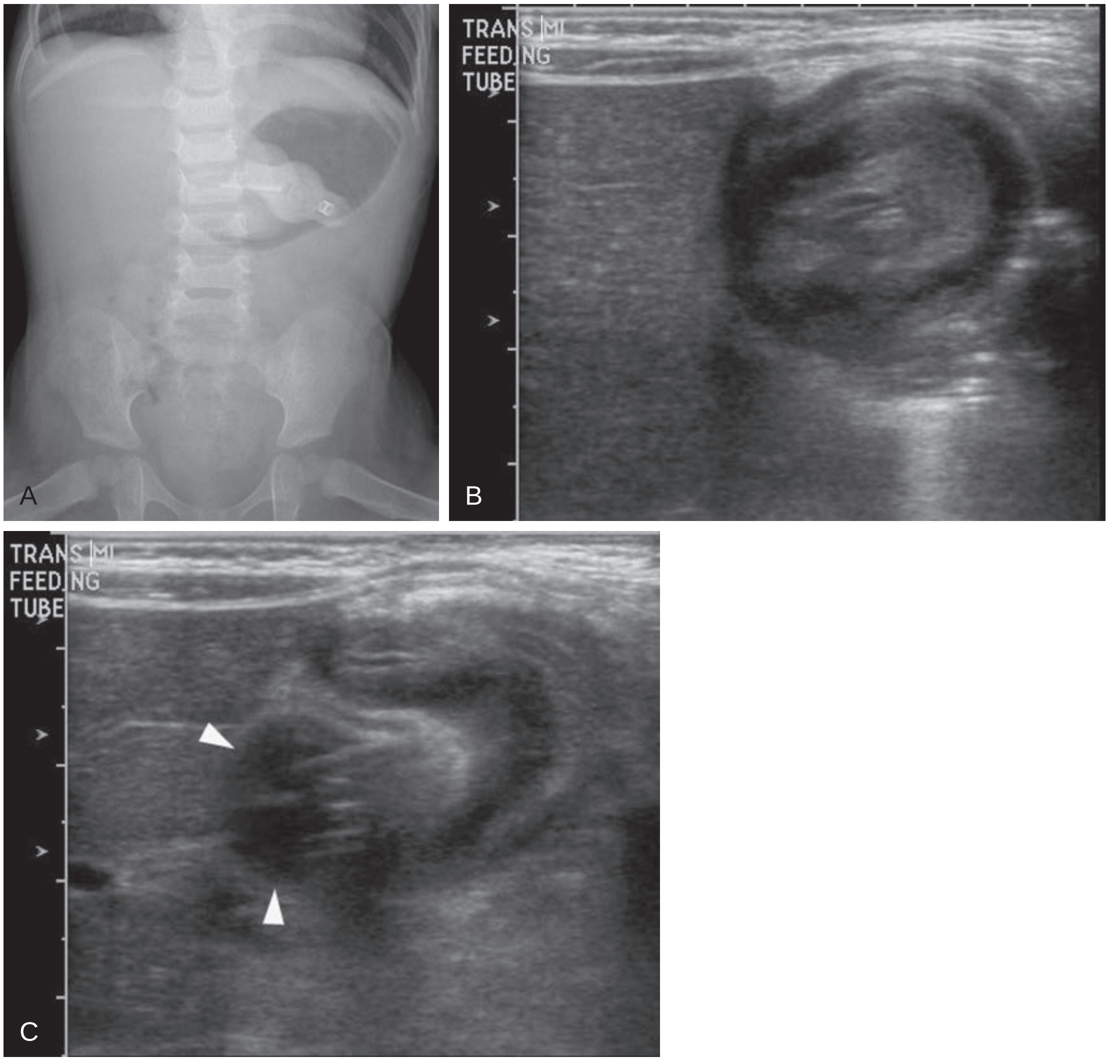

**Figure 103.3. Retrograde duodeno-gastric intussusception.** (A) Radiograph of a 3-year-old boy with a gastrostomy tube, who presented with vomiting demonstrates a gastrostomy tube, a dilated air-filled stomach with a mass-like lesion at the antrum, and a paucity of distal bowel gas consistent with gastric outlet obstruction. (B) Right upper quadrant sonogram demonstrates an intussusception. (C) US image immediately adjacent to (B) confirms that the gastrostomy tube balloon *(arrowheads)* is related to the intussusception.

(Fig. 103.3A). Ultrasound demonstrates the classic appearance of bowel within bowel at the gastric outlet[36,40,44] and may show a balloon as a lead point, particularly in retrograde intussusception (Fig. 103.3B and C). UGI will demonstrate a coiled spring appearance as the contrast passes into the intussusception; the amount of contrast may be small and the findings relatively subtle, therefore a high index of suspicion is helpful in arriving at the correct diagnosis.[44] On CT, the intussusceptum will be seen extending along the course of the duodenum, particularly well when outlined by air or contrast medium.[45]

***Treatment.*** Introduction of air or saline through the tube has been successful in reduction of intussusception,[36] although antegrade intussusceptions can be treated by replacement of the GJ tube over a wire.[38] This complication can be prevented by changing to a smaller bore GJ tube, removing the pigtail, or shortening the length of GJ tube.[46] If the intussusception occurs around a nasojejunal tube, the tube should be removed.[42] Retrograde intussusception is usually managed by deflation of the balloon,[40] although, in some cases of supervening ischemia, surgical resection has become necessary.[47]

## INFLAMMATORY CONDITIONS

### Duodenal Ulcer Disease

***Overview.*** Ulcer disease can involve the stomach and/or the duodenum and, as in the stomach, it is often associated with *Helicobacter pylori* infection, a pathogen that is estimated to colonize/infect approximately half the world's population.[48] Gastritis and gastric ulcers are discussed in Chapter 101.

***Etiology.*** The etiology of duodenal ulcerations is a result of overwhelming the inherent defense mechanisms, which include epithelial cell renewal and regeneration, duodenal bicarbonate production, preservation of mucosal blood flow, and production of prostaglandins.[49] The understanding of peptic and duodenal ulcer disease in both adults and children has changed dramatically since the elucidation of the role of *H. pylori* infection by Warren and Marshall in 1984[50,51] for which they were awarded the Nobel Prize in 2005. Because *H. pylori* is trophic for gastric epithelium, duodenal ulcers related to *H. pylori* are believed to occur over sites of gastric metaplasia[52]; they are thus related to increased acid secretion and decreased bicarbonate output by the duodenum, thus lowering luminal pH and precipitating bile acids, which would otherwise exert an inhibitory effect on *H. pylori* growth. Acid hypersecretion additionally promotes the activation of pepsinogen to pepsin facilitating mucosal ulceration.[52]

A higher rate of *H. pylori* infection has been reported in children with duodenal ulcers (62%) than in those with peptic ulcers (20%), although other sources do not confirm this relationship.[53] Transmission of *H. pylori* is mainly by the oral-oral or fecal-oral route, and requires contact with intestinal secretions.[54,55] Colonization with this pathogen has greater prevalence in locations with suboptimal sanitary infrastructure and crowded living conditions.[55] Childhood is the primary period of colonization by *H. pylori*, with cases often clustering within families secondary to intrafamilial transmission.[55] In Western nations, there is a decreasing prevalence of *H. pylori* colonization, being reported as low as 27% in children from Western European centers, although this may be underreported secondary to culture of specimens from the stomach rather than the duodenum.[56]

With reduction of *H. pylori*, the proportion of duodenal ulcers unrelated to *H. pylori* increases. Other causes of duodenal ulcer disease include therapy with nonsteroidal anti-inflammatory medications (NSAIDs). These agents promote ulceration by inhibition of cyclooxygenase 1 and 2 enzymes, which have a role in maintaining the integrity of the gastric epithelium and its mucous barrier, as well as in the response to inflammatory processes. NSAIDs may also increase the production of inflammatory mediators such as leukotrienes.[49]

***Clinical Presentation.*** Most children with duodenal ulcer disease present with symptoms that include epigastric tenderness, pain that wakes the child from sleep at night, hematemesis, melena, anorexia, poor weight gain, and vomiting.[53,56,57] Extragastric or extraduodenal manifestations include failure to thrive with growth disturbance in addition to poor weight gain, iron deficiency anemia, and idiopathic thrombocytopenic purpura.[55]

***Imaging.*** UGI has been largely supplanted in the diagnosis of duodenal ulcer disease by endoscopy, which has become the diagnostic gold standard and also allows the biopsy and culture of detected abnormalities. When UGI is performed, double contrast technique is more sensitive in the detection of ulcer disease, although this is much more difficult to perform in younger patients and impossible to perform in infants.

Despite the shift to endoscopy, ulcers should be detected during UGI if present. Duodenitis, which could be secondary to multiple etiologies beyond ulcer disease, is manifested by thickening of the duodenal folds, with a historically cited sensitivity of 45% in detecting duodenal inflammation.[57] The imaging appearance of duodenal ulcers in children is similar to that in adults, with the most common finding in an acute ulcer being contrast within an ulcer crater (Fig. 103.4). Radiating folds representing surrounding mucosal edema may also be seen. When the ulcer is on the nondependent wall of the duodenum, air will fill the ulcer outlined by barium. Chronic duodenal ulcers may lead to a scarred and deformed duodenum, but these are uncommon in children. So-called "giant duodenal ulcers" are rare, occur more commonly in association with NSAIDs, and have been found in patients with end stage renal disease and with Crohn disease.[52]

Ultrasound is not typically performed in patients with known duodenal ulcer disease; however, thickening of the bowel wall has been described, as well as surrounding fluid and gas in cases of perforation.[58]

On CT, thickening of the duodenal wall may be detected, as well as contrast within an ulcer crater.[59] In cases of perforation, periduodenal fluid and retroperitoneal and intraperitoneal free air may be identified, along with contrast extravasation if oral contrast was used (Fig. 103.5).[28]

***Treatment.*** *H. pylori* is considered a group I carcinogen, and the goal of therapy is eradication.[60] Although in the initial reports the pyloric organisms were sensitive to multiple antibiotics,[61] not all current strains demonstrate similarly wide susceptibility. Eradication of the organisms in symptomatic patients requires triple or quadruple therapy, with testing of resistance profiles recommended.[60,62,63]

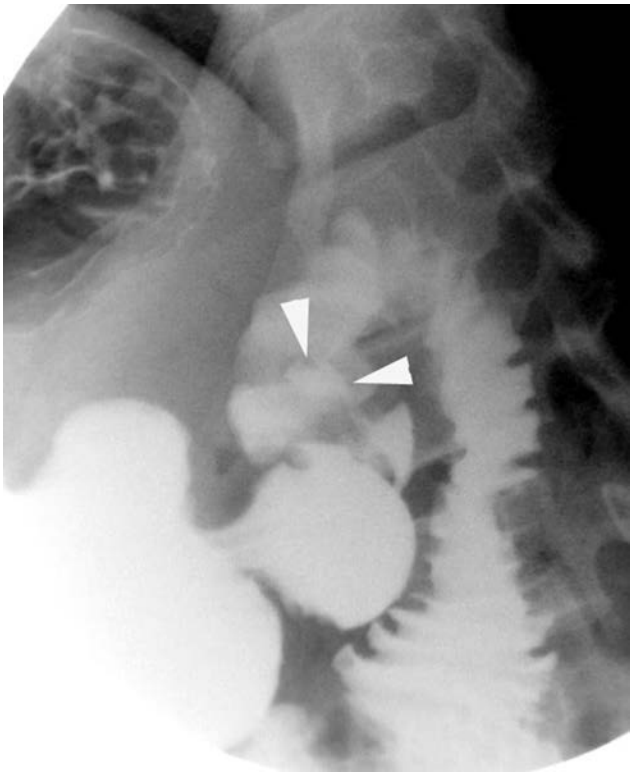

**Figure 103.4. Duodenal ulcer.** UGI spot image of the duodenal bulb in a boy with 1-week history of abdominal pain reveals a collection of contrast in the ulcer crater *(arrowheads)*. *(Case courtesy of Dr. Tamar Ben-Ami, Chicago, IL.)*

## Zollinger-Ellison Syndrome

***Overview.*** The Zollinger-Ellison syndrome refers to autonomous oversecretion of the hormone gastrin by a gastrinoma of the duodenum or pancreas, resulting in unusually severe and refractory ulcer disease, typically accompanied by diarrhea. The condition is rare, with an incidence quoted as 1 to 3 new cases per million population.[64] Gastrinomas and the Zollinger-Ellison syndrome can occur sporadically or, in approximately 15% to 38% of cases, as part of the multiple endocrine neoplasia Type 1 (MEN-1) syndrome;[64–66] conversely, the Zollinger-Ellison syndrome occurs in approximately 21% to 70% of patients with MEN-1.

The Zollinger-Ellison syndrome is typically diagnosed in the fifth decade, with approximately 90% presenting between the ages of 20 and 60 years of age.[66] The syndrome tends to present at a younger age when part of the MEN-1 syndrome. Approximately 8.6% occur in children, about 4 times more commonly in boys, typically no earlier than the second decade, although the diagnosis has been reported in a 5-year-old girl.[65,67,68]

Most tumors are located in the wall of the duodenum or in the head of the pancreas but can also be located in more distant regions, including the heart, ovary, kidneys, and mesentery. Tumors can be both small and multiple, presenting a challenge to diagnosis.[69–71] However, the majority of gastrinomas occur in the so-called gastrinoma triangle, which is located to the right of the superior mesenteric artery, and bounded superiorly by the confluence of the cystic and common bile ducts, inferiorly by the junction of

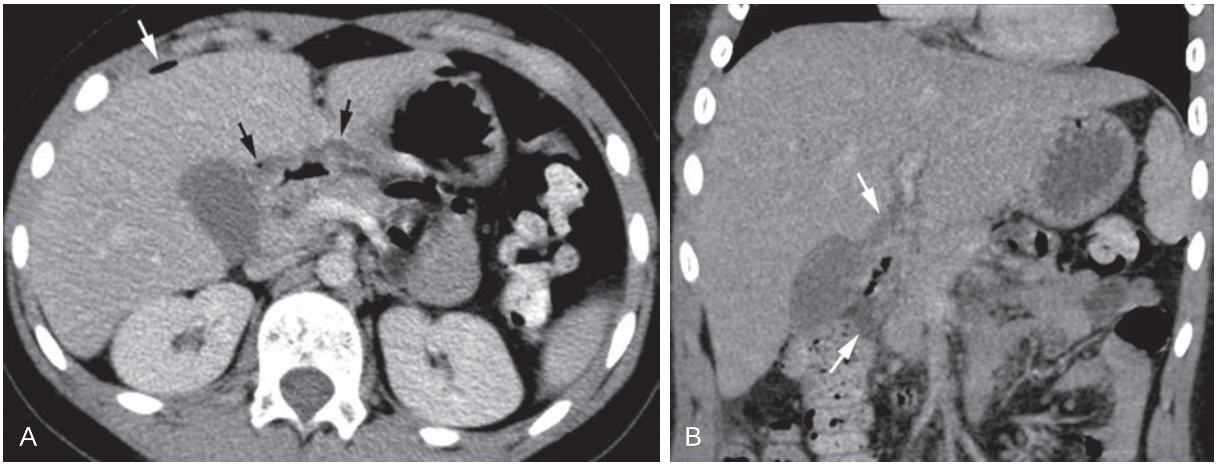

**Figure 103.5. Perforated duodenal ulcer.** (A) Contrast-enhanced CT image in a 9-year-old boy with 2-day history of abdominal pain, fever, and decreased activity shows thickening of the duodenum, with a small amount of periduodenal fluid and free air *(black arrows)* as well as intraperitoneal free air *(white arrow)*. (B) Coronal reformatted CT image shows thickening of the duodenum, and periduodenal fluid *(arrows)*.

the second and third portions of the duodenum, and medially by the junction of the head and body of the pancreas.[69,72]

***Etiology.*** Autonomous neoplastic overproduction of gastrin results in acid hypersecretion and extensive ulcer disease. The cause of sporadic gastric tumors is not known; however, MEN-1 is the result of an autosomal dominant mutation in the tumor suppressor gene MEN-1, encoding the protein MENIN. Parathyroid hyperplasia, pancreatic endocrine tumors (of which gastrinoma is the most common), pituitary adenomas, and adrenal adenomas occur in this syndrome. Patients are also prone to develop carcinoid tumors; gastric, thymic, and bronchial lesions; lipomas; and skin lesions including melanomas.[66]

***Clinical Presentation.*** The triad of abdominal pain, weight loss, and diarrhea in conjunction with ulcer disease (typically negative for *H. pylori*) is highly suggestive of Zollinger-Ellison syndrome. Patients may also present with hematemesis, tarry stools, and anemia. The diagnosis of gastrinoma and Zollinger-Ellison syndrome should prompt investigation for MEN-1, particularly in children.[66,67] Some patients with MEN-1 may present initially with evidence of hyperparathyroidism, such as urolithiasis; manifestation of gastrinoma may follow, sometimes as much as 25 years later.[73] Approximately 60% of gastrinomas are malignant, and 50% have metastasized at diagnosis.[69,74]

The primary ulcer site is the duodenum, and ulcers can occur in the distal duodenum as well as the jejunum, sites that should raise concern for gastrinoma. In a pediatric series of patients with Zollinger-Ellison syndrome, the primary ulcer site was duodenum in 72% and the jejunum in 28%.[67]

Successful treatment with proton pump inhibitors may delay the diagnosis by assuaging symptoms.[64,66] The diagnosis is made by demonstrating gastrin hypersecretion by measurement of fasting gastrin levels and acid secretion. However, in patients who are on proton pump inhibitors, fasting serum gastrin levels may be sufficiently elevated to overlap with those seen in patients with Zollinger-Ellison syndrome[66]; in such cases, proton pump inhibitors should be withdrawn for approximately 1 week before repeating the test.[64] In addition to fasting gastrin levels, provocative tests are also employed, utilizing secretin, calcium, and meal stimulation.[66]

***Imaging.*** The classic finding on UGI examination is the presence of ulcers in the duodenum, particularly distal duodenum, or in the jejunum, as well as thickening of duodenal and gastric folds.[66] Ulcer disease is now more often evaluated endoscopically, which shows thickened gastric folds in up to 94% of patients with Zollinger-Ellison syndrome.[64]

Ultrasonography has not been found to be sensitive in detecting gastrinomas either inside or outside the liver and pancreas. However, endoscopic ultrasound (EUS) is much more sensitive, with detection rates as high as 93% in some patients; however, it is much less helpful in distal lesions located close to or in the tail of the pancreas.[75] On CT, identification of hypervascular pancreatic gastrinomas is optimized with rapid bolus technique, with thin collimation and reformats, possibly requiring dual phase arterial and portal venous imaging.[76] A recent review found a nearly 100% sensitivity of EUS and CT in detection of pancreatic neuroendocrine tumors.[77] Contrast-enhanced MRI was thought to be sensitive and complementary to EUS in a recent report.[75] Somatostatin receptor scintigraphy using [$^{111}$In-DTPA-DPhe$^{1}$]octreotide was found to be 70% sensitive in the detection of the tumors.[66] More recently, PET-CT with $^{68}$Ga-labelled somatostatin analogues has shown great sensitivity in detection of neuroendocrine tumors.[78] PET-CT with these agents showed superior sensitivity when compared with MRI, CT, and 18F-FDG PET (approaching or reaching 100%), and identified extrapancreatic and duodenal lesions.[77–80] Direct venous sampling after selective arterial injection of secretin or calcium to elicit gastrin release (selective arterial secretagogue injection [SASI] test) can detect more than 90% of gastrinomas smaller than 5 mm that may otherwise elude imaging diagnosis.[71,81]

***Treatment.*** Control of hyperacidity is one of the key elements in survival.[66,82] Historically, this was achieved with gastrectomy, but today suppression of excess acid production is achieved medically with proton pump inhibitors. The management of patients is geared toward treatment of other manifestations of the MEN-1 syndrome if present, as well as the gastrinoma itself. Although most gastrinomas demonstrate slow growth, 25% show more rapid growth, and approximately 60% to 90% demonstrate malignant behavior.[70] In a study of 151 patients, more than half of those with sporadic gastrinomas were free of disease after surgery, and most of these were able to achieve long-term cure; this approach is preferred in patients with sporadic gastrinoma.[70] In patients with MEN-1 and gastrinoma, some authors advocate a pancreas-preserving total duodenectomy to achieve cure in some of the patients, as well as laparoscopic intervention.[71,83,84]

## Inflammatory Bowel Disease

***Overview.*** Although involvement of the duodenum with Crohn disease is nearly universally accompanied by ileal or ileocolic disease,[85,86] there is a wide difference in the reported percentage with duodenal involvement.[87] This is likely related to the fact that patients with duodenal disease do not have symptoms distinct from those with more distal involvement.[86,88,89] In one endoscopic study of Crohn patients, 31.9% had involvement of the duodenal bulb and 18.1% of the second portion of the duodenum.[90] Another review found that 53.3% of children with Crohn disease had upper GI involvement, and of these 63% had duodenal involvement alone or in combination with esophageal and gastric lesions.[91]

***Etiology.*** The etiology of Crohn disease remains unknown, although a genetic predisposition is underscored by familial occurrence and concordance of the disease in monozygotic twins (44%–58%).[92] Please see Chapters 104 and 106 for additional discussion.

***Clinical Presentation.*** Patients with duodenal involvement tend to present at a younger age than patients with distal involvement,[93] typically with abdominal pain, general malaise, and weight loss.[94] These patients tend to have more severe clinical manifestations and course.[91]

Complications related to duodenal involvement include involvement of the ampullary region of the duodenum, leading to biliary and pancreatic duct obstruction,[95] as well as pancreatitis, although the latter could be related to other causes such as medications used to treat the primary disease.[96] Fistula formation also occurs, although it is believed that fistulas between the duodenum and small bowel or colon usually originate in the latter, rather than in the duodenum.[86]

***Imaging.*** Just as the diagnosis of Crohn disease has shifted from radiography to endoscopy, the imaging modalities have shifted from radiography to cross-sectional imaging, including ultrasound with color or power Doppler, CT, and MRI, with MR enterography (MRE) largely being used to follow patients in many centers.[97] However, if a UGI is requested in a patient with abdominal pain and weight loss, the diagnostic findings should be appreciated.

The findings on UGI are similar to those found in distal bowel. Double contrast studies are more sensitive than single contrast examinations in identifying the aphthous lesions that characterize the early stages of the disease. These will most typically be found in the antrum, pylorus, and duodenum. Duodenal fold thickening, luminal narrowing, wall thickening, and fistula and sinus tract formation may also be seen (Fig. 103.6).

Ultrasound is able to detect bowel wall thickening, and Doppler is able to detect the hyperemia characteristic of active Crohn disease, findings that are well documented in terminal ileal disease.[98–101]

CT is helpful in patients with bowel obstruction and other patients who are unable to tolerate MRI because of procedure length and other requirements such as sedation. Duodenal findings include fold thickening, increased enhancement, and stricture formation.[28,59,102]

MRE is becoming the ideal modality in the routine imaging evaluation of patients with Crohn disease. The findings in the duodenum are similar to those in other bowel segments.[103,104]

***Treatment.*** Therapy for duodenal Crohn disease typically includes exclusion of *H. pylori*, and its treatment if found. Treatment then consists of proton pump inhibition to inhibit gastric secretion and promote ulcer healing, as well as corticosteroids. Biologics such as anti-TNFα (tumor necrosis factor) and immunomodulators continue to be evaluated for efficacy in achieving mucosal healing.[105] Strictures are amenable to endoscopic balloon dilatation. Patients who do not respond to medical management or who develop gastrointestinal hemorrhage may need surgical intervention.[86]

## Cystic Fibrosis

***Overview.*** There are multiple manifestations of cystic fibrosis (CF) in the gastrointestinal tract; duodenal involvement includes duodenal fold thickening, ulceration, and strictures.[106] Duodenal and gastric ulceration has been reported in as many as 10% of autopsy reports of pediatric patients with CF.[107]

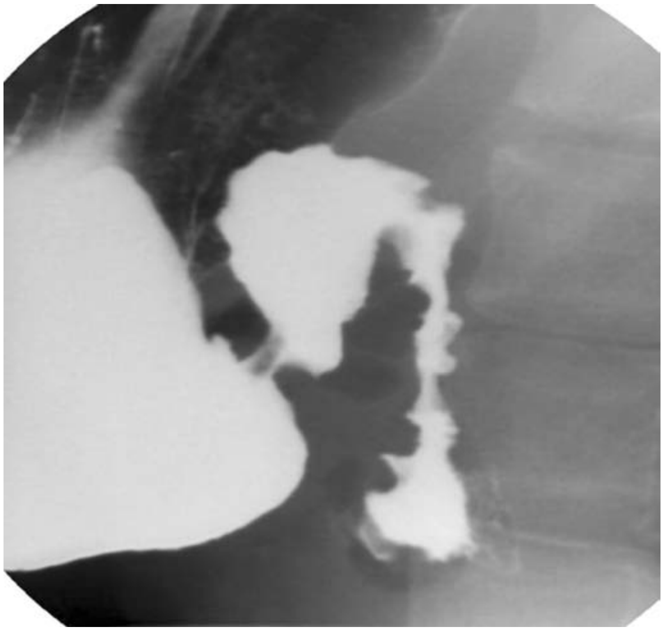

**Figure 103.6. Crohn disease.** UGI spot image demonstrates mucosal fold thickening in the duodenum. There was extensive disease elsewhere in the bowel. *(Case courtesy of Lakshmana Das Narla, Richmond, VA.)*

***Etiology.*** Impaired secretion of bicarbonate by the duodenum and pancreas curtails the ability to buffer gastric acid.[108] Thickening of duodenal folds is believed to be related both to hyperacidity in the environment, abnormal mucus production, and hypertrophy of Brunner glands.[107] Hyperacid duodenal environment also leads to precipitation of bile salts and decreased fat absorption.

Inflammatory changes in the gut of CF patients have been found through identification of products of T-cell activation[109] and output of inflammatory proteins.[110] The etiology of inflammatory changes in the duodenal mucosa may include factors such as increased antigenic load secondary to pancreatic insufficiency and defective digestion of luminal contents,[109] and altered intestinal flora.[111]

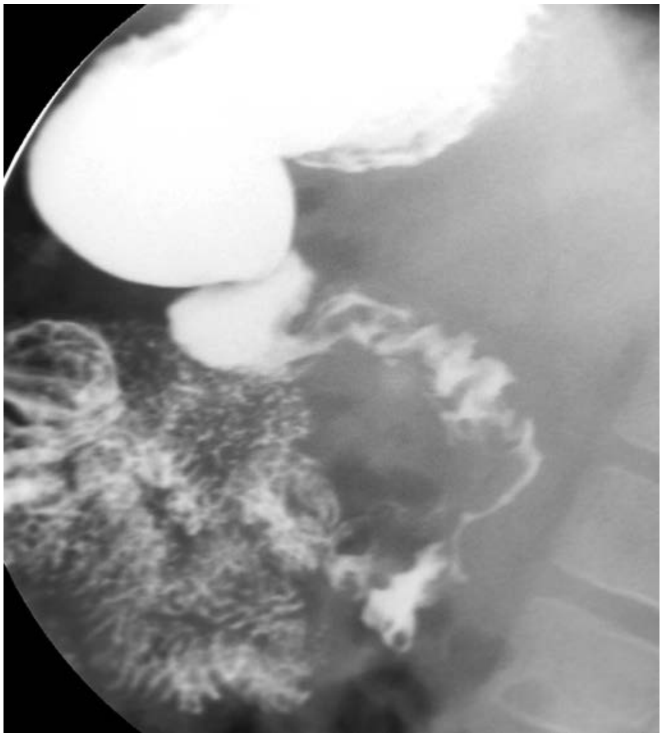
***Clinical Presentation.*** Patients usually present with abdominal pain; hematemesis may occur if there is ulcer disease.[107] Patients may also manifest symptoms of severe gastroesophageal reflux, thought partly related to gastrointestinal dysmotility and the need for frequent postural drainage.[112]

***Imaging.*** UGI typically demonstrates thick and coarse duodenal folds, particularly along its first and second portions, with some distortion and kinking of the duodenal contours, at times simulating a mass lesion,[113] ulceration,[107] or frank stricture formation (e-Fig. 103.7).[106,108]

***Treatment.*** Patients are treated with proton pump inhibitors or histamine-2 ($H_2$) receptor antagonists to decrease the acidity of the duodenal environment, which helps prevent ulceration as well as increase the ability to absorb fats and fat-soluble vitamins.[114,115]

## NEOPLASMS

***Overview.*** Duodenal neoplasms are uncommon lesions. Neoplasms that are characteristic to the duodenum include lesions related to Brunner glands, adenomas associated with polyposis syndromes, and neuroendocrine tumors. Gastrointestinal stromal tumors (GIST), clear cell sarcomas, and clear cell myomelanocytic tumor (PEComa) have also been reported, although these are highly unusual.[116,117] Brunner gland hyperplasia has been described as three types: diffuse through the duodenum, circumscribed and confined



**e-Figure 103.7. Cystic fibrosis.** UGI spot image in a patient with cystic fibrosis demonstrates duodenal fold thickening. *(Case courtesy of Dr. Steven Kraus, Cincinnati, OH.)*

to its first portion, and Brunner gland hamartoma, which refers to lesions larger than one centimeter.[118] These hamartomatous lesions are rare, more often occurring in adults during or after middle age, but can occur in children and have been reported in early infancy, more commonly in the more proximal duodenum.[119,120]

Most duodenal polypoid lesions in pediatric patients are associated with polyposis syndromes. Familial adenomatous polyposis (FAP) is the most common systemic abnormality in patients with duodenal adenomatous polyps; conversely, adenomatous duodenal polyps occur in approximately 90% of FAP patients. Periampullary duodenal carcinoma is the most common extracolonic tumor in adult patients with FAP.[121,122] In an endoscopic study of 24 pediatric patients with FAP, periampullary adenomas were present in 41%.[123] Children with Peutz-Jeghers syndrome develop hamartomatous polyps in the duodenum,[121] although 3% to 6% of hamartomas develop adenomatous changes.[122] Brunner gland hypertrophy develops in patients with juvenile polyposis,[121] but cancers of the duodenum have also been reported in this population.[122]

Duodenal neuroendocrine tumors may be sporadic, or associated with MEN-1 or neurofibromatosis type 1. Approximately two-thirds of duodenal neuroendocrine tumors are G cell gastrin tumors, of which nearly one-third are associated with the Zollinger-Ellison syndrome. Somatostatin-producing D cell tumors represent approximately one-fifth of duodenal lesions, nearly exclusively located in the periampullary region.[124,125]

***Etiology.*** The hyperplasia of Brunner glands that occurs in uremic patients is thought to be related to the elevated gastrin levels and hyperacidity that occurs in patients with end-stage renal insufficiency.[118,126,127] Brunner gland hamartomas are associated with chronic renal failure, chronic pancreatitis, peptic ulcer disease. and infection with *H. pylori*.[128]

Mutations that render the product of tumor suppressor genes ineffective are of paramount importance in the development of malignancy. FAP patients have a mutation within the adenomatous polyposis coli *(APC)* gene located at chromosome 5q21. Peutz-Jeghers has been mapped to the *STK* (serine threonine kinase 11) gene on chromosome 19p13.3. Genetic loci in separate kindred with juvenile polyposis have been reported in the *SMAD4* gene located on chromosome 18q21.1 and the *PTEN* gene on chromosome 10q23.[121,122]

***Clinical Manifestations.*** Patients with Brunner gland hyperplasia are typically asymptomatic. When symptoms occur, patients tend to present with bleeding, obstruction, pain, vomiting, and diarrhea.[118] Large lesions such as Brunner gland hamartoma can present with gastric outlet obstruction, and biliary obstruction and pancreatitis when affecting the periampullary region.[128]

Duodenal carcinoids may manifest as Zollinger-Ellison syndrome. D cell somatostatin-producing tumors arising in the duodenum are usually too small to produce clinically apparent symptoms related to hormone overproduction.[129]

***Imaging.*** A large lesion, such as a giant Brunner gland hamartoma may demonstrate evidence of gastric outlet obstruction on abdominal radiographs.[128] On UGI, a filling defect within the duodenal bulb may be demonstrated (Fig. 103.8). Single or multiple polyps, seen with FAP or Peutz-Jeghers syndromes, appear as a multitude of filling defects, at times complicated by intussusception (e-Fig. 103.9). Duodenal carcinoids have been described as intraluminal or mural filling defects, sometimes with ulcerations, and occasionally producing obstruction by intussusception.[124] CT detection is optimized by the use of negative luminal contrast, with marked arterial enhancement decreasing on the portal venous phase.[76,125] On MR, they have been described as low signal on T1-weighted images, heterogeneously high signal on water-sensitive sequences, and have early arterial hyperenhancement.[124,129]

***Treatment.*** Brunner gland hyperplasia does not require specific treatment if asymptomatic. Conservative treatment consists of control of gastric acidity with proton pump antagonists and $H_2$ blockers. Brunner gland hamartomas may be amenable to endoscopic removal, although larger or more diffuse lesions may need more extensive surgical polypectomy, or segmental or more extensive duodenal resection.[128] Children with FAP undergo periodic endoscopic screening, as most duodenal adenomas are not symptomatic. Management of periampullary adenocarcinoma includes pancreaticoduodenectomy. Endoscopic ampullectomy may be helpful in some patients with early lesions.[123]

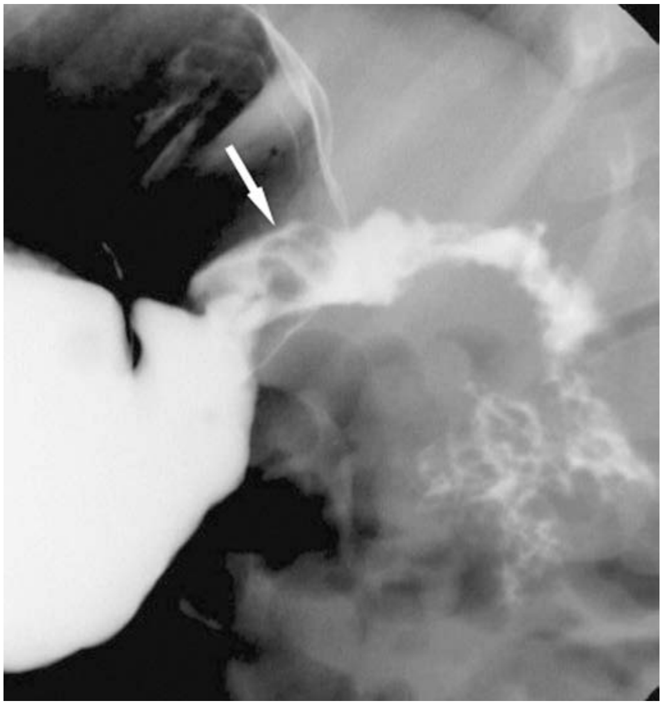


**Figure 103.8. Brunner gland hyperplasia.** UGI spot image shows a less than 1 cm filling defect *(arrow)* in the duodenal bulb consistent with Brunner gland hyperplasia. *(Case courtesy of Kimberly Applegate; Lexington, KY.)*

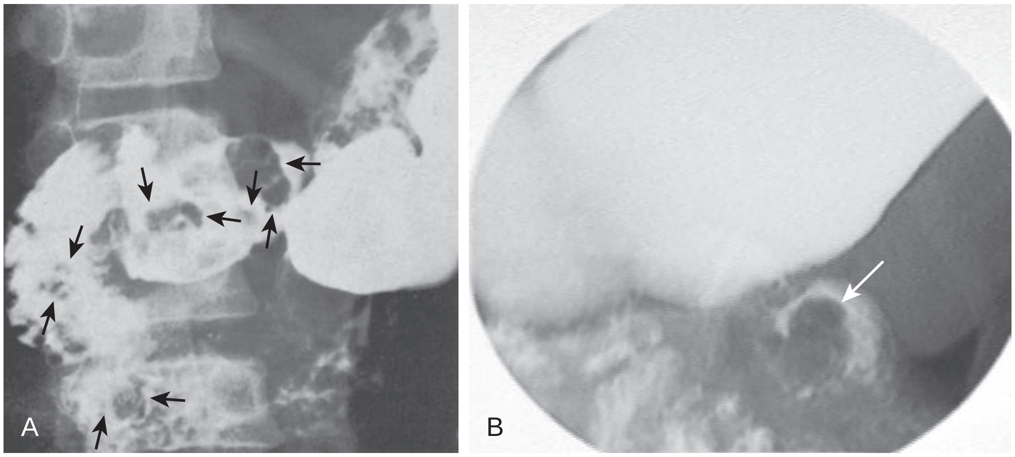
KEY POINTS

- The normal angle between the aorta and the SMA is 25 to 60 degrees, and the distance between the aorta and the SMA is 10 to 28 mm.
- SMA syndrome-predisposing conditions include Nissen fundoplication, cerebral palsy, traumatic brain injury, posterior spinal fusion, burn, lumbar hyperlordosis, and spinal traction/cast.
- Causes of duodenal hematoma include nonaccidental trauma and other blunt injuries to the epigastrium, such as handlebar injuries, motor vehicle crashes, and sports injuries.
- Duodenal intussusception is a complication of post-pyloric GJ tubes, which act as a lead point.
- Duodenal ulcer disease is associated with infection by *Helicobacter pylori*, which is estimated to colonize/infect approximately half the world's population.
- Zollinger-Ellison syndrome refers to autonomous oversecretion of the hormone gastrin by a gastrinoma, resulting in unusually severe and refractory ulcer disease, accompanied by diarrhea. Approximately 15% to 38% of cases occur as part of MEN-1.
- Duodenal involvement in patients with Crohn disease is identified more frequently with endoscopic evaluation.



**e-Figure 103.9. Peutz-Jeghers syndrome.** (A) UGI shows multiple polyps in the duodenum *(arrows)* in a 12-year-old boy with Peutz-Jeghers syndrome. He also had polyps in the stomach, the colon, and the remainder of the small intestine. (B) A 9-year-old boy with Peutz-Jeghers syndrome presenting with symptoms of intermittent obstruction. UGI spot image of the proximal jejunum demonstrates a filling defect *(arrow)* due to duodenojejunal intussusception. A hamartomatous duodenal polyp was found to be the lead point at endoscopy. *(Case courtesy of R. Paul Guillerman, Houston, TX.)*

- Duodenal ulceration in patients with CF is related to impaired secretion of bicarbonate and increased acid production, producing an acidic duodenal environment.
- Most pediatric duodenal polyps that are not associated with Brunner gland hyperplasia are associated with polyposis syndromes. Duodenal adenomatous polyps occur in approximately 90% of patients with familial adenomatous polyps.

# 104 Acquired Lesions of the Small Intestines

Mary-Louise C. Greer

The pediatric duodenum, jejunum, and ileum are subject to a range of acquired pathologies. In this chapter, the etiology, pathophysiology, and clinical manifestations of small bowel obstruction (SBO), infectious and noninfectious inflammatory bowel disease (IBD), and intestinal infiltrative and neoplastic disorders will be discussed.

## SMALL BOWEL OBSTRUCTION

***Overview.*** Acquired SBO may be partial or complete, acute or chronic, and intermittent. It is relatively uncommon in children, particularly in infants under 1 year of age, in whom congenital causes of obstruction are more common (see Chapter 102). Congenital anomalies can, however, result in acquired SBO, with an inguinal hernia containing herniated bowel causing obstruction if incarcerated, or adhesions after neonatal gastroschisis repair. Acquired neonatal insults such as necrotizing enterocolitis (NEC) can cause ischemic strictures.

Abnormalities that mimic obstruction include chronic intestinal pseudoobstruction, manifest by variable distension of the gastrointestinal (GI) tract, defined as being “repetitive episodes or continuous symptoms and signs of bowel obstruction, including radiographic documentation of dilated bowel with air-fluid levels, in the absence of a fixed, lumen-occluding lesion.”[1,2]

***Etiology.*** As in adults, the majority of acquired SBO in children is secondary to adhesions or hernias.[3,4] Less common causes include tumors, inflammatory or fibrotic strictures in IBD, volvulus associated with malrotation or Meckel diverticulum, foreign body (FB) ingestion, and small bowel intussusception (see Chapter 107).[3–6]

### Adhesions

Adhesions are a common cause of obstruction in patients who have undergone prior abdominal surgery, reportedly affecting 1% to 6% postoperatively, 80% occurring within 3 months.[3,7] In neonates, adhesions are seen particularly after surgery for repair of abdominal wall defects such as gastroschisis. In older children, adhesive obstruction occurs most often after ileostomy formation and closure (25%) and Ladd’s procedure for malrotation (24%), with lower rates for general laparotomy (6.5%). Rates are less than 1% after appendectomy, although higher if perforated.[3,7]

### Incarcerated Hernia

Hernias are responsible for approximately 10% of bowel obstructions.[3] Inguinal hernias are a relatively common condition in children, with an overall incidence between 0.8% and 4.4%.[8] The vast majority are indirect hernias related to a patent processus vaginalis.[9] The incidence of inguinal hernia is 10 times higher in boys than girls.[10] Inguinal hernias have both a higher incidence (~30%) and a higher risk of incarceration (31%) in premature infants.[11] Internal hernias can be paraduodenal (see Chapter 102), occurring around an incompletely fixated falciform ligament or a Meckel diverticulum.[5,12]

### Tumors

Tumors may cause bowel obstruction from extrinsic compression or as intrinsic lesions triggering intussusception secondary to polyps or to lymphoma, typically Burkitt lymphoma. Tumors are further discussed later in this chapter.

### Omphalomesenteric Duct Remnants

Omphalomesenteric remnants or Meckel diverticula are the residua of the embryologic yolk stalk. Present in 2% to 4% of the population, 4.8% of people will develop a spectrum of GI complications that make diagnosis challenging.[12] When failing to regress, the obliterated lumen can form a fibrous cord, sometimes with cystic remnants, attaching the mid–small intestine to the anterior abdominal wall. Distal SBO in Meckel diverticulum can result from a mechanism similar to adhesions, bowel herniation, or from intussusception.[5,12] Other manifestations include GI bleeding from ectopic gastric or rarely pancreatic tissue. Gastric ectopia is usually seen without SBO, but ectopic pancreatic tissue is strongly associated with intussusceptions (see Chapter 102).[5]

### Adynamic Ileus

Adynamic ileus can cause bowel distension and may mimic mechanical obstruction. Adynamic ileus occurs after major abdominal operations, and if prolonged it may be difficult to differentiate from an early postoperative or recurrent obstruction.[3] Adynamic ileus may also occur in the setting of burns, trauma, and certain medications. The pathophysiology of postoperative ileus remains incompletely understood, but the disruption of normal autonomic GI motility is multifactorial and related to pharmacologic, inflammatory, hormonal, metabolic, and neuropsychologic influences.[13]

### Foreign Body Ingestion

Ingestion of FBs by infants and children, most frequently between 6 months and 6 years, can potentially cause SBO if held up at the terminal ileum.[3,14] The increasing incidence of multiple magnet ingestion poses unique risks; if self-apposing across different parts of the intestine, they may cause obstruction and/or mucosal erosion and perforation.[15]

***Clinical Presentation.*** SBO in children presents most frequently with crampy abdominal pain, vomiting (variably bilious), anorexia and obstipation, with constant pain, lethargy, and abdominal distention if prolonged.[7] Nausea and bilious vomiting predominate in proximal obstruction, with less distension.[4] Infants and young children may display only irritability and food refusal. Peritonitis, tachycardia, and fever can be indicative of bowel ischemia, with accompanying leukocytosis or lactic acidosis.

***Imaging.*** Patients with long-standing complete obstruction will demonstrate dilated loops of bowel with differential air-fluid levels on horizontal-beam images and absence of stool and gas in the colon (Fig. 104.1A and B). In partial obstruction, gas and stool may be present in the colon; however, a caliber difference between

## Abstract:

Acquired lesions of the small intestines range from commonly encountered small bowel obstruction (SBO), infectious and non-infectious inflammatory disorders, to infiltrative diseases, and more rarely, intestinal neoplasms. This review considers these and other acquired small bowel diseases in neonates, children and adolescents. Their etiologies, pathophysiology, clinical manifestations, imaging and treatment are discussed.

Adhesions are the commonest cause of pediatric SBO, less frequently incarcerated hernias, Meckel diverticulae, intussusceptions and tumors. Ingested foreign bodies (FB) have the added risk of possible perforation if a battery or more than one magnet is swallowed. Early recognition is important as surgical intervention may be warranted e.g. FB removal. Radiographs show dilated bowel with air-fluid levels. Although hyperperistalsis seen on ultrasound can help differentiate SBO from adynamic ileus, computed tomography (CT) remains a key tool in diagnosis.

Whilst infectious enteritis is a major cause of childhood morbidity and mortality, the role of imaging is limited. In comparison, imaging is central to the diagnosis of pediatric inflammatory bowel disease (IBD), helping distinguish Crohn disease from ulcerative colitis and IBD-unclassified, document extent, complications and treatment response. Magnetic resonance enterography, ultrasound and CT have largely replaced fluoroscopy.

This diagnostic imaging pathway change is similar in the evaluation of functional and infiltrative disorders such as cystic fibrosis, protein-losing enteropathies, graft-versus-host disease and IgA vasculitis, considered here in more detail. So too is the diagnosis and staging of benign and malignant small bowel neoplasms, nuclear medicine having a greater role in lymphoma, neuroendocrine and gastrointestinal stromal tumors.

## Keywords:

small intestinal tumors

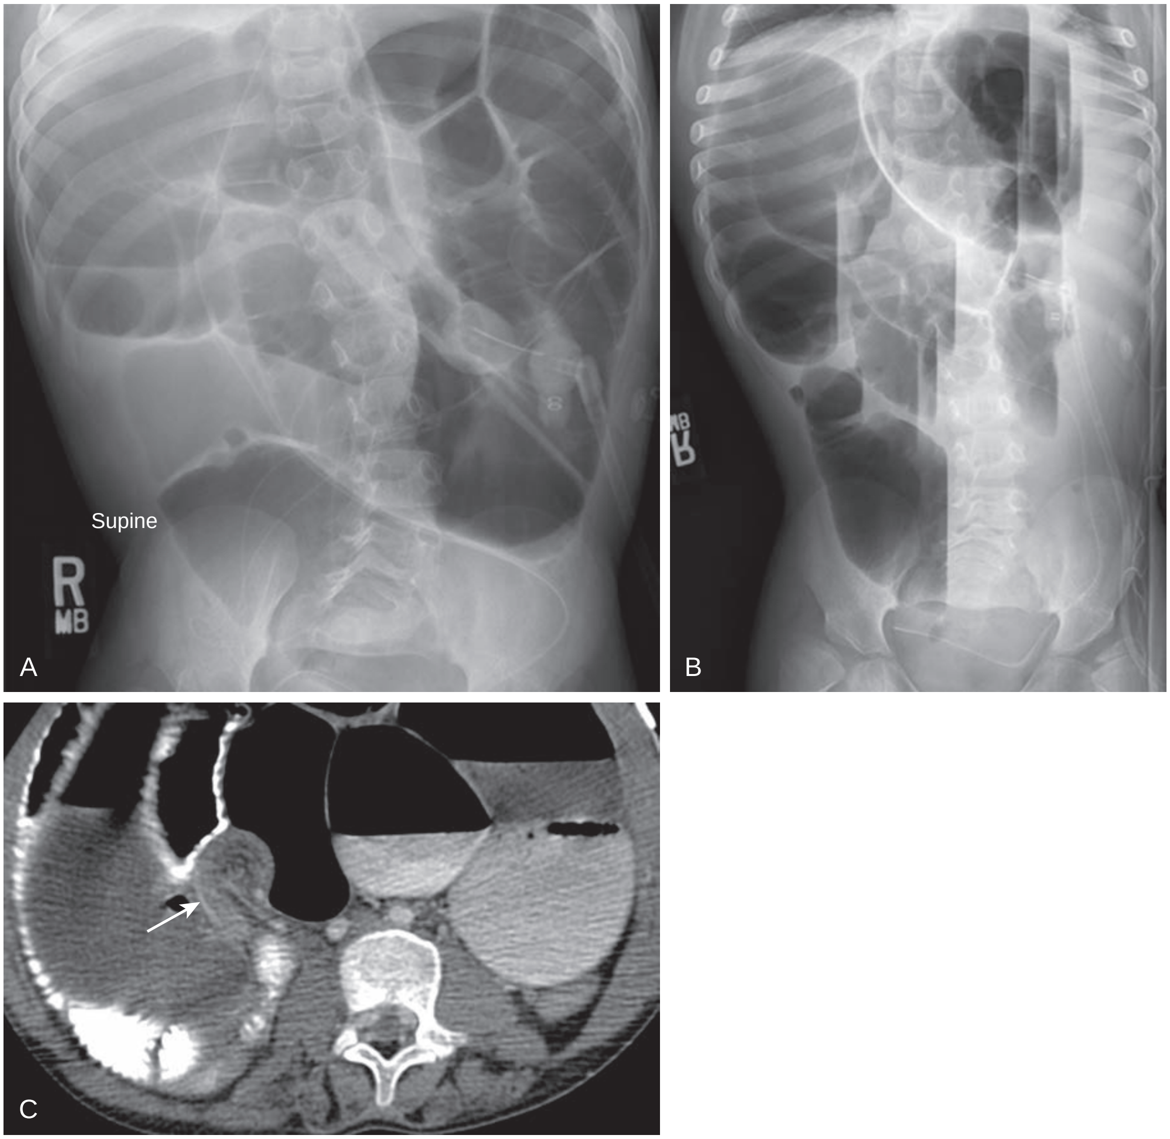

**Figure 104.1. Small bowel obstruction caused by adhesions.** (A) Supine radiograph of the abdomen in an 8-year-old boy with a history of multiple abdominal operations and increasing abdominal distension shows dilated, gas-filled loops of bowel. (B) Horizontal-beam left lateral decubitus image demonstrates multiple differential air-fluid levels. (C) Axial contrast-enhanced CT image shows a transition zone *(arrow)* between dilated proximal bowel loops and collapsed distal bowel loops. As oral contrast is seen in dilated proximal and nondilated distal bowel loops, the obstruction is incomplete. Adhesions resulting in a small bowel obstruction were lysed at surgery.

proximal loops of dilated bowel and bowel distal to the obstruction should remain evident.

Conventional radiographs may reveal the level of obstruction but in many cases poorly differentiate incomplete obstruction from adynamic ileus. Radioopaque FBs such as magnets or batteries may be evident on x-ray, with serial imaging advocated depending on FB location.[3,14] The level and, at times, the cause of obstruction may be more readily demonstrated on computed tomography (CT) or ultrasound (US), including FBs that may be radiolucent on radiographs (Fig. 104.2). Small bowel follow-through (SBFT) is rarely done, usually reserved now for young infants.

Adynamic ileus can simulate mechanical obstruction on plain radiographs. Supine radiographs of the abdomen show dilated loops of bowel in both conditions; however, mechanical obstruction usually causes proximal dilation with reduced caliber of the distal bowel, whereas adynamic ileus typically causes uniform dilatation of the entire small and large bowel.

In neonates, it is often not possible to differentiate small and large bowel; a prone cross-table lateral view of the rectum can be helpful to assess caliber of distal bowel when obstruction is suspected. In older children, on upright views, mechanical obstruction can show a step-laddered arrangement to bowel, often with pronounced fluid distension accompanying the air-fluid levels. Conversely with adynamic ileus the air-fluid levels are frequently more scattered and with more gaseous distension, both better seen with decubitus views. Decubitus views are also important in evaluating for free intraperitoneal air.

There is a renewed interest in US in diagnosing SBO. Point-of-care US for pediatric SBO is evolving although is not yet

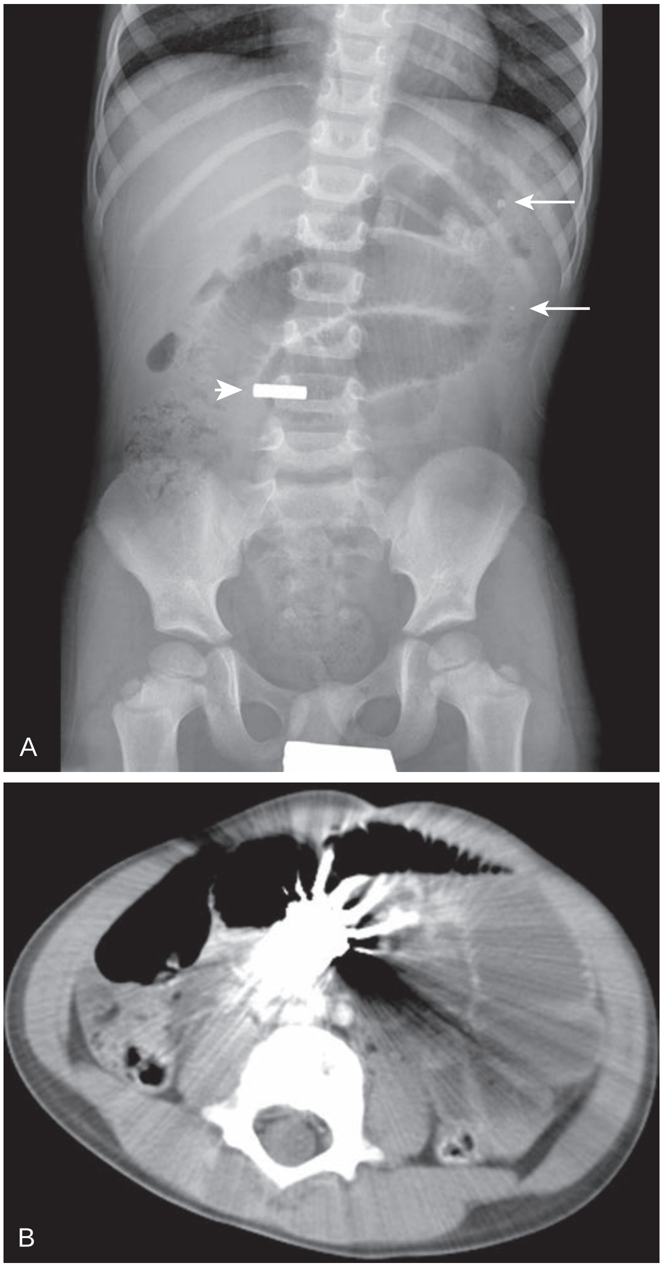

**Figure 104.2. Foreign body ingestion from a magnet causing small bowel obstruction.** A 5-year-old boy presented with a 24-hour history of abdominal pain and bilious vomiting after ingestion of a radioopaque FB, presumed to be a battery *(broad arrow),* seen on supine abdominal radiograph (A) in the midabdomen. There is marked gaseous distension of proximal small bowel loops with a paucity of bowel gas distally indicating SBO. Note numerous folds in dilated segment in keeping with jejunum. Smaller radioopaque foci seen remote from the large FB *(small arrows)* were later confirmed to be in colon. (B) Abdominal CT without oral contrast demonstrated the obstructing FB at level of transition point in the umbilical region, with grossly dilated fluid-filled proximal small bowel loops and collapsed bowel distally. At surgery, localized perforation was found with a protruding FB—a magnet—with one large and several smaller parts at level of the SBO.

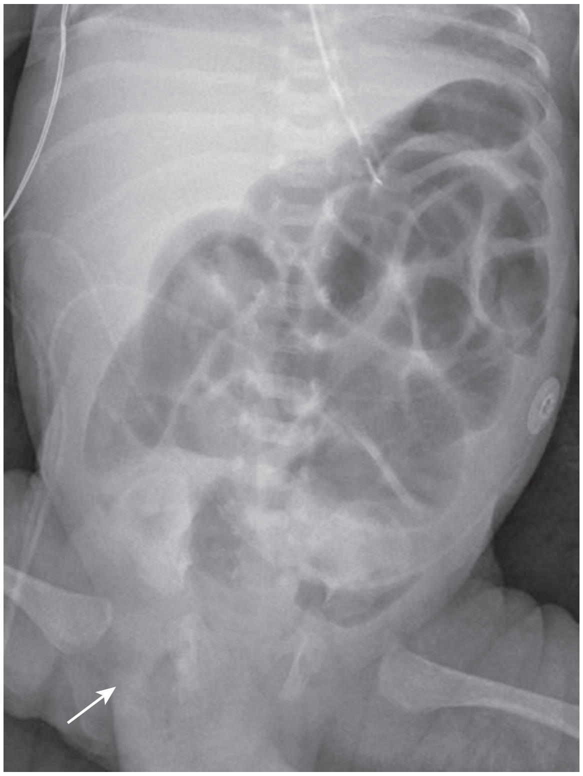

**Figure 104.3. Small bowel obstruction caused by inguinal hernia.** Supine radiograph of the abdomen in a 1-month-old, former 26-week preterm boy, who presented with a distended abdomen and a right inguinal hernia, demonstrates dilated, gas-filled loops of bowel. Bowel gas is seen within the right inguinal hernia *(arrow)*. Obstructive symptoms improved after manual reduction of the hernia.

validated.[16,17] In mechanical obstruction, US can show distended fluid-filled proximal loops (>2.5 cm) and collapsed distal loops, hyperperistalsis, and "to-and-fro" motion upstream from the obstruction. In contrast, peristalsis may be diminished in adynamic ileus, with uniformly distended fluid-filled bowel loops. On occasion, intrinsic lesions can be seen, such as strictures in IBD (Video 104.1) or intussusceptions (without or with pathologic lead point such as Meckel diverticulum or lymphoma), or extrinsic causes such as a tumor. Infrequently, bowel tethering with or without volvulus or angulation from an adhesion or peritoneal band is evident.

CT can be helpful in revealing the level and occasionally the cause of the obstruction. Administration of oral contrast is not always necessary (see Fig. 104.1C), and only water-soluble agents should be administered if bowel perforation is suspected. CT is particularly helpful in diagnosing closed-loop obstruction and obstruction related to adhesions, with dilated bowel loops seen proximally and collapsed bowel distal to a transition point of obstruction, sometimes with swirling vessels. The diagnosis of an incarcerated hernia is typically established by history and physical exam, although radiographs (Fig. 104.3) or US may occasionally be used to confirm the diagnosis.

***Treatment.*** Although a majority of children are managed conservatively, more require surgical intervention than adults to minimize gut ischemia and necrosis, which remains a high risk.[4,7] This requires careful triage and monitoring for clinical change. Those with symptoms of partial obstruction usually respond well to bowel decompression. Prompt surgical intervention is warranted if fever, leukocytosis, or unremitting pain are present or develop, or conservative treatment does not resolve symptoms of partial SBO within 48 hours.[7]

In the absence of peritoneal signs, the treatment of choice for an incarcerated inguinal hernia is manual reduction, which has a success rate of 80%, followed by repair 24 to 48 hours after reduction.[10,11] For umbilical hernias persisting beyond 4 years of age, surgery is advocated because of the increasing risk of incarceration with age.[18]

Early postoperative SBO has traditionally consisted of prolonged bowel rest and decompression via nasogastric tube. However small bowel intussusception should be excluded, as this may require laparotomy.[7] In FB ingestion, particularly multiple magnet ingestion in a symptomatic patient, early surgical review is required to consider endoscopic or laparoscopic removal.[15] Some advocate magnet removal even when asymptomatic due to the risk for severe GI injury and death (see Fig. 104.2).[14] In chronic intestinal pseudoobstruction, treatment depends on the underlying cause and may include prokinetics; surgery in the form of gastrostomy, jejunostomy, and/or loop enterostomy; and total parenteral nutrition (TPN).[2]

## INFLAMMATORY CONDITIONS OF THE SMALL BOWEL

### Infectious Diseases

***Overview.*** Infectious diarrhea is a major source of childhood morbidity and mortality under 5 years of age, with 1.7 billion episodes reported in 2010, and an estimated 700,000 deaths attributable to it in 2011, 72% under 2 years. Undernutrition is a major risk factor. Viruses, bacteria, and parasites are causative agents of acute gastroenteritis in children, with the leading causes rotavirus and cholera preventable by vaccination.[19–21]

***Etiology.*** *Viral Infection.* Viruses are one of the most common causes of acute infectious diarrhea, defined as at least "three loose stools per day for less than 14 days."[21] Globally, the most common and severe viral gastroenteritis is due to rotavirus, highest in number in Africa but with peak severity and mortality in the Western Pacific (32.6%), and lowest in the Americas (23.4%). Less common severe viral infections are astrovirus, adenovirus, and norovirus *(Caliciviridae)*.[19–21]

*Bacterial Infection.* Bacterial pathogens are estimated to cause between 2% and 10% of infectious diarrhea cases in developed countries[20]; *Vibrio cholerae* accounts for 1% globally, with severe diarrhea and mortality rates of up to up to 4.5%.[19] *Shigella*, *Salmonella*, *Escherichia coli*, and *Campylobacter* are the most common in the United States.[20]

*Clostridium difficile* can be isolated from the intestine of up to 50% of normal neonates, decreasing to less than 5% by 2 years of age. Illness-associated *C. difficile* infection is seen with a decrease in other intestinal flora secondary to exposure to broad-spectrum antibiotics, resulting in antimicrobial-associated diarrhea or pseudomembranous colitis.[20]

Rarely, *Mycobacterium tuberculosis* (TB) can involve the intestine in children.[22–24]

*Parasitic Infection. Giardia lamblia*, *Entamoeba histolytica*, and *Cryptosporidium* are parasitic causes of infectious diarrhea, all seen globally, and mostly not severe, although occasionally *Cryptosporidium* can be.[19,20] The helminthes including nematodes or roundworms, and the platyhelminthes or flatworms, are estimated to infect one-third of those in developing countries, with children and adolescents harboring the largest loads.[25]

*Human Immunodeficiency Virus.* Approximately 3.2 million children under 15 years of age are infected with human immunodeficiency virus (HIV) worldwide, often in conjunction with other endemic conditions, such as TB, malaria, cytomegalovirus (CMV), and helminthic infections.[25–27] Although antiretroviral therapy (ART) has decreased the prevalence of vertical mother-to-child transmission (MTCT) and perinatal HIV in developing countries, approximately 240,000 children are newly infected annually, primarily through postnatal MTCT.[27]

***Clinical Presentation.*** *Viral Infection.* Viral gastroenteritis commonly manifests with vomiting followed by severe watery diarrhea, nausea, abdominal pain, headaches, and low-grade fever, often accompanied by upper respiratory tract symptoms.[28] Others like norovirus are often milder and self-limiting.

*Bacterial Infection.* Considerable overlap occurs in clinical symptoms of viral and bacterial enteritis. High fever, shaking chills, and blood and mucus in stools is infrequent in viral gastroenteritis.[20] Diagnosis may be established by stool leukocytes and positive stool culture. Intestinal TB can present with fever, anorexia, abdominal pain, distension and diarrhea, and weight loss that may mimic Crohn disease (CD).[24]

*Parasitic Infection.* Symptoms of *Giardia* infection vary from asymptomatic to foul-smelling diarrhea with flatulence, abdominal distension, and anorexia. Diagnosis is from stool microscopic smear examination or immunofluorescence antibody testing.[20]

*Cryptosporidium* infection is usually self-limited in the immune competent child, may be asymptomatic, or can be confused with viral gastroenteritis.[29] In immunocompromised patients, including those with HIV, the course can be protracted with severe, chronic diarrhea and subsequent malnutrition and dehydration, which may result in death.[20,29]

*Helminthic* infestations can present with low-grade fever and nonbloody watery diarrhea or gut obstruction as in intestinal *Ascaris lumbricoides*. Chronic infection can lead to physical and cognitive impairment in children.[3,25,30]

*Human Immunodeficiency Virus.* Persistent diarrhea is a manifestation of the clinical syndrome of AIDS.[19] HIV can directly affect the gut or coexist with other pathogens, leading to or compounding severe malnutrition and subsequent growth retardation.[27] The child with HIV may also be more susceptible to opportunistic infections (e.g., CMV, *Mycobacterium avium-intracellulare*, and fungi, especially *Candida albicans*).[19,26]

***Imaging.*** Imaging is not generally indicated in the evaluation of infectious diarrhea. Abdominal radiographs may demonstrate a nonobstructive pattern of dilated fluid-filled loops (see previous section). Absence of stool throughout the colon is common, with air-fluid levels in the rectum. Pneumatosis intestinalis is rarely seen, more so in immune-compromised patients.[31]

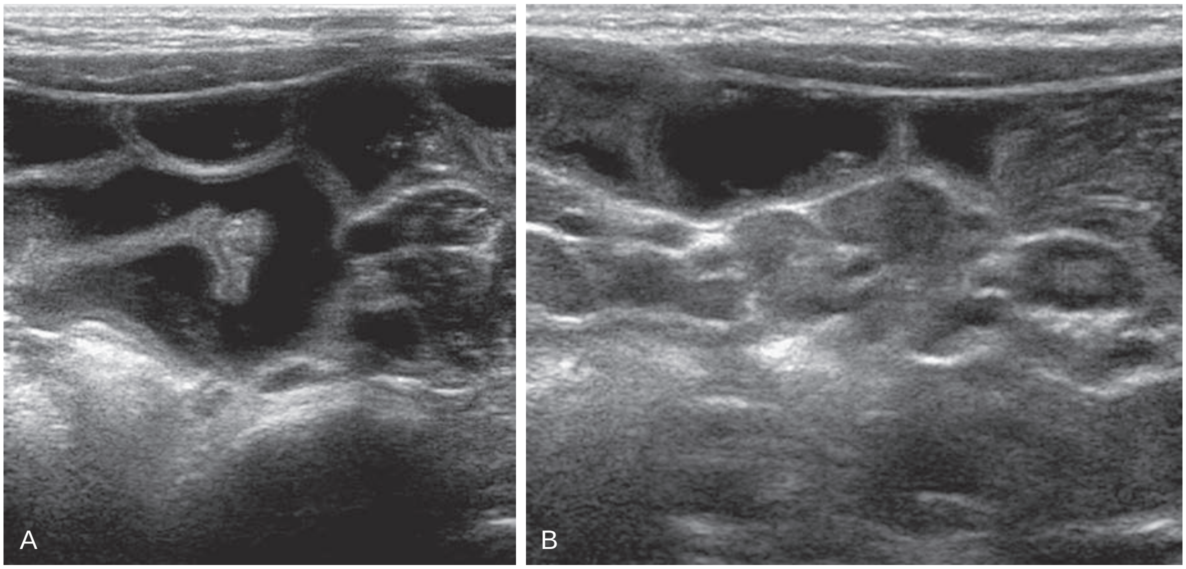
US may show fluid-filled small bowel loops, with or without wall thickening, free fluid, and lymphadenopathy in viral gastroenteritis (e-Fig. 104.4).[32] In intestinal TB, enlarged nodes may be centrally hypoechoic and the ascites finely septated; distortion of the ileocecal region/ascending colon rarely may be seen on barium enema.[22] US may reveal transient small bowel intussusception during periods of hyperperistalsis.

In *Ascaris* intestinal infestation, the roundworm may be seen at US as four echogenic lines in parallel, best seen with a high-frequency transducer, and US can exclude related complications such as intussusception or biliary ascariasis.[3,30] Features relating to helminthic infections can also be seen on SBFT, including barium dilution, mild mucosal fold thickening, rapid or delayed transit times, and, on occasion, delineation of the parasitic gut.

The terminal ileum and cecum are often involved in bacterial enteritis, such as with *Yersinia*, termed infectious ileocecitis. Unlike intestinal TB, infectious ileocecitis may be seen on US, CT, and SBFT and barium enema, as mural thickening with variable involvement of the more distal large bowel (Fig. 104.5). US or CT may also reveal regional lymphadenopathy.[28,33]

HIV enteropathy may be seen on SBFT as increased nodularity or mucosal effacement, more usually secondary to opportunistic infection with CMV or *Cryptosporidium* infection.[19,34]

***Treatment.*** Treatment is dependent upon the underlying causative agent. Viral gastroenteritis is typically a self-limited condition but may warrant supportive measures such as rehydration.



**e-Figure 104.4. Gastroenteritis.** A 21-month-old boy was seen with vomiting and irritability. (A) Ultrasonography requested for clinical concern of intussusception reveals distended, fluid-filled loops of bowel that are otherwise normal. (B) Additional image in the right lower quadrant reveals multiple enlarged mesenteric nodes, which were hyperemic on color Doppler interrogation (not shown). *(Courtesy Marta Hernanz-Schulman MD, Nashville, TN.)*

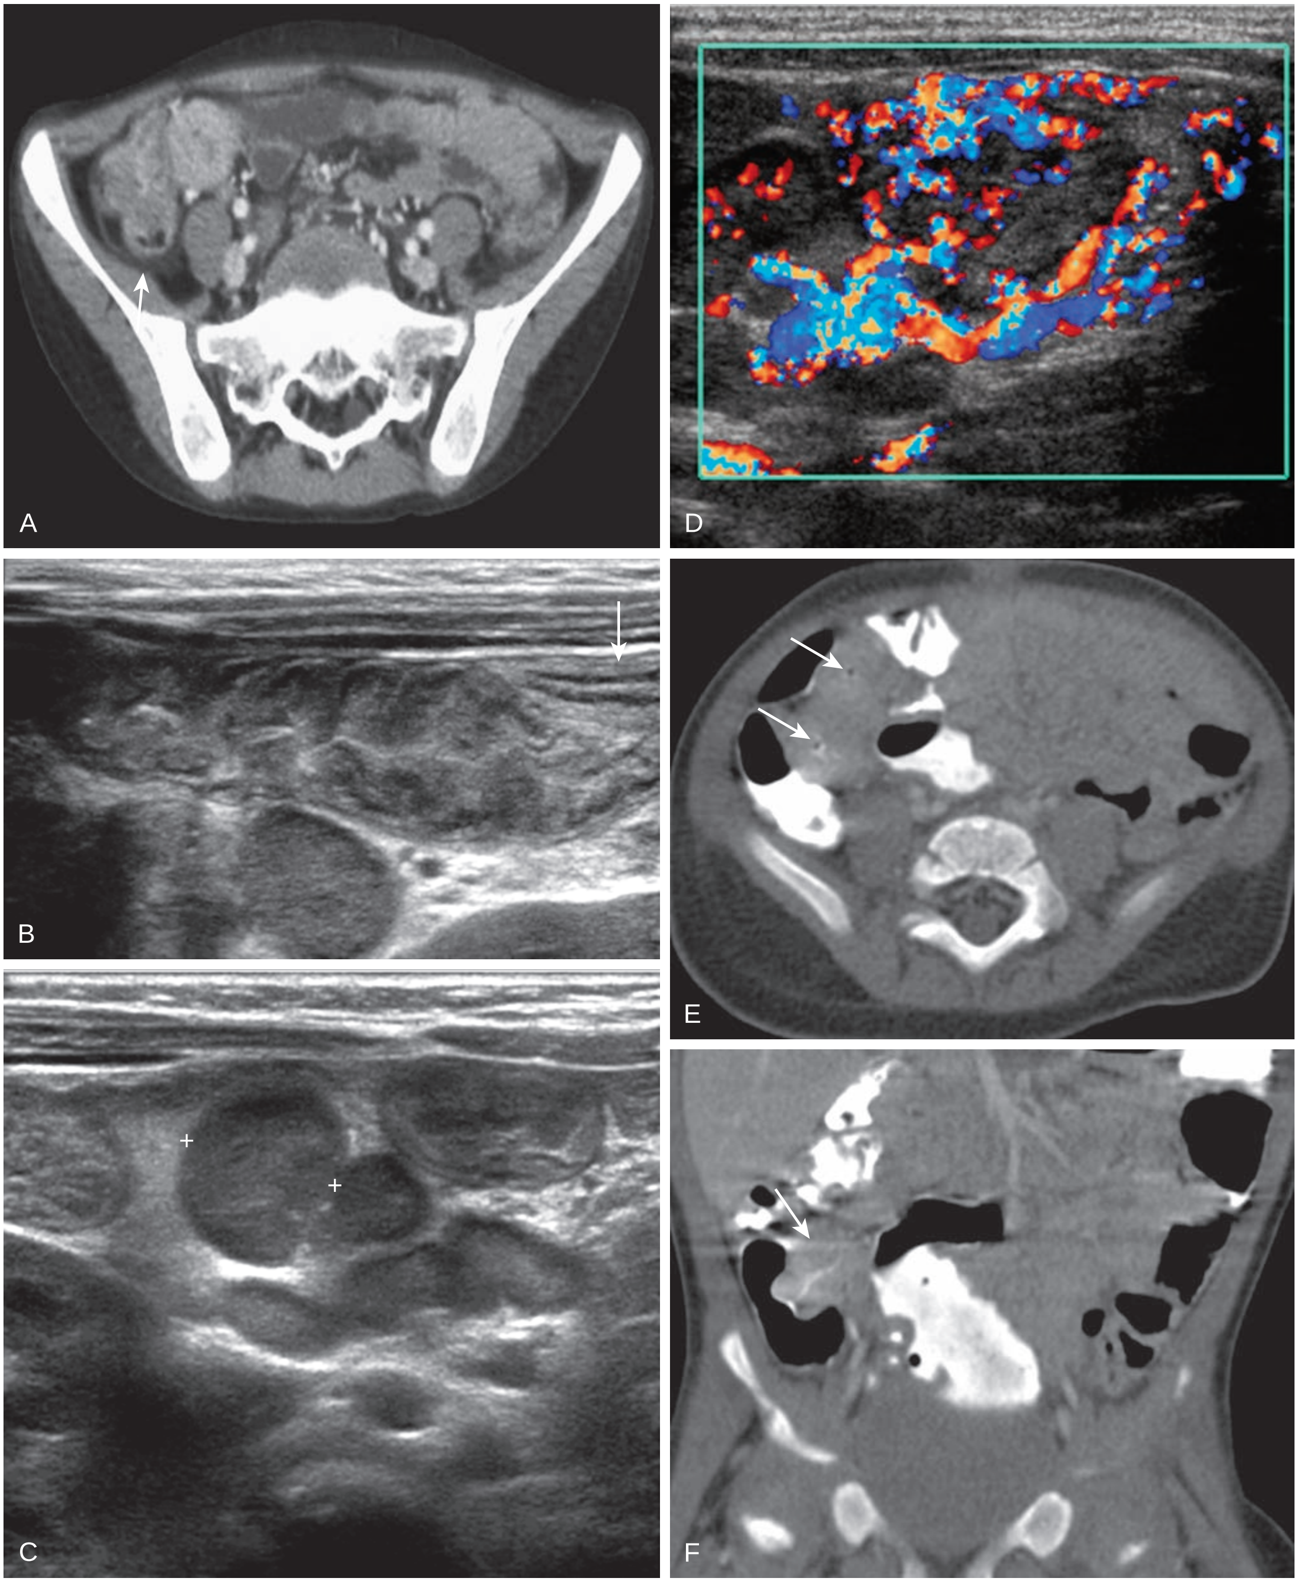


**Figure 104.5. Bacterial enterocolitis.** (A) *Shigella enteritis.* Axial contrast-enhanced CT reveals concentric thickening and enhancement of the terminal ileum and cecum, along with a small amount of pericecal fluid *(arrow)*. *Shigella sonnei* was cultured from the stool. (B) Transverse sonogram of the right lower quadrant in a 5-month-old with mucous diarrhea and abdominal pain and suspected intussusception shows a markedly thickened terminal ileum, along with a visible transition to normal bowel *(arrow)* more proximally. A large lymph node is seen deep to the terminal ileum. (C) Transverse sonogram in same infant as shown in (B), obtained slightly more cephalad, reveals a large nodal aggregate medial to the ascending colon and anterior to the lower pole of the right kidney (*calipers* outline one of the nodes). (D) Color Doppler image in the same infant shows marked hyperemia in the thick-walled terminal ileum and in the surrounding mesentery and lymph nodes. (E) *Yersinia* enteritis. Axial contrast-enhanced CT in a 9-month-old boy who had a 10-day history of fever, emesis, and voluminous diarrhea demonstrates pronounced thickening and luminal narrowing of the terminal ileum *(arrows)*. (F) Coronal reformat image of same patient as shown in (E) demonstrates similar findings. Stool cultures were positive for *Yersinia enterocolitica*.

Bacterial enterocolitis also includes supportive therapy, with antimicrobial therapy not always necessary depending on the severity of illness and immunocompetency of the patient. Agents such as metronidazole and nitazoxanide are active against *Giardia* and *Cryptosporidium*, respectively. Treatment of helminthic infections is relatively limited, particularly when considering the global ubiquity of these infections, and it includes diethylcarbamazine and newer agents such as albendazole and praziquantel.[20,25] Measures to increase vaccination for rotavirus and cholera, improve delivery of ART, and prevent MTCT of HIV will significantly reduce pediatric morbidity and mortality from infectious enterocolitis.[19,27]

## Inflammatory Bowel Disease

***Overview.*** IBD includes CD, ulcerative colitis (UC), and IBD-unclassified (IBD-U). CD, characterized by transmural granulomatous inflammation of the GI tract, can affect anywhere from the mouth to anus, whereas in UC, continuous nongranulomatous mucosal inflammation is limited to large bowel.[35] Inflammation can progress to penetrating and/or fibrostenotic disease. These are chronic, relapsing, and remitting conditions.[36,37] CD is almost three times more frequent than UC in children, with IBD-U comprising less than 10% of cases. The incidence of IBD is increasing worldwide with wide geographic variability; the highest annual incidence of CD is reported as 20.2 per 100,000 person-years in North America and UC 24.3 per 100,000 person-years in Europe.[38,39] Pediatric onset occurs in up to 25% of patients, often of greater severity than adult-onset IBD.[40,41] Increasingly recognized is a small cohort of very young children presenting with IBD less than 6 years, known as *very early onset IBD* (VEO-IBD).[38,41,42]

***Etiology and Pathophysiology.*** According to consensus guidelines on imaging in IBD, current understanding of causation suggests IBD "results from an inappropriate inflammatory response (immune dysregulation) to intestinal microbes in a genetically susceptible host," with both genetic and environmental contributors.[43–45] There are genotypes common to the major phenotypes of CD and UC, some overlapping and some unique, likely accounting for different phenotypic subtypes. This variability is accompanied by different rates of disease progression and severity, more pronounced in children and adolescence, particularly in VEO-IBD. This suggests a phenotype-genotype association, although inconstant, with evidence of genotypic susceptibility linked to single nucleotide polymorphism, with *NOD2* having the strongest link to CD.[46–49] To better understand this phenotype-genotype association, a classification system more accurately capturing pediatric IBD location and extent has been adapted from the adult Montreal Classification, known as the *Paris Classification*.[48] This incorporates age-based pediatric-specific disease elements such as greater extent/pancolitis in UC, increased upper GI tract disease and coexistent penetrating and stricturing disease in CD, and growth delay.[48] A 5-year review of phenotype in IBD patients from the EUROKIDS Registry with CD identified 16% with ileal/ileocecal disease (L1), 27% with isolated colonic disease (L2), 53% with ileocolonic disease (L3), and isolated upper GI tract disease in 4% (L4 a+b) (Fig. 104.6).[47]

On review of UC patients from this registry, atypical UC features were macroscopic rectal sparing (5%), cecal patches (2%), backwash or reflux ileitis (10%) with pancolitis, and mild upper GI erosions or ulcers (4%).[50] Perianal disease is almost exclusively seen in CD and IBD-U, and phenotypic variability is now being recognized, with increase in rectal and jejunal involvement in perianal CD.[51]

Disease phenotype at diagnosis in pediatric Crohn's disease: 5-year analyses of the EUROKIDS Registry.* Inflamm Bowel Dis. *Feb 2013;19[2]:378–385.)*

***Clinical Presentation.*** As in adults, children and adolescents with IBD can present with diarrhea, often having mucus and/or bloodstained stool, vague abdominal pain, weight loss, and unexplained anemia.[35] Perianal disease can include fissures, ulcers, abscesses, fistulae, and skin tags, seen in approximately 10% of pediatric CD patients at diagnosis.[52] Distinct from adults is linear growth retardation, as reflected in the Paris Classification, delayed onset of puberty, reduced bone mineral density, and malnutrition.[41,48] VEO-IBD is more severe with isolated colonic disease, profound impact on growth and development, and can be fatal.[38,41,42] Patients may have ongoing subclinical inflammation and be asymptomatic.[53] Approximately 30% of affected individuals have a positive family history, and there is a 50% concordance between monozygotic twins.[54]

Extraintestinal manifestations of IBD include hepatobiliary disease (e.g. primary sclerosing cholangitis in UC) and musculoskeletal disorders such as sacroiliitis, with related symptoms sometimes triggering screening for IBD. They should be kept in mind when imaging for small and large bowel disease.[55]

Distinguishing CD and UC can be challenging, with diagnosis dependent upon a complete, standardized diagnostic workup including esophagogastroduodenoscopy (EGD) and ileocolonoscopy, and small bowel imaging with capsule endoscopy or magnetic resonance enterography (MRE) as defined by the revised Porto criteria. This is recommended in all except those with definitive UC, for accuracy and to minimize those designated as IBD-U (Fig. 104.7).[35,49]

A range of established pediatric clinical activity scores (e.g. PCDAI and PUCAI [Pediatric CD and UC Activity Indices, respectively]) incorporate history, examination, and laboratory data, quantifying baseline and ongoing disease activity; a score less than 10 being remission in PCDAI. As mucosal healing rather than symptom remission is increasingly the goal of treatment, poor correlation of these indices with endoscopic evidence of mucosal inflammation has prompted development of alternate noninvasive image-based scoring systems, MRE in particular, to define activity and guide treatment.[45,48,56] Multivariate logistical regression of itemized features of CD activity has been undertaken—bowel wall thickness, edema, ulceration, and relative contrast enhancement for inflammation in the MaRIA Score (validated with endoscopy/biopsy), adding diffusion-weighted imaging in the Clermont score; adding strictures for the Lémann damage score; and for an MRE global score (MEGS) length of disease (validated against fecal calprotectin), with varying sensitivities and specificities.[57–59] Although validation is ongoing and use is not yet standard in clinical practice, MRE is proving robust in assessing mucosal healing in adults as well in limited studies to date in children, with pediatric-specific MRE-based indices under development.[60–62]

**Figure 104.7. Evaluation of child/adolescent with intestinal or extraintestinal symptoms suggestive of IBD.** Atypical UC is a new IBD category consisting of five phenotypes and reflects a phenotype that should be treated as UC. IBD-U may be entertained as a tentative diagnosis after endoscopy and can be used as a final diagnosis after imaging and a full endoscopic workup. UC is divided into typical UC and atypical UC. *CD*, Crohn disease; *EGD*, esophagogastroduodenoscopy; *FM*, fecal marker; *IBD*, inflammatory bowel disease; *MRE*, magnetic resonance enterography; *UC*, ulcerative colitis; *WCE*, wireless capsule endoscopy. *(Redrawn from Levine A, Koletzko S, Turner D, et al. ***Imaging* (*Table 104.1*).** Imaging algorithms have substantially altered in recent years, in line with changing treatment targets and outcome measures.[49,68] Detection of IBD and distinction between CD and UC are key at presentation, as well as exclusion of other diseases such as infectious ileitis or appendicitis. At diagnosis and on follow-up, imaging objectives include defining disease location and extent (specifying involved segment length, activity and severity, and where possible characterizing as inflammation or damage), all with treatment implications. In the acute setting, assessment for acute flare, abscess, or obstruction from stricture should ideally occur within 24 hours.[43] Surgical planning is increasingly done with MRE rather than fluoroscopy.[69]

## Abdominal Radiography

With acute abdominal pain in IBD, radiography can demonstrate perforation or obstruction, with images likely to include an erect chest or upright abdominal image. Although no longer routinely used in IBD assessment, familiarity with the more reliable radiographic signs is still important. These include mucosal irregularity in the colon and small bowel and an abnormal stool pattern with stool absent or limited to a single loop.[43,70] Extraintestinal manifestations of IBD such as renal or biliary calculi or sacroiliitis may be seen.

## Ultrasound

Interrogation of bowel is now often used in imaging pediatric IBD because it lacks ionizing radiation, has wide availability and low cost, and is usually well tolerated, even with use of oral contrast.[66] However, its role in initial screening is limited as it has variable accuracy in disease detection (particularly MRE).[43,63,71] While used for monitoring disease activity, treatment response, assessment of acute flares, and disease complications, reproducibility has been questioned.[72] The use of nonabsorbable oral contrast and intravenous contrast-enhanced US has been shown to improve sensitivity, specificity, and accuracy for disease detection in CD including strictures.[43,63] Compared with MRE and capsule endoscopy, conventional or contrast-enhanced US have shown similar sensitivities, but variable specificities. In the small bowel, US is best for terminal and distal ileum but poor for proximal to midsmall bowel.[66,71–73] US shear wave elastography is one of a number of promising noninvasive techniques to assess bowel fibrosis.[74]

Mural features in IBD include (1) bowel wall thickening greater than 3 mm (normal 1.5–3 mm in the terminal ileum and 2–3 mm in the colon); (2) "stiffness" where thick or distended loop remains noncompressible/unchanging; (3) increased echogenicity/loss of stratification; (4) Doppler hypervascularity (Fig. 104.8); (5) serosal irregularity/speculation; and (6) reduced peristalsis.[63,64,66] Vessel density of density greater than 2 vessels/cm$^2$ and wall thickness greater than 5 mm have shown high specificity (88%) for active disease.[75] Stenoses can be seen as persistent luminal narrowing (≤2 mm), reduced or absent peristalsis, with upstream dilatation and hyperperistalsis. Extramural features include (1) a halo of echogenic, hyperemic mesentery (>4 mm) relating to fibrofatty proliferation, (2) regional lymphadenopathy (short axis ≥8 mm), (3) abscess (sensitivity 83%–91%), and (4) fistula–hypoechoic tracts, occasionally containing echogenic foci if gas, extending to adjacent bowel, genitourinary structures, or skin; they can be associated with tethered or sharply angulated juxtaposed bowel loops (sensitivity 31%–87%).[64,71] Backwash or reflux ileitis is seen in conjunction with pancolitis in UC with less mural thickening or extramural abnormality. Lymphoid hyperplasia can mimic both entities, again

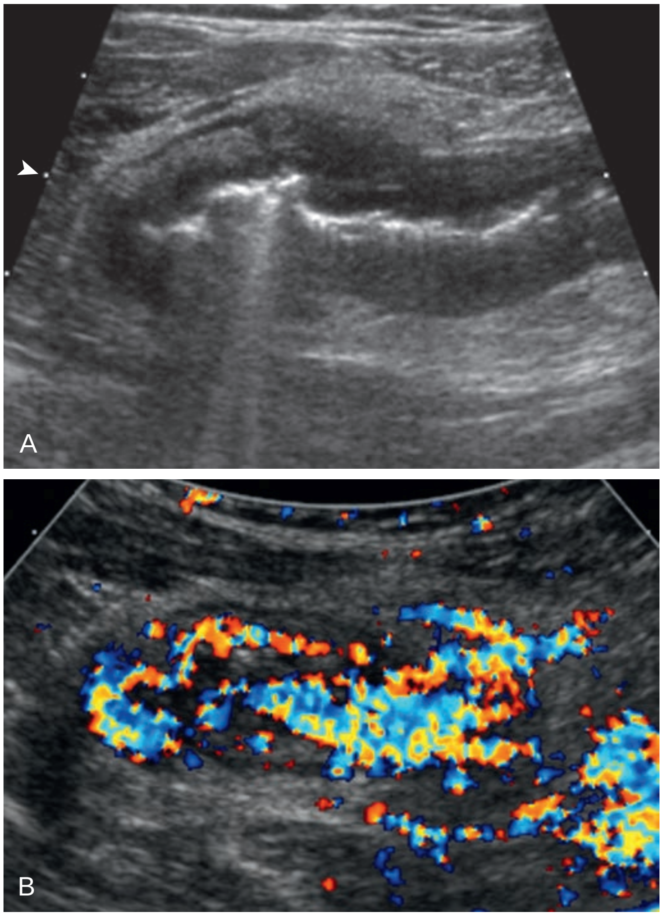

**Figure 104.8. Crohn disease.** Transverse gray-scale (A) and color Doppler (B) sonograms of the right lower quadrant of an adolescent boy with Crohn disease show a markedly thickened and hyperemic terminal ileum. *Arrowhead* in (A) is the focal zone centered on the bowel.

with less diffuse mural thickening, often with rounded hypoechoic lymphoid follicles and normal peristalsis.

## Fluoroscopy

SBFT and small bowel enteroclysis have largely been replaced by other modalities, in particular MRE and computed tomographic enterography (CTE) to a lesser extent.[49,68] Although more sensitive in demonstrating mucosal lesions such as erosions and superficial ulcers, these other modalities better demonstrate mural and transmural features of IBD, with the added advantage of no ionizing radiation with MRE and US.[76] Fluoroscopic studies are now reserved for patients in whom MRE or CTE is contraindicated. Typical features in terminal ileal CD include shallow poorly defined ulcers with surrounding edema; linear, serpiginous ulcers; and a swollen disorganized fold pattern, with loss of pliability on compression. In comparison, lymphoid hyperplasia has small nodular filling defected.[77] Loop separation from wall thickening and/or fibrofatty proliferation, strictures and fistulae can be demonstrated.

## Computed Tomography

CTE is performed after ingestion of sufficient low-density oral contrast to achieve bowel distension and intravenous iodinated contrast, imaging at either 45 seconds (enteric phase) or 70 seconds (portal venous phase).[78] With sensitivities ranging from 60% to 90% and specificities 90% to 100% for detection of CD, it is used in some pediatric centers as baseline imaging to document the presence and extent of IBD (although some prefer MRE to avoid ionizing radiation).[35,43,49] However, short acquisition times, less operator dependence than US, wide accessibility, high spatial resolution, and reduced need for sedation or anesthesia make it a viable alternative (see https://acsearch.acr.org/docs/69470/Narrative/).[43,78]

Bowel wall thickening (>3 mm) and hyperenhancement are hallmarks of CD on CTE.[79,80] Disease activity, with active inflammation evidenced by wall thickening, avid enhancement, submucosal edema, and mesenteric inflammation, correlate well with histologic evidence of inflammation. However, CTE is less predictive of fibrosis than MRE.[65] As with US, stenoses can be evidenced by luminal narrowing and prestenotic dilatation. Additionally, upstream fecalization or the “small bowel feces” sign can be indicative of SBO (Video 104.1; Fig. 104.9 and e-Fig. 104.10). The peri-intestinal features of comb sign, fibrofatty proliferation, phlegmon, and abscesses are well depicted. Fistulae are variably seen, with abscesses and fistulae often arising just proximal to stenosed bowel.[78,80] In the acute setting, when larger volumes of contrast may not be tolerated, conventional abdominal CT with no or limited oral contrast may be sufficient for a diagnosis of bowel obstruction, perforation, or abscess (see Video 104.1). IBD-related pathologies such as renal and biliary calculi, and some musculoskeletal changes can also be depicted on CT.

## Magnetic Resonance Imaging

In addition to detecting diseased segments in small bowel CD, MRE helps define extent, activity, and complications. MRE requires ingestion of weight-based doses of hyperosmolar biphasic oral contrast agents, typically up to 1400 mL, intravenous gadolinium-based contrast agents, and antispasmodic agents to optimize small bowel visualization. Conventional rapid and fluid-sensitive sequences provide anatomic and functional information, using dynamic (cine) and static pre- and postcontrast sequences to delineate the bowel wall and mesentery.[81–83] Advanced imaging techniques include delayed contrast enhancement (DCE) imaging with subtraction, diffusion-weighted imaging (DWI), and magnetization transfer pulses generating ratios (MTR), increasingly used to better define activity and differentiate active inflammation from fibrosis.[84–89] While validation sufficient to guide therapy is ongoing, enhancement gain greater than 24% between 70 seconds and 7 minutes, with or without ulcers, shows promise in distinguishing minimal and marked fibrosis and inflammation in CD.[85,90] The diagnostic capabilities plus the lack of ionizing radiation and excellent soft tissue contrast resolution have led to widespread use of MRE in pediatric IBD, particularly for serial imaging, and can be performed satisfactorily at 1.5 and 3 Tesla field strengths.[49,68,91]

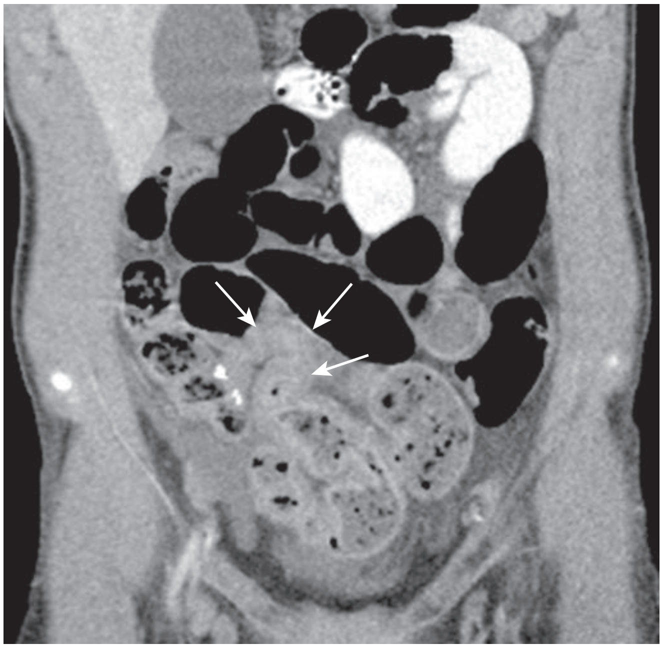

**Figure 104.9. Crohn disease stricture.** Coronal reformatted contrast-enhanced CT image through the pelvis of a 15-year-old boy with Crohn disease presenting with worsening abdominal pain and vomiting 2 years post ileal resection. An anastomotic stricture is demonstrated measuring 4.8 cm *(arrows)* with collapsed lumen, bowel wall thickening, and fecalization of upstream ileum, with staples to the right of the *arrows*.

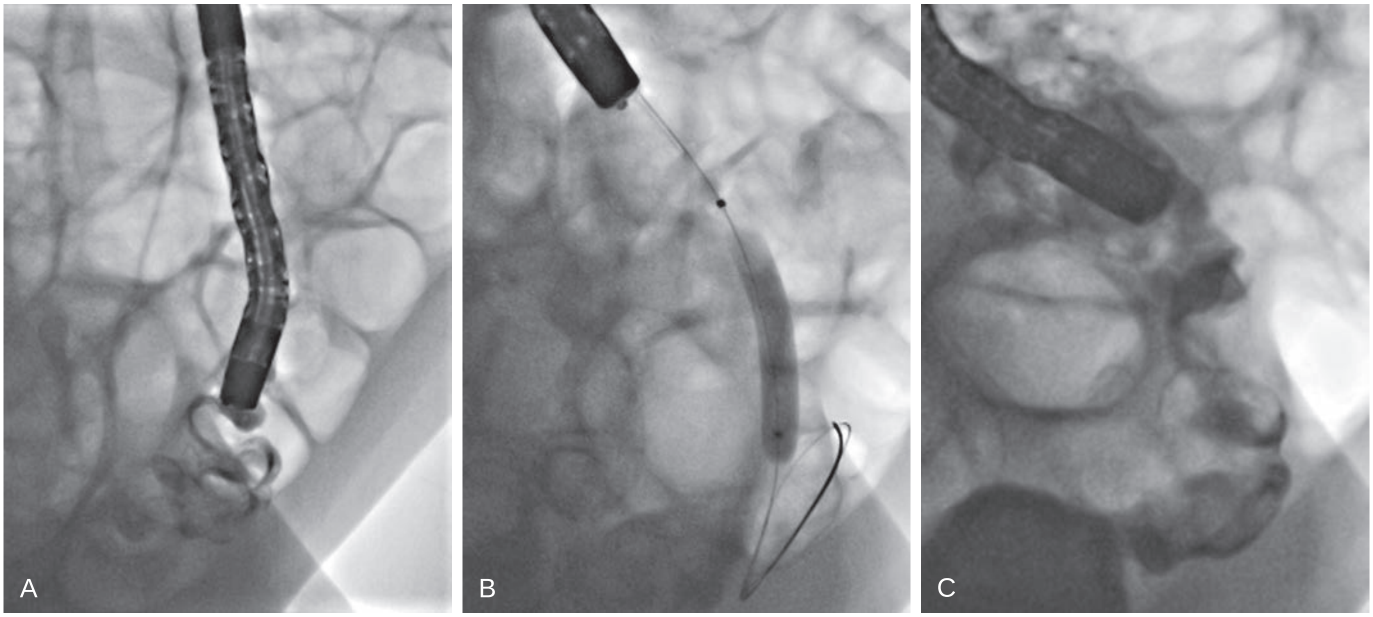
The majority of CD small bowel findings on CTE apply equally to MRE. Mural features include skip or continuous lesions with bowel wall thickening greater than 3 mm (which can be eccentric), hyperenhancement, mucosal ulceration, pseudosacculation, and strictures with luminal narrowing and prestenotic dilatation (>3 cm).[59,92,93] MRE additionally can show mural edema with T2 hyperintensity and mucosal or stratified enhancement in active disease, reduced T2 signal relative to skeletal muscle, and variably transmural enhancement in chronic or fibrotic disease, with diseased segments having abnormally increased or decreased peristalsis on cine imaging (Video 104.2).[94,95] Restricted diffusion is seen in active inflammation with increased mural signal on trace images and reduced signal on the apparent diffusion coefficient (ADC) map (Fig. 104.11). While less reliable on its own, DWI accuracy improves when used in conjunction with conventional MRE sequences, particularly if DWI is viewed first.[96,97] Extramural features include penetrating lesions: sinuses, fistulae, and abscesses (Fig. 104.12). Abscesses, rim-enhancing fluid collections, can be difficult to distinguish from fluid-filled bowel, and central restriction on DWI improves conspicuity.[98] Sinuses and fistulae have variable signal depending on contents (gas, fluid, feces) and are better demonstrated when DWI supplements T2-weighted or postcontrast T1-weighted sequences. Fistulae occur in 8.2% of pediatric CD within 12 months of diagnosis and 24.5% by 10 years, and additional features include tethering of adjacent bowel loops, and simple or stellate tracts to bowel, skin, or genitourinary structures, often



**e-Figure 104.10. Crohn disease stricture.** (A–C) Colonoscopy and pre-, mid-, and postballoon dilatation images show persistent narrowing that required resection.

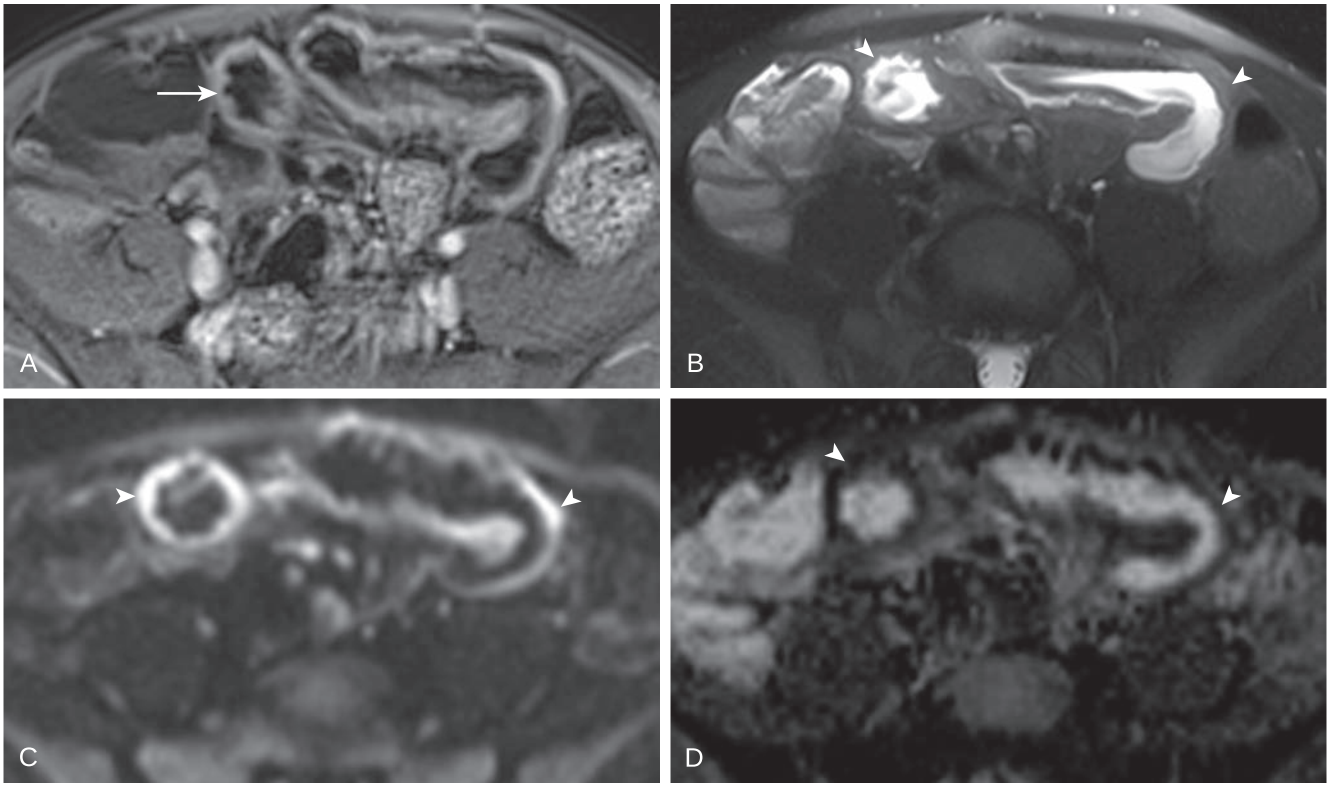


**Figure 104.11. Crohn disease with active inflammation in distal ileum in an 11-year-old boy.** (A) Axial fat-suppressed contrast-enhanced T1-weighted 3D gradient echo MR image, (B) axial single-shot T2-weighted image, and (C and D) diffusion-weighted imaging (DWI) with (C) trace image at $b = 800\ s/mm^2$ and (D) ADC map. Moderate transmural hyperenhancement is evident in an inflamed bowel loop in the midpelvis on (A) with deep ulceration *(arrow)*. There is T2 bowel wall hyperintensity on (B) and corresponding areas of restriction on DWI seen on trace image (C) as increased signal and on ADC map as decreased signal (D) *(arrowheads)*. Mild fibrofatty proliferation and comb sign are seen in the adjacent mesentery.

arising just proximal to or at the level of a stricture.[93,95] Other extraintestinal features are fibrofatty proliferation, vasa recta engorgement (comb sign), regional lymphadenopathy, perimural mesenteric edema and enhancement, intraperitoneal fluid, and phlegmons.[82] Increasingly, qualitative and quantitative MRE analyses are being used as biomarkers of treatment response.[83,99]

Identified IBD-related extraintestinal findings can include sclerosing cholangitis and biliary calculi, with magnetic resonance cholangiopancreatography (MRCP) usually performed separately (see Chapter 88), and enthesitis-related arthropathy and sacroiliitis, with bone marrow edema well seen on DWI.[55,100,101]

## Nuclear Medicine

Radiolabeled white blood cell scintigraphy and $^{18}$F-fluorodeoxyglucose (FDG) positron emission tomography (PET)/CT or PET/MRI can demonstrate active inflammation in small and large bowel in IBD, documenting extent and assessing treatment response. Decreased $^{18}$F-FDG uptake in areas of fibrosis can aid distinction of fibrotic and inflammatory structures. Radiation burden limits routine use in pediatric imaging.[43,74,102]

## Special Considerations

VEO-IBD rates special mention because of its more serious prognosis and the extra challenges in performing CTE and MRE in children under 6 years of age. While US may be used for initial imaging (with particular focus on colon), increasing utilization of MRE under general anesthesia has had good success, requiring only minor modification in technique.[103]

Fortunately, the risk of IBD-related malignancy is extremely low in children and adolescents, occurring more in CD. Leukemia and lymphoma are most common and usually treatment related. Long-term implications of therapy must thus be balanced against severe IBD outcomes.[41,104,105] Disease-related malignancies are less frequent and include small and large bowel adenocarcinoma and cholangiocarcinoma. Diagnostic imaging is neoplasm specific rather than surveillance focused.

***Treatment.*** In parallel with advances in GI tract imaging has been a paradigm shift in the treatment of pediatric CD and UC away from clinical endpoints and toward mucosal healing (and potentially transmural healing) with the primary goal of induction and maintenance of remission aided by biologic agents targeting molecular pathways.[45,53,83] Reversing inflammation and limiting progression has lead to improved quality of life, fewer complications, and less surgical intervention.[41,53] Medical therapies are implemented based on clinical and endoscopic disease activity indices, and increasingly imaging biomarkers, to promote to mucosal and transmural healing.[53,59] Treatment options include exclusive enteral nutrition, corticosteroids, immunomodulators, antibiotics, and biologic agents.[41] When refractory to medical therapy or with severe fistulizing or fibrostenotic disease, surgical intervention is indicated encompassing abscess drainage, balloon dilatation, strictureplasty, or surgical resection (see e-Fig. 104.10).[106]

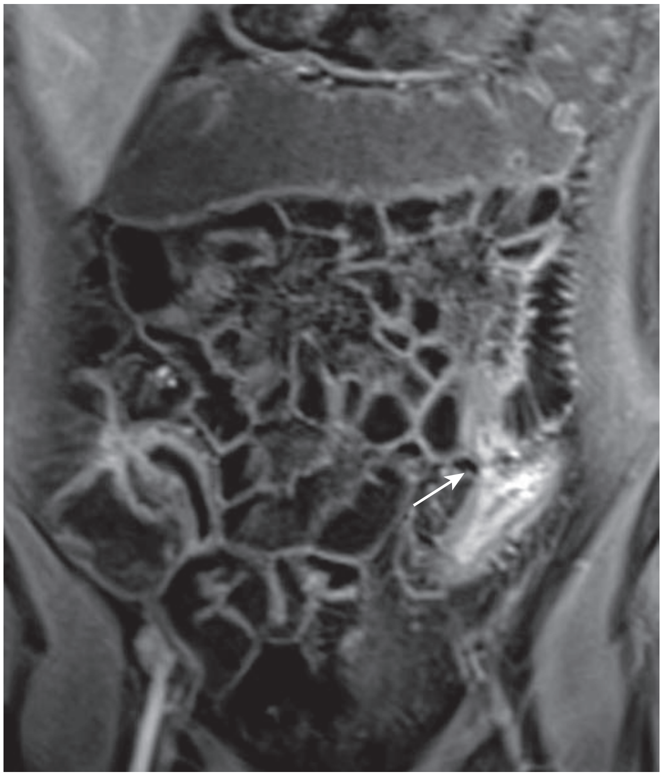

**Figure 104.12. Crohn disease enterocolic fistula and terminal ileitis.** Coronal fat-suppressed contrast-enhanced T1-weighted 3D gradient echo MR image demonstrates tethered loops of inflamed bowel with thick walls and transmural hyperenhancement in the left lower quadrant with fistula between the jejunum and distal descending/sigmoid colon *(arrow)*. Stratified hyperenhancement of thick-walled terminal ileum is more in keeping with active inflammation.

## Behçet Disease

***Overview.*** Behçet disease is an uncommon, immune-mediated vasculitis. This chronic, relapsing condition involves multiple organ systems, including the GI tract in 0.7% to 50%, neurologic, and cardiovascular systems.[107,108] Mean age of onset is 25 to 30 years, although rare presentations from 10 to 15 years of age occur.[109] Disease prevalence in Asia is approximately 30 per 100,000 population with more common GI involvement, with prevalence in North America of approximately 7 per 100,000.[107,108,110]

***Etiology.*** Behçet disease is an autoinflammatory disease of complex genetic trait, associated with mutations in the gene for familial Mediterranean fever, manifest as vascular endothelial dysfunction and an excessive inflammatory response, termed pathergy.[110]

***Clinical Presentation.*** Diagnosis is made by established clinical criteria from the International Study Group for Behçet disease with recurrent mouth ulcers plus at least two other major criteria: ocular involvement (e.g., uveitis), skin lesions (e.g., erythema nodosum), recurrent genital ulcerations, and a positive pathergy test.111 Most frequent GI symptoms include abdominal pain, diarrhea, and bleeding.[108]

***Imaging.*** Ulceration is most common in the ileocecal region. Double contrast barium enema (or enteroclysis), better than single contrast studies, demonstrate deep, localized, relatively large, "collar-button" ulcers, and long segment thickening of adjacent mucosal folds from lympangiectasia.107,108 Complications can include aneurysmal dilatation of the terminal ileum, perforation, fistulae, and cecal masses. The entire GI tract can be affected, mimicking CD.[107]

***Treatment.*** Medical therapies include corticosteroids and other immunosuppressants during disease exacerbations and increasingly biologic therapy for refractory lesions.[107,108,110] Surgical resection of severely involved segments can result in recurrence, between 40% and 80% within 2 years of surgery, often located near the initial anastomosis.[107]

# FUNCTIONAL AND INFILTRATIVE DISEASES

## Cystic Fibrosis

***Overview.*** Cystic fibrosis (CF) is an autosomal recessive condition caused by a lack or dysfunction of CF transmembrane conductance regulator *(CFTR)* protein resulting from a variety of mutations mapped to locus q31.2 of chromosome 7. This protein is involved in the regulation of chloride ion transport across cell membranes in the lungs, digestive system, reproductive tract, and skin. It is the most common genetic defect in Caucasians; 3.3% of white Americans are carriers of a *CFTR* mutation versus 1.1% of Asian Americans, with an homozygous prevalence approximating 1 in 3500 in white Americans.[112,113]

***Clinical Presentation.*** GI symptoms occur in 85% to 90% of CF patients, arising from constipation, obstruction, mucus accumulation, disturbed motility, dysbiosis with bacterial overgrowth, and chronic intestinal inflammation.[113] Meconium ileus occurs in the newborn period (see Chapter 102). In older children and adolescents, the most common intestinal abnormality is distal intestinal obstruction syndrome (DIOS), formerly known as *meconium ileus equivalent*, occurring in approximately 15% of patients.[114] Children present with colicky abdominal pain and a palpable right lower quadrant mass from impacted fecal material in the ileocolic region. Because mild to severe constipation is a common concomitant condition, the DIOS diagnosis is reserved for patients with signs and symptoms of SBO.

Intussusception, usually ileocolic, is seen in 1% to 17% of CF patients.[113,114] Presenting around 10 years of age, intermittent abdominal pain is often milder than in idiopathic intussusception, and some patients are asymptomatic.[115]

***Imaging.*** In DIOS, radiographs show small bowel dilatation with air-fluid levels; bubbly fecal material may also be present, particularly in the right lower quadrant.[115] If CT is performed; dilated small bowel loops can be followed to the site of impaction in the distal ileum (Fig. 104.13).

The appendix in patients with CF is typically distended by mucoid contents, and although its contents may be expressible with compression, appendiceal diameter alone is not a reliable criterion for diagnosis of appendicitis in these patients; periappendiceal findings therefore become particularly important.[116,117]

US is the modality of choice for diagnosing intussusception, sometimes demonstrating a pathologic lead-point (e.g., inspissated secretions, enlarged lymphoid follicles, or a distended appendix). In CF patients with malabsorption and less-specific GI symptoms, US may show bowel loop dilatation greater than 2 cm, short segments of moderate wall thickening and hypervascularization, and altered motility, especially in the ileocecal region.[113]

***Treatment.*** Although most patients with DIOS respond to enemas that include mucolytic agents, water-soluble contrast enemas given under fluoroscopic control also may be effective, refluxing into the terminal ileum and repeating over a 24- to 48-hour period as required to completely relieve the impaction.[115] Surgical management may be needed in patients who do not respond to nonsurgical techniques.

Some intussusceptions spontaneously resolve but if ileocolic, and there is no perforation or peritonitis, a fluoroscopically guided air or sonographically guided saline enema reduction is performed.[114,118]

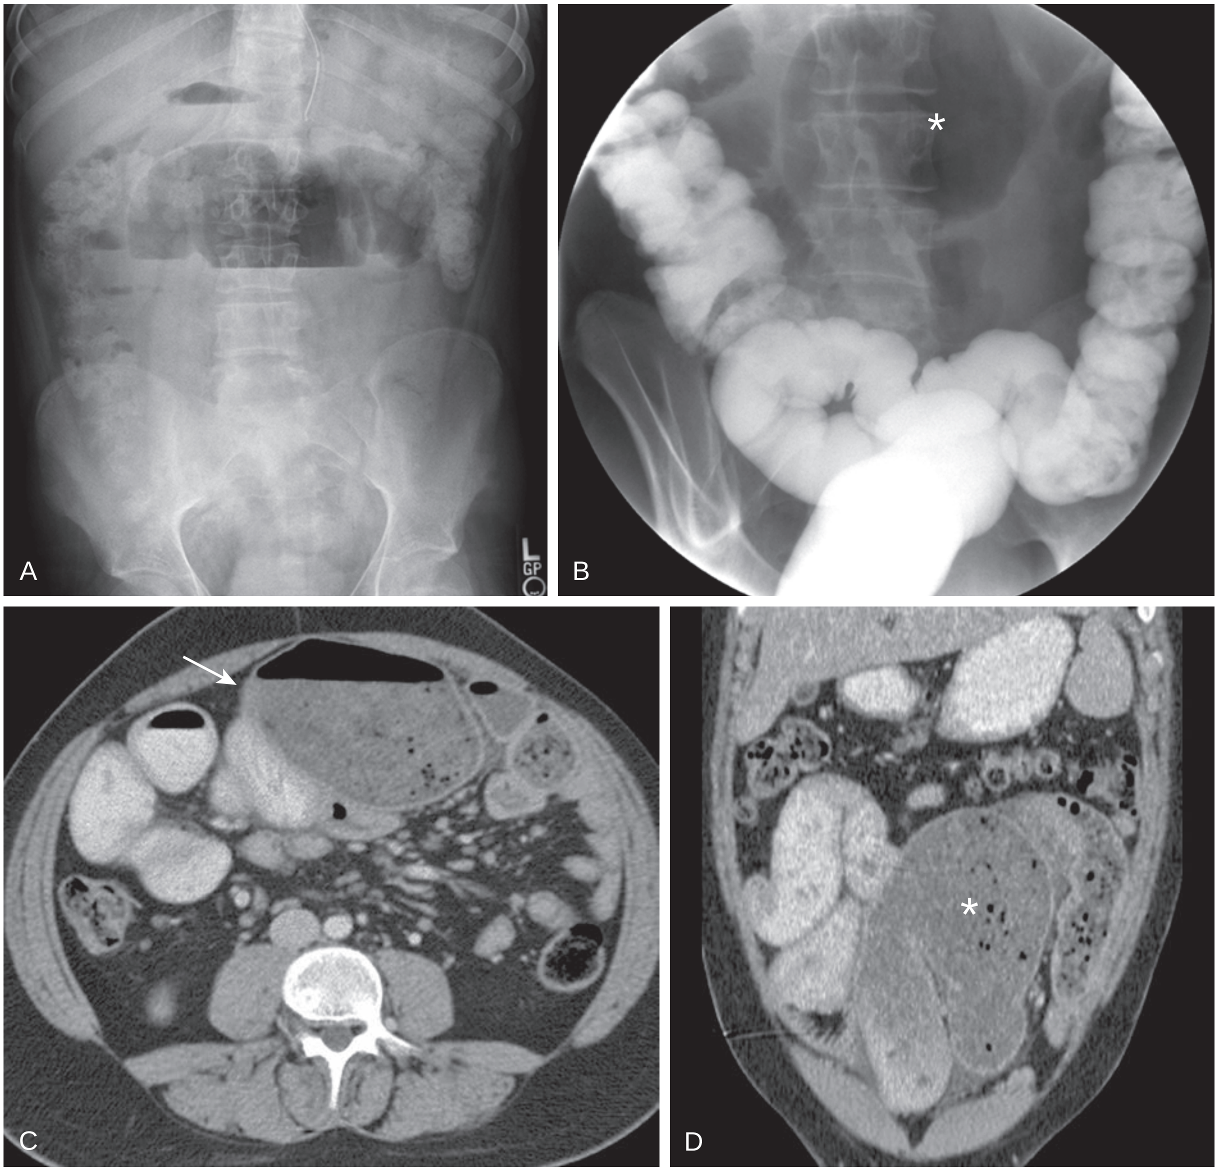

**Figure 104.13. Distal intestinal obstructive syndrome.** (A) Upright abdominal radiograph in a 7-month-old boy with cystic fibrosis and increasing abdominal distension, pain, and emesis shows a dilated, gas-filled bowel loop in the central abdomen with an increased air-fluid level. (B) Contrast enema image shows no substantial reflux into the terminal ileum and persistence of the abnormally dilated bowel loop in the midabdomen *(asterisk)*. (C) Axial contrast-enhanced CT image shows flocculent material in a dilated midabdominal bowel loop *(arrow)*. (D) Coronal reformat confirms the axial findings. Flocculent material dilating the small bowel is again seen *(asterisk)*. Distal ileal obstruction was confirmed at laparotomy.

## Protein-Losing Enteropathies

***Overview.*** Protein loss through the GI tract may be related to a range of underlying abnormalities, including immune-mediated dysfunction, such as celiac disease, or to lymphatic obstruction, such as in intestinal lymphangiectasia.

***Etiology.*** *Celiac Disease.* Celiac disease is the most common cause of intestinal malabsorption in childhood. Also known as *nontropical sprue* or *gluten enteropathy*, it is an autoimmune disease caused by gluten intolerance, a protein present in wheat and related species, including barley and rye. The disease is more prevalent in Western Europe and North America, affecting as many as 1 of every 80 to 300 persons.[119] The hypersensitivity to gluten is related to the tissue transglutaminase (TTG) enzyme, which acts as the autoantigen. Diagnostic tests include measurement of IgA antibody to human recombinant TTG, as well as quantitative serum IgA evaluation. Diagnosis is made when small bowel biopsy documents villous atrophy. The disorder is associated with type 1 diabetes mellitus; Down, Turner, and William syndromes; and IgA deficiency.[119]

*Whipple Disease.* Whipple disease is a chronic systemic bacterial infection caused by *Tropheryma whipplei* that is most common in middle-aged men but has been associated with acute illnesses such as diarrhea in young children.[120,121] While *T. whipplei* infection is common (incidence of 2%–11% in Europe), Whipple disease is rare but increasing.[122] It is characterized by the presence of macrophages that persist even after eradication of the initiating organism. Macrophages from affected patients have normal phagocytosis but appear to be unable to effectively handle the bacterial antigens.[120]

*Intestinal Lymphangiectasia.* Intestinal lymphangiectasia is characterized by dilation of intestinal lymphatics that results in protein loss as lymph leaks into the lumen of the intestine. Primary intestinal lymphangiectasia is associated with developmental abnormalities of the intestinal lymphatics and may be associated with abnormal lymphatics elsewhere in the body. Secondary intestinal lymphangiectasia occurs in patients with diseases such as sarcoid or lymphoma that cause obstruction of the intestinal lymphatics.[123] Secondary disease may also be seen when there is an increase in intralymphatic pressure because of an increase in venous pressure (e.g., constrictive pericarditis) or increased right atrial pressures (e.g., Fontan physiology after single ventricle repair or congestive heart failure).[119,124]

*Miscellaneous Protein-Losing Enteropathies.* Patients with immunodeficiency syndromes may have a clinical and radiographic picture similar to celiac disease. Other causes of protein-losing enteropathy include allergic gastroenteropathy, IBD, infectious mononucleosis, and polyarteritis nodosa.

***Clinical Presentation.*** *Celiac Disease.* Most children affected with celiac disease come to medical attention between 4 and 24 months of age with failure to thrive, abdominal distension, and diarrhea. Diarrhea is considered one of the hallmarks of the disease, although it is absent in 10% of patients; in fact, some children may present with constipation. Children may experience anemia with iron and folate deficiency, hypertransaminemia, arthritis, and behavioral disturbances. Adolescents have delayed puberty, anorexia, and clinical findings related to the hypocalcemia and hypoproteinemia of malabsorption.[119]

*Whipple Disease.* Patients with classic Whipple disease present with systemic manifestations, most commonly migratory arthralgias involving larger joints, chronic diarrhea and weight loss, and chronic localized infections (e.g., endocarditis, uveitis, encephalitis, and hyperpigmentation resembling Addison disease). Acute infections include gastroenteritis, pneumonia, and/or bacteremia, although some carriers are asymptomatic.[120,122]

*Intestinal Lymphangiectasia.* Several syndromes are associated with intestinal lymphangiectasia, such as neurofibromatosis type 1 (NF1), Turner, Noonan, Klippel-Trénaunay, and Hennekam. Patients with either primary or secondary intestinal lymphangiectasia typically have diarrhea and edema related to hypoproteinemia, failure to thrive, and other symptoms related to malabsorption.[123]

***Imaging.*** The first step in the evaluation of the patient with protein-losing enteropathy is to exclude common etiologies such as malnutrition and liver and renal disease. Diagnosis is made by documentation of enteral protein loss by determining the clearance of alpha$_1$-antitrypsin (A1AT) from plasma.[125]

$^{99m}$Technetium or $^{111}$In-labeled human serum albumin ($^{99m}$Tc/$^{111}$In-HSA) scintigraphy has also been used to document enteral protein leakage. $^{99m}$Tc has higher sensitivity but lower specificity than $^{111}$In-labeled tracers, with pooled sensitivities and specificities of 87% (81%–92%) and 62% (51%–72%).[126] Because of the intermittent nature of the protein loss and the need for serial scanning for up to 24 hours, many centers now utilize A1AT testing. However, scintigraphy has a distinct advantage of localizing the site of protein loss (i.e., large and/or small bowel or stomach).[127]

Abdominal radiographs in patients with celiac disease may show nonspecific small bowel distension, whereas Whipple disease lacks distension.

US findings in celiac disease include bowel dilatation (>2.5 cm), bowel wall thickening (≥3 mm), fold reversal (effaced mucosa in the jejunum and thickened in the ileum), increased or decreased peristalsis, and extraintestinal features including mesenteric lymphadenopathy and ascites. Small bowel intussusceptions are also seen.[128] These findings resolve when a gluten-free diet is instituted. Any significant mesenteric adenopathy in celiac disease should raise a suspicion for lymphoma.[129] Intestinal lymphangiectasia may have features related to edema with gallbladder and bowel wall thickening, mesenteric edema and ascites, and occasionally lymphatic malformations.

Classic SBFT imaging findings described in celiac disease consist of luminal distension, thickened mucosal folds, and contrast flocculation and segmentation; the latter two are uncommonly seen with modern-day barium preparations. As in US, mucosal folds may show reversal. The duodenum may exhibit mucosal erosions or thickened nodular folds. Similar thickening of small bowel folds is seen without dilatation in Whipple disease (e-Fig. 104.14). Barium studies in patients with intestinal lymphangiectasia may show mild bowel dilatation and thickened folds (Fig. 104.15), although a substantial number of affected children have a normal SBFT.

Patients with immunodeficiency syndromes may have a clinical and radiographic picture similar to celiac disease. Some affected patients have radiographic findings of lymphoid hyperplasia, particularly in the distal ileum.[130]

Abdominal CT is not routinely used in investigation of protein-losing enteropathy. Low-density lymphadenopathy, hepatosplenomegaly, and ascites may be seen in Whipple disease, and similar features to that seen on US in intestinal lymphangiectasia. Bowel can also have a “halo” reflecting intramural edema (inner low density and outer high density), also seen in IBD and ischemic enteritis, with the lack of lymphadenopathy aiding distinction from celiac and Whipple disease.[131] MRE is an emerging tool in the investigation of protein-losing enteropathy.[95,132] Recent development of dynamic magnetic resonance (MR) lymphangiography, delineating the central conducting lymphatics, shows promise in investigation of unexplained protein-losing enteropathy.[133]

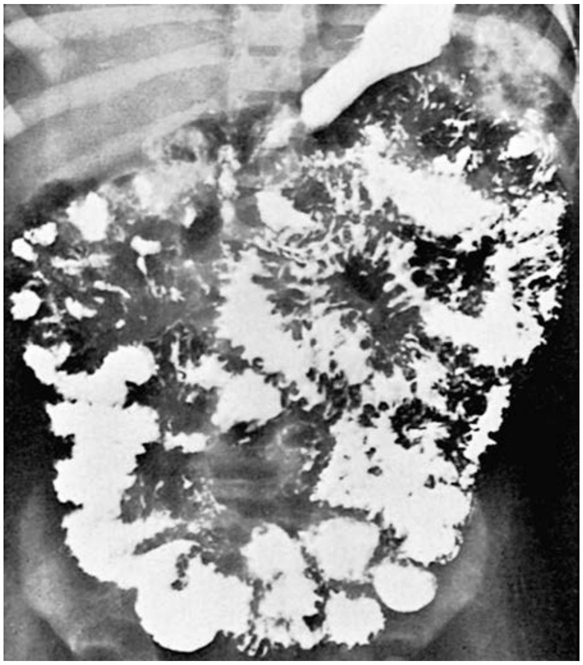

**Figure 104.15. Intestinal lymphangiectasia.** Small bowel series in a 3-year-old girl with intestinal lymphangiectasia shows marked coarsening and thickening of the mucosal folds.

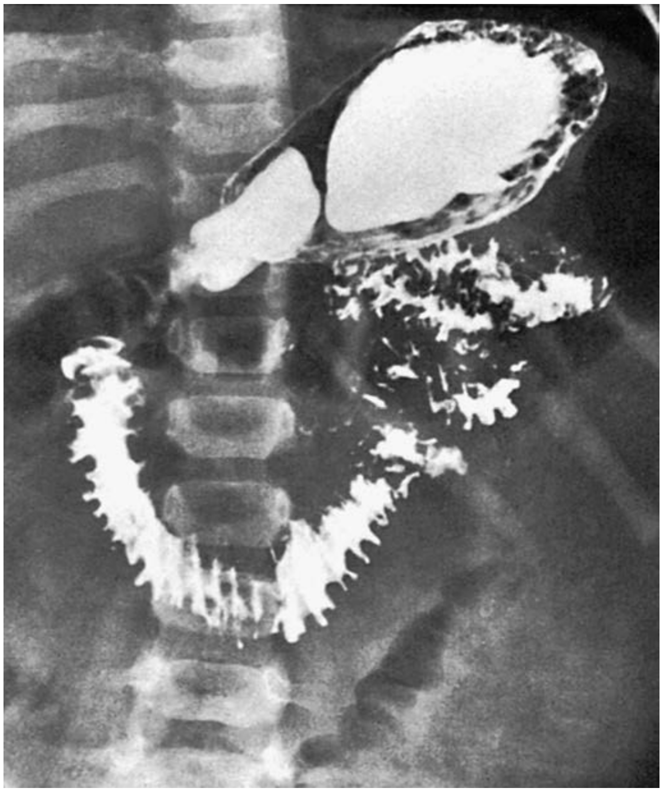


**e-Figure 104.14. Whipple disease.** Upper gastrointestinal series in a 2-year-old boy with Whipple disease reveals marked thickening of the duodenal and jejunal folds.

***Treatment.*** Therapeutic approaches for protein-losing enteropathy vary depending on the underlying etiology; the goal of the treatment is to correct the underlying abnormality and nutritional supplementation.

The treatment for celiac disease is a lifelong gluten-free diet. Prolonged antibiotic treatment is required for Whipple disease, with the combination of doxycycline and hydroxychloroquine now advocated. Even with this new regimen, lifelong monitoring is needed because of the risks of recurrence and reconstitution inflammatory syndrome.[122]

In patients with lymphangiectasia, treatment includes a low-fat diet primarily consisting of medium chain triglycerides and high protein. In secondary lymphangiectasia, attention is paid to the primary problem.

## Graft-versus-Host Disease

***Overview.*** Graft-versus-host disease (GVHD) can result from hematopoietic stem cell transplantation. GVHD occurs when the donor lymphocytes react with the tissues of the host, with an inflammatory cascade that often begins in the GI tract.[134,135] Three conditions are generally required for the development of GVHD: (1) the graft must contain immunologically competent cells; (2) the host must possess important transplant alloantigens that are lacking in the donor graft so that the host appears foreign to the graft; and (3) the host must be incapable of mounting an effective immunologic reaction against the graft.[136,137]

***Etiology.*** GVHD results from donor T-cell epithelial damage in the host target organs.[137] Pathophysiology of GVHD includes pretransplant host tissue injury secondary to preparative ablative radiation and chemotherapy, activation of donor T-lymphocytes, and cytotoxicity against target host cells through the effected inflammatory cascade mediated through histocompatibility antigens.[134,135] The most important elements in the development of GVHD relate to the degree of human leukocyte antigen mismatch.[135] GI symptoms are the sequelae of destruction of the intestinal crypts leading to patchy or diffuse mucosal ulceration.[137]

***Clinical Presentation.*** Acute GVHD occurs within the first 100 days, and commonly within 30 to 40 days, after transplantation.[137] Patients usually have a combination of dermal, hepatic, and GI abnormalities. Dermatitis is manifested as a pruritic, maculopapular rash that may proceed to desquamation. Hepatitis results from involvement of the biliary epithelium and may progress to coagulopathy, encephalopathy, and liver failure. GI manifestations include anorexia, nausea, vomiting, severe diarrhea (often bloody), hematochezia, crampy abdominal pain, and ileus. Other organs, including the esophagus and conjunctiva, may also be involved. The diagnosis of intestinal involvement in acute GVHD can be confounded by a concurrent infectious gastroenteritis.[137,138]

Chronic GVHD can develop as early as 40 to 50 days posttransplant, de novo, or as a variable progression of acute GVHD; clinical, histologic, and immunologic findings are most important in defining disease. The majority of patients have skin abnormalities that include desquamation and vitiligo, which may progress to scleroderma-like changes. Severe mucositis of the mouth and esophagus may occur, and, while infrequent, GI involvement can result in localized inflammation or strictures in the esophagus and rarely the small bowel. Chronic cholestatic liver disease may also occur. Involvement of the hematopoietic system may lead to thrombocytopenia, and this (along with progressive onset, elevated bilirubin, and lichen planus) points to a poor prognosis.[137]

In summary, intestinal damage is a feature of acute GVHD, while the esophagus is the major GI region affected in chronic GVHD.[138] Incidence of GVHD is slightly higher in intestinal transplant patients at 5%, especially isolated transplants, affecting the native GI tract along with usual sites of disease.[139]

***Imaging.*** Patients receiving bone marrow transplantation are at risk of GVHD and other complications related to direct toxicity from pretransplant ablative chemotherapy and radiation, and infections. Clinical presentations may overlap, and imaging may be required to narrow the differential diagnosis.

Abdominal radiographs show a pattern of adynamic ileus with separation of bowel loops, thickening of the bowel wall, and air-fluid levels. Less commonly seen are pneumatosis intestinalis and ascites. On occasion, the abdomen may be completely gasless (e-Fig. 104.16A).

Contrast studies are rarely performed in these patients but may show characteristic (though not pathognomonic) diffuse luminal narrowing with featureless bowel creating a “ribbon” or “toothpaste” appearance.[138,140]

US is usually the primary mode of intestinal evaluation in acute GVHD. This reveals loss of stratification of the bowel wall, with variable small bowel and colonic mural thickening, with two or more intestinal sites aiding distinction from other causes. Ileal and colonic dilatation is infrequent.[141,142] Doppler demonstrates a markedly hyperemic bowel wall with elevated velocities in the superior mesenteric artery (SMA). Supervening ischemic changes may be identified in patients with undetectable mural flow and decreased SMA velocities, which is associated with a poor prognosis.[143] Extraenteric features include ascites, periportal edema, pericholecystic fluid, and gallbladder wall thickening and hyperemia.

Less commonly performed, CT findings in GVHD can be striking (see e-Fig. 104.16B and C). Bowel loops are variably distended with fluid, with marked contrast enhancement of the mucosa.[144] Oral contrast can obscure the mucosal enhancement and is poorly tolerated by these children, so it is avoided.[144] Engorgement of the vasa recta is the most common extraintestinal finding seen on CT and is indicative of hyperdynamic circulation. The target-like appearance to bowel and extraenteric features as seen at US and CT are similar on MRI.[145]

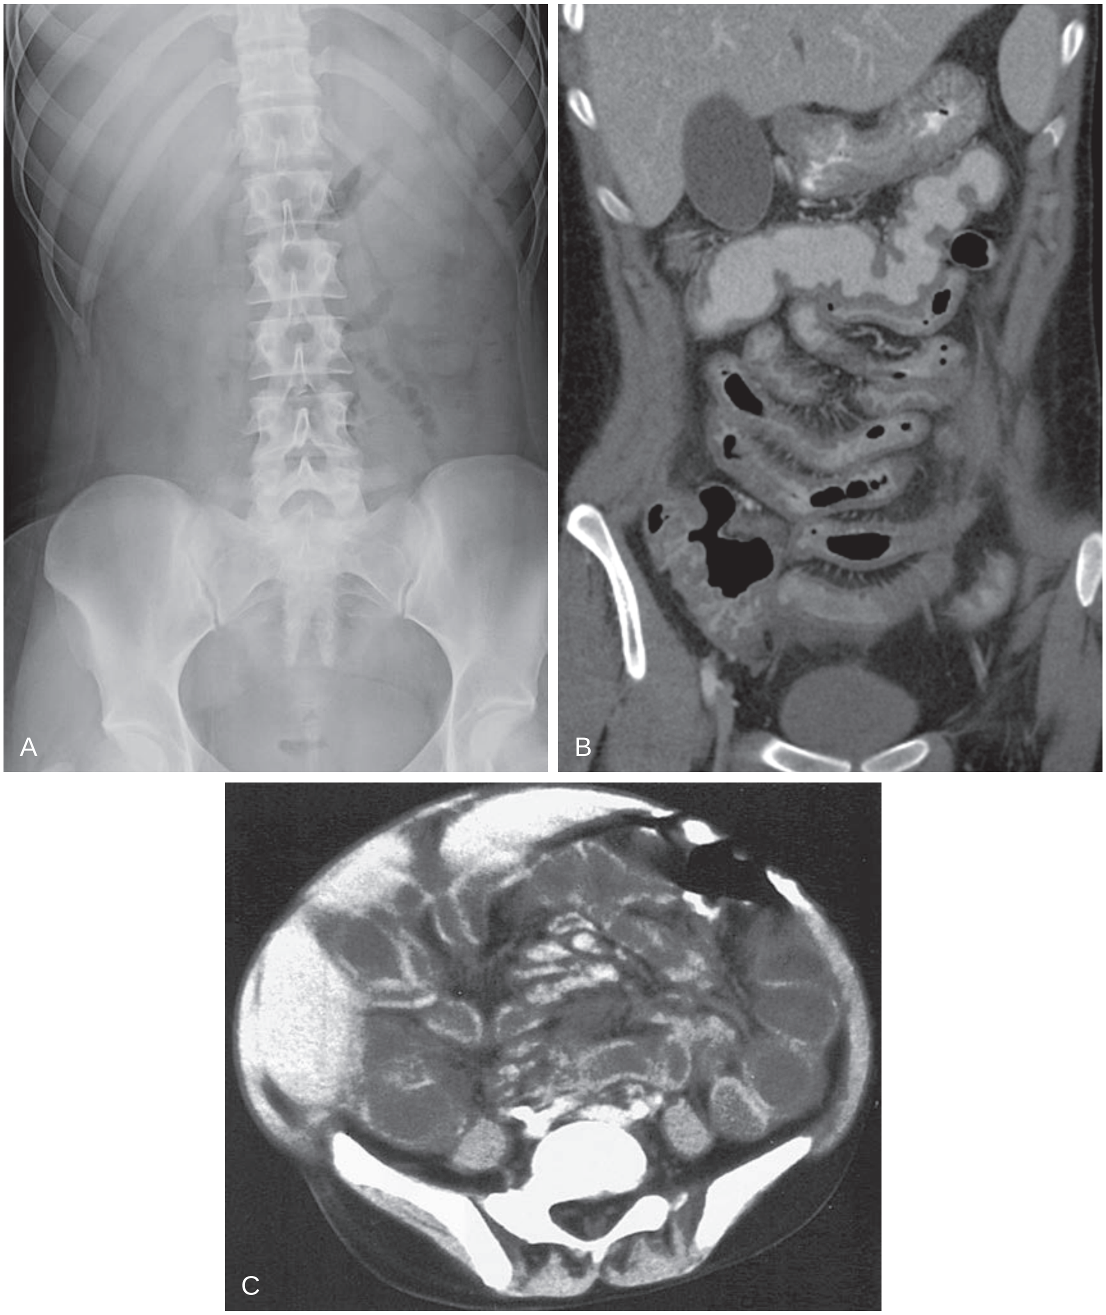
***Treatment.*** Treatment is aimed primarily at prophylaxis to prevent GVHD by using immunosuppressive agents (initially corticosteroids). Posttransplant immunosuppressive therapeutic management after onset of GVHD is generally less effective.[137,140]

## Immunoglobulin A Vasculitis (Henoch-Schönlein Purpura)

***Overview.*** Immunoglobulin A vasculitis (IgAV), formerly known as *Henoch-Schönlein purpura*, is the most common vasculitis of childhood and affects the small vessels in the skin, joints, GI tract, and kidneys. The incidence of IgAV is approximately 10 to 20 per 100,000 population and is most common in children between 2 and 6 years of age, although 30% of cases are in patients over age 20 years.[146,147]

***Etiology.*** A vasculitis of small vessels, nongranulomatous and ANCA-negative, it is characterized by IgA-dominant immune complex deposits in capillaries, venules, and arterioles.[148] Pathogenesis remains unknown with suspected genetic predispositions and implication of a range of coexistent organisms including group A beta-hemolytic *Streptococcus* and *Mycoplasma*.[146]

***Clinical Features.*** Consensus criteria define IgAV as having a palpable purpura (mandatory) plus one of the following: diffuse abdominal pain, biopsy showing predominant IgA deposition, arthritis or arthralgia, or renal involvement (proteinuria or hematuria).[147] ANCA-negative laboratory findings can be a consideration.[148] Classically presenting after an upper respiratory tract infection with lower extremity palpable purpura, lesions above the waist, and clinically evident edema are associated with GI involvement.[149] Although 20% to 50% have renal involvement, only 1% to 3% progress to end-stage renal failure.[149] Arthralgias and GI symptoms may precede the characteristic rash in 30% to 43% of patients. GI symptoms are seen in



**e-Figure 104.16. Graft-versus-host disease (GVHD).** (A) Supine abdominal radiograph in an 18-year-old girl with voluminous watery diarrhea 95 days after unrelated-donor bone marrow transplant, shows a nonspecific paucity of bowel gas. (B) Coronal contrast-enhanced CT image demonstrates diffuse bowel wall thickening. Severe gastrointestinal GVHD was confirmed by additional clinical data. (C) Axial contrast-enhanced CT in another child with GVHD shows marked edema of the bowel wall with deep mucosal enhancement.

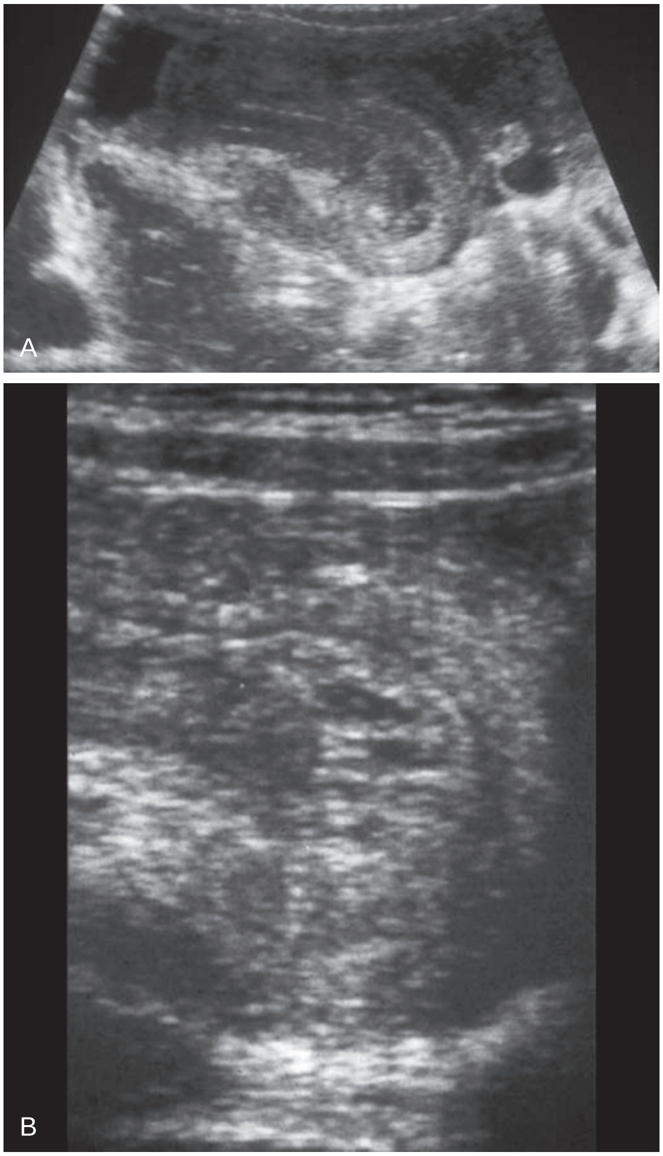


**Figure 104.17. IgA Vasculitis (Henoch-Schönlein purpura) with intussusceptions.** (A) Transverse sonogram of the left lower quadrant in a 6-year-old girl with acute abdominal pain reveals a thick-walled small bowel loop with intussusception. (B) Linear transducer image of the tip of the intussusception shows thick-walled bowel layers and sonolucent spaces in the intussuscepted mesentery consistent with edema. At surgery several hours later, an irreducible ileoileal intussusception was identified, which needed segmental bowel resection; the typical petechial rash appeared the following day. *(Courtesy Marta Hernanz-Schulman MD, Nashville, TN.)*

approximately 50% to 75% of patients and include nausea, vomiting, colicky abdominal pain, and hematochezia.[146] Bleeding into the bowel wall can rarely lead to intussusception, approximately 70% ileoileal. Complications include ischemia and perforation (Fig. 104.17).[148]

***Imaging.*** US may reveal bowel wall thickening with skip areas of abnormality (Fig. 104.17 and e-Fig. 104.18), reduced peristalsis, bowel dilation, mesenteric lymphadenopathy and edema, and intraperitoneal-free fluid, which are nonspecific.[146,148] Small bowel intussusception may be seen (see following section). Radiographs should be obtained if there is suspected bowel perforation.[146] Fluoroscopic contrast studies, CT, and MRI are not usually indicated. Intravenous radiographic contrast media (iodinated or gadolinium-based) should be avoided in the presence of renal impairment. Strictures may occur as a late sequela of the disease, likely from vasculitis with secondary focal areas of ischemia.

***Treatment.*** GI manifestations of IgAV generally require no treatment, although administration of corticosteroids has been reported to improve symptoms and shorten the symptomatic period.[146] While most intussusceptions reduce spontaneously, this is not always the case, and serial US may be needed to ensure resolution.[148]

## Small Bowel Intussusception

***Overview.*** Intussusceptions in young children are typically ileocolic or ileoileocolic (see Chapter 107). Small bowel intussusceptions are more frequently identified as an incidental finding with the widespread use of cross-sectional imaging.[150]

***Etiology.*** Small bowel intussusceptions are typically short segment, transient, and asymptomatic.[151,152] Exceptions include those caused by a focal lead point such as Meckel diverticulum, duplication cysts, polyps, small bowel hemangiomas, and lymphoma. Small bowel intussusceptions may also be seen with bowel thickening in gastroenteritis, IgAV, CF, or celiac disease (e-Fig. 104.18). In addition, small bowel intussusceptions may occur in association with gastrojejunostomy (GJ) tubes, typically in the jejunum, or during the postoperative period.[153]

***Clinical Presentation.*** Compared with ileocolic intussusception, symptoms in small bowel intussusception are less severe or absent, with only vomiting seen with any frequency.[154] Patients with a small bowel intussusception secondary to a lead point that does not reduce spontaneously present with abdominal pain and bowel obstruction.[151]

***Imaging.*** US is the first-line modality in intussusception evaluation; they appear as a laminated "pseudomass" longitudinally and "target" sign transversely. Findings that indicate a transient intussusception include short length (<3 cm), thin diameter (<2.5 cm), preserved wall motion, and absence of a lead point.[151] Additional features favoring small bowel versus ileocolic intussusception are absence of either a fat core or lymph nodes inside the lesion.[154] The findings are similar on US and CT (see Chapters 103 and 107).[150,151] Interrogation of the intussusception and adjacent bowel may demonstrate a focal or diffuse pathologic lead point as earlier discussed, mesenteric lymph nodes within the complex, and evidence of bowel obstruction. GJ tubes can be seen as a central shadowing, with or without a hyperechoic focus.[153]

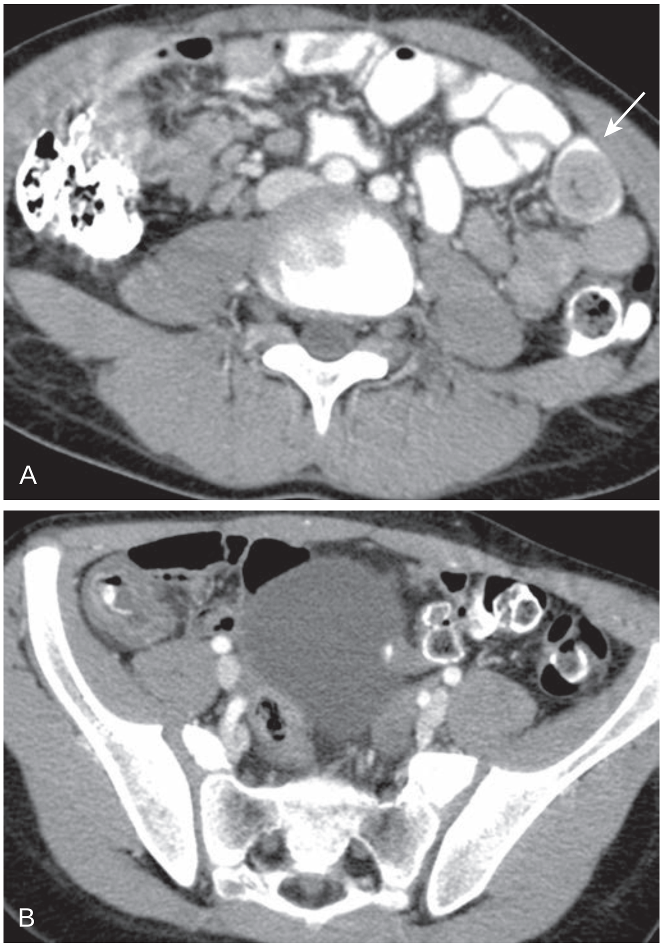
***Treatment.*** Small bowel intussusception in the absence of a lead point or bowel obstruction should be treated symptomatically, with serial US usually demonstrating spontaneous resolution, often during a single examination. Pathologic SBOs are not amenable to image-guided enema reduction and require surgical management.

## TUMORS

### Benign Tumors

#### Polyps

Polyps can be occur throughout the GI tract, most commonly in the colon, and are histologically classified as neoplastic polyps (e.g. adenomas) and nonneoplastic polyps (e.g., hyperplastic, inflammatory, and hamartomatous polyps [HP]). Although rare compared with other polyps, HP are the most common in children, over 90% being solitary juvenile polyps in the rectosigmoid. Multiple HP occur in hamartomatous polyposis syndromes (such as Peutz-Jeghers syndrome [PJS]), which are associated with a high risk of malignancy (Chapter 108).[155]



**e-Figure 104.18. IgA vasculitis (Henoch-Schönlein purpura).** (A) Axial contrast-enhanced CT images in a 9-year-old girl with abdominal pain, fever, and bloody stools demonstrate a transient small bowel (ileoileal) intussusception *(arrow)* and (B) pronounced thickening of the terminal ileum.

## Peutz-Jeghers Syndrome

***Overview.*** PJS is an autosomal-dominant syndrome with incomplete penetrance characterized by mucocutaneous pigmentation and hamartomatous polyps of the GI tract. The estimated prevalence is approximately 1 per 100,000–195,000 individuals.[155,156]

***Etiology.*** PJS has been attributed to mutations in the *STK11* gene (serine/threonine kinase 11, alias *LKB1*) on chromosome 19p13.3.[156]

***Clinical Presentation.*** The characteristic mucocutaneous pigmentation from pigment-laden macrophages usually precedes polyp formation and is seen in approximately 95% of patients as brown or black pigmentation of the vermillion border, buccal mucosa, face, palms, and soles. Typically present during early childhood, they often fade at adolescence.[156] Polyps occur most commonly in the small bowel, followed by the colon and stomach, sparing the esophagus. The most common clinical presentation is with symptoms of SBO with abdominal pain due to an intussusception (69% of patients having at least one episode by 16 years of age), followed by rectal bleeding and anemia. The first GI symptoms can occur in early childhood, with 50% to 75% of patients presenting before 20 years of age.[155,157] Patients with PJS have 1% to 2% risk of malignancy by 20 years increasing to 31% by 50 years, with GI tract malignancies the most common.[158] Associated extraintestinal malignancies may involve the testes, breasts, pancreas, reproductive organs, and less frequently the thyroid, gallbladder, and biliary tree.[158]

***Imaging.*** Diagnosis is usually made based on the combination of mucocutaneous rash and on biopsy of the polyp, most commonly in the small bowel, with decreasing frequency in the colon and stomach.

US is the main modality for diagnosis of small bowel intussusceptions as previously described. Although polyps are not well seen sonographically, they are variably described as hypo- or hyperechoic polypoidal masses (e-Fig. 104.19).[153]

For surveillance, SBFT, enteroclysis, and CT are now discouraged because of ionizing radiation risks.[159] MRE is as effective as SBFT in detecting polyps, and for polyps greater than or equal to 15 mm is equivalent to videocapsule endoscopy and has better localization.[159,160] It is likely MRE will be incorporated into surveillance protocols as these findings are further validated. For now, comprehensive surveillance for polyps involves upper GI endoscopy, videocapsule endoscopy, and ileocolonoscopy starting at 8 years of age, with additional organ screening from puberty onward.[160,161]

***Treatment.*** Intussusceptions require surgical resection unless they resolve spontaneously, which can be monitored with serial US. Polypectomy can be performed endoscopically, usually for polyps 10 to 15 mm, if symptomatic or rapidly growing. Experimental agents for chemoprevention, such as rapamycin, are being developed and tested.[156] Cancer surveillance is part of the patients' lifelong care.

## Benign Neoplasms

***Overview.*** Primary neoplasms in the GI tract represent less than 5% of all neoplasms in children, and are even rarer in the upper GI tract.[162] Benign neoplasms in the small intestine include hemangiomas, vascular malformations, neurofibromas, fibromas, leiomyomas, lipomas, and lipoblastomas. Most benign small bowel tumors manifest with GI bleeding or intussusception.

***Etiology.*** Hemangiomas can be solitary or multiple and may occur as an isolated finding or in association with a syndrome. Patients with Klippel-Trénaunay syndrome are seen with visceral and cutaneous hemangiomas. Telangiectasias (dilated superficial blood vessels) may occur in the small intestine in Osler-Weber-Rendu syndrome. Vascular malformations that involve the small intestine have also been reported in association with other soft tissue vascular malformations.[163]

Neurofibromas may occur in isolation or as a manifestation of NF1, where they are the most frequent bowel neoplasm, seen in approximately 10% to 25% of patients.[164]

Fat-containing small intestinal neoplasms include lipomas and lipoblastomas. These appear primarily within the intestinal wall or in the adjacent omentum or retroperitoneum. Lipoblastomas are rare tumors related to embryonal fat, occurring almost exclusively in children; 90% come to medical attention within the first 3 years of life.[165,166]

***Clinical Features.*** Hemangiomas may manifest with GI bleeding, obstruction as a lead point for intussusception, or perforation.[163] Neurofibromas that involve the small bowel are often asymptomatic, however, they may be seen initially with GI bleeding or with obstruction secondary to intussusception or segmental volvulus.[164] Lipomas may ulcerate when larger than 2 cm and may lead to intestinal bleeding or intussusception,[167] and lipoblastomas, although benign, may recur locally in as many as 25% of cases.[165]

***Imaging.*** Rarely, abdominal radiographs may reveal a soft tissue density with localized mass effect. More usually patients present with abdominal pain and signs of SBO, with dilated bowel loops and fluid air levels secondary to intussusception. Fluoroscopic contrast studies are rarely indicated but may reveal a luminal filling defect or a mural mass. US is the preferred modality for intussusception diagnosis, as well as looking for a focal pathologic lead point, although these are rarely discerned.[153] Lipomas and lipoblastomas demonstrate characteristic low density on CT and fat intensity on MRI.[165,167]

***Treatment.*** Neurofibromas that are symptomatic typically undergo surgical excision.[168] Lipoblastomas are treated by complete resection, and mesenteric lipoblastomas may require resection of adjacent intestinal loops.[165,166]

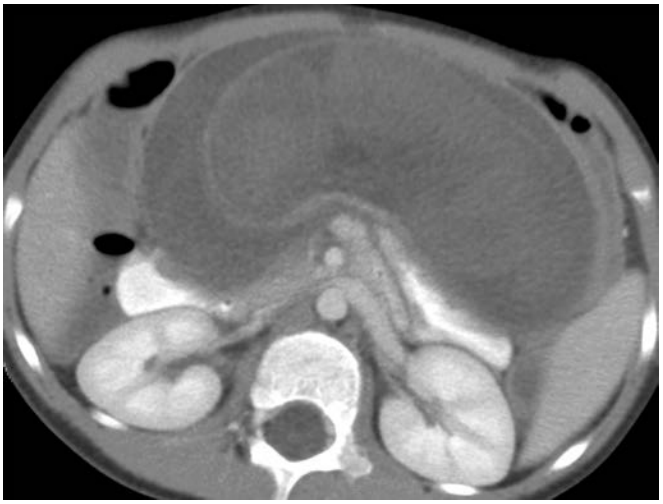
# Malignant Tumors

***Overview.*** With the exception of lymphoma, malignant tumors of the small intestine in children are exceedingly rare.[162] GI stromal cell tumors (GIST) are considered potentially malignant[169] and as such will be discussed here, along with lymphoma and neuroendocrine (carcinoid) tumors. Patients with PJS, considered previously, may also develop GI malignancies. Other polyposis syndromes that primarily affect colon are further discussed in Chapter 108.

## Gastrointestinal Stromal Tumors

***Etiology.*** The most common mesenchymal tumor of the stomach and intestine, GIST are very rare in children and adolescents, representing 1% to 2% of all GIST with an incidence of 0.02 per million under 14 years (median age 13 years) and up to 70% occurring in girls.[170,171] Arising from the interstitial cells of Cajal in smooth muscle, pediatric GIST are similar to adult GIST demonstrating positive stains for CD117/c-KIT and CD34 but different in that only 15% have mutations in somatic receptor tyrosine kinase gene KIT and platelet-derived growth factor receptor alpha (PDGFRA), referred to as wild type (WT) GIST.[172] GIST can be sporadic, familial (Carney-Stratakis syndrome, both paragangliomas, and GIST), part of the nonhereditary syndrome Carney triad (gastric GIST, extra-adrenal paraganglioma, pulmonary chondroma), or associated with other syndromes (e.g., NF1).[171]

***Clinical.*** GIST most frequently manifest with GI bleeding and secondary anemia. Other symptoms can include vomiting, abdominal pain, early satiety, a palpable mass, weight loss, and obstruction.[172,173] They are often multifocal, particularly gastric GIST in Carney triad but can present as a single, often exophytic mass that can ulcerate. Sixty percent are gastric, 20% to 30% in small intestine; in children, 20% to 29% have metastases at diagnosis, usually to regional lymph nodes, liver, and peritoneum (<2% in adults).[170–172,174]



**e-Figure 104.19. Hamartomatous polyps causing intussusception.** Axial contrast-enhanced CT image in a 4-year-old boy with severe episodic abdominal pain shows a small bowel (jejunojejunal) intussusception with a high-grade obstruction. Infarcted hamartomatous polyps were present on the pathologic specimen of the resected intussuscepted bowel.

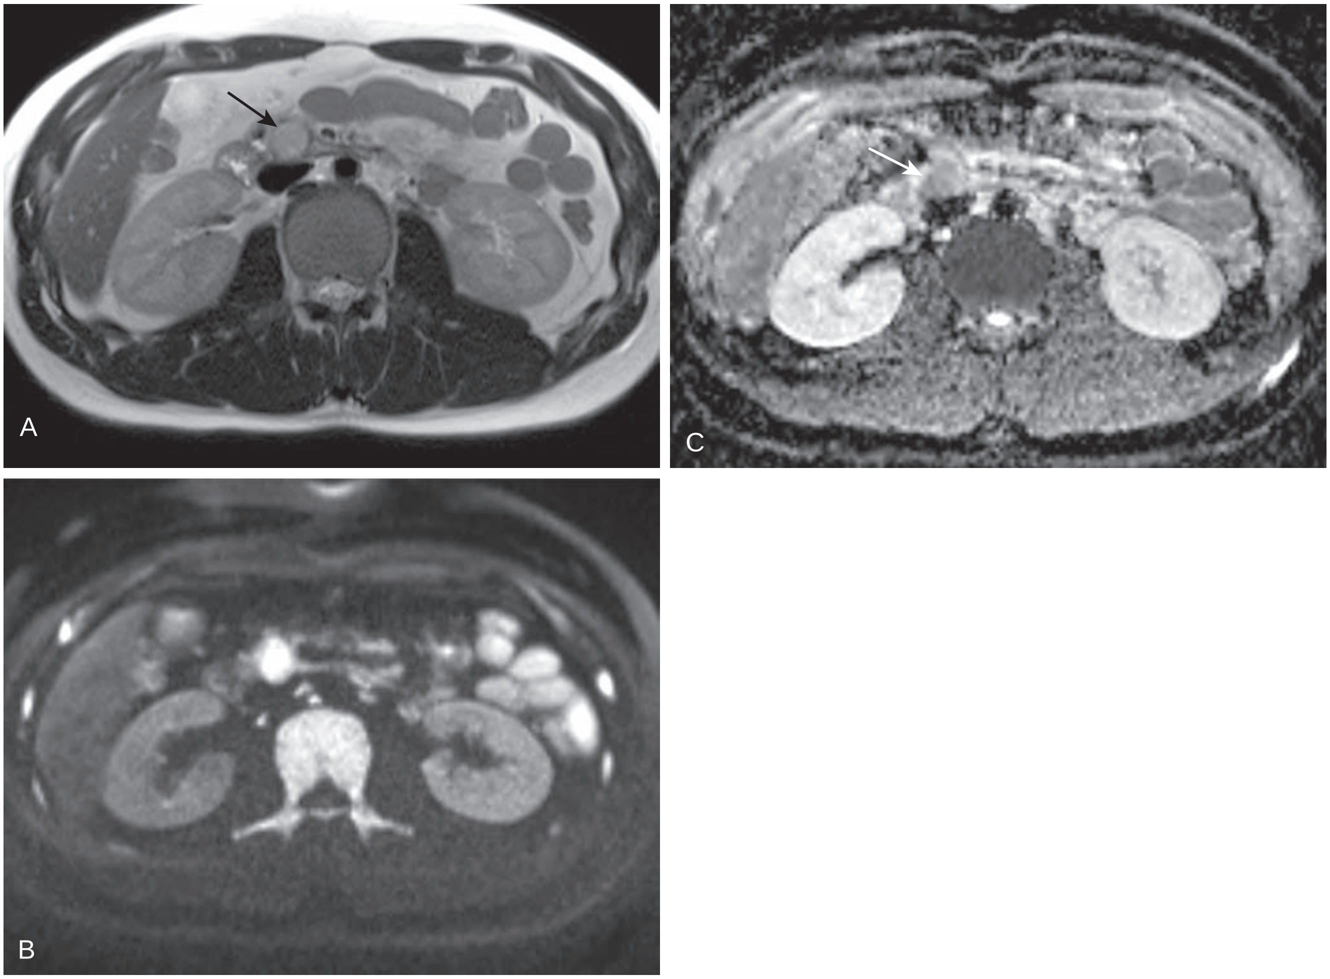


**Figure 104.20. Gastrointestinal stromal tumor (GIST).** A 14-year-old boy with melena. Axial single-shot fast spin echo (SSFSE) sequence (A), DWI b = 800 s/mm$^2$ (B), and ADC map (C) MR images show a T2 hyperintense, diffusion-restricting mass *(arrow)* arising from the third portion of the duodenum.

***Imaging.*** Abdominal radiographs may show a soft tissue mass with local mass effect, or SBO or gastric obstruction. With ionizing radiation concerns and reported sensitivity of 35%, fluoroscopic contrast studies are rarely performed but may demonstrate a circumscribed, rounded gastric or intestinal filling defect or obstruction. US is often the first study to detect a mass, which appears lobular and hypoechoic with central cysts or necrosis and intermediate peripheral vascularity; size varies between a few millimeters to 25 cm. US can localize GIST origin as well as screen for metastases.[175] CT and MRI postintravenous contrast are used in diagnosis and staging showing lobular, single or multifocal soft tissue density/intensity masses with peripheral enhancement, and central necrosis, cysts, or hemorrhage.[176] $^{18}$F-FDG PET/CT and PET/MRI are particularly sensitive for GIST and have a role in defining occult metastases, as well as monitoring treatment response or recurrence (Fig. 104.20).[170]

***Treatment.*** Pediatric GIST tend to be indolent in spite of metastatic disease, especially small tumors (<2 cm) that may be monitored with endoscopic US.[170] Local surgical resection is the primary treatment due to resistance to standard chemotherapy; however, recurrence is high (40%–90% in adults).[172] If KITc or PDGFRA mutation is positive, adjuvant therapy with ongoing surveillance imaging is an option, although this is yet to be standardized.

## Gastrointestinal Tract Lymphoma

***Overview.*** Burkitt lymphoma is the most frequent subtype of non-Hodgkin lymphoma (NHL) that occurs in children. More than one-third of the cases occur in children between 5 and 9 years of age (median age at presentation being 8 years), with a male predominance. The GI tract is involved in 22.5% to 57.5%.[177,178] The second-most common NHL in children is diffuse large B-cell lymphoma (DLBCL), accounting for 20% of pediatric NHL, more common in adolescents. While widely disseminated in 75%, the GI tract is the most common extranodal site. Anaplastic large cell and T-cell lymphoblastic NHL rarely involve the GI tract, and Hodgkin lymphoma is nodal.[179] Lastly, posttransplant lymphoproliferative disease (PTLD) commonly involves the GI tract after liver, kidney, pancreas, lung, or heart transplant. The incidence is from 5% to 33%, with a median onset 5 years posttransplant, and is highest after pancreas transplantation.[180] The distal small bowel is the most common site. Imaging features are similar to other NHL.

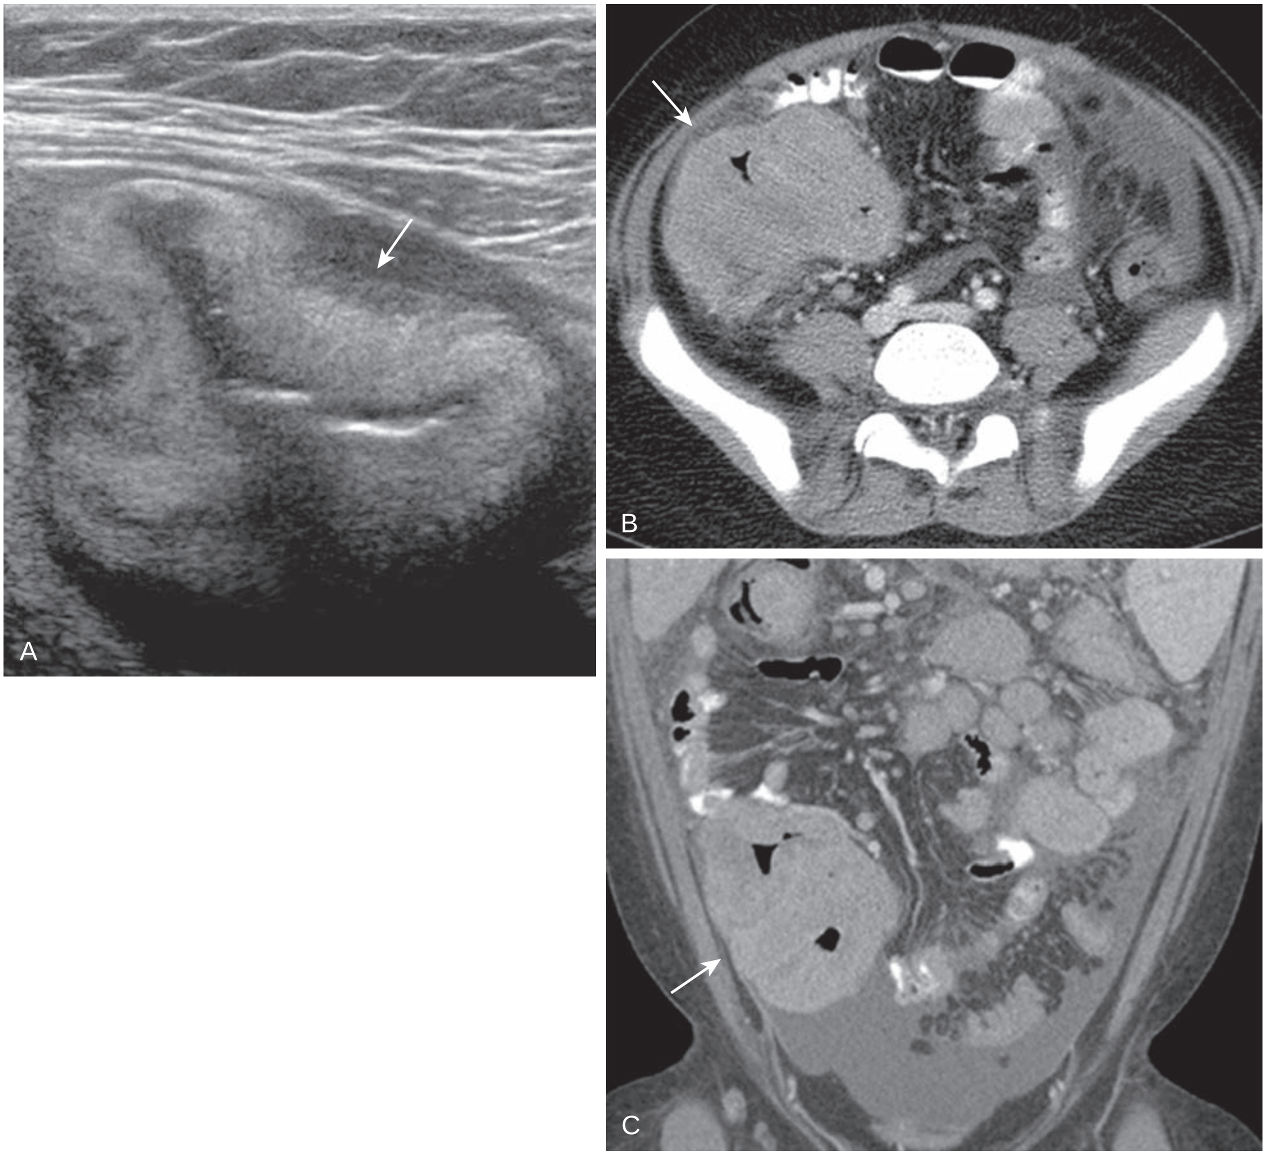

**Figure 104.21. Burkitt lymphoma.** (A) Transverse abdominal sonographic image in a 12-year-old boy who presented with abdominal pain, nausea, and diarrhea shows pronounced bowel wall thickening *(arrow)*. (B) Correlative axial contrast-enhanced CT image confirms thickening of bowel in the right lower quadrant *(arrow)* and moderate ascites. (C) Coronal reformat again shows the involvement of the bowel with tumor *(arrow)* and additionally demonstrates ascites.

## Burkitt Lymphoma

***Etiology.*** Burkitt lymphoma is a monoclonal B-cell lymphoma that occurs in three principal forms: endemic, sporadic, and immunodeficient. The endemic form, originally identified in Uganda in 1958, occurs in equatorial Africa and Papua New Guinea, with a 95% association with the Epstein-Barr virus (EBV). The sporadic form is seen in North America, Northern and Eastern Europe, and the Far East, and its association with EBV is 15%. The immunodeficient form is associated with immune-compromised states, particularly with HIV infection, congenital deficiencies, and iatrogenic immunodeficiencies such in allograft recipients.[177,179]

***Clinical Presentation.*** Primary pediatric GI tract lymphomas preferentially involve small and large bowel, rather than the stomach in adults.[181] Terminal ileum, cecum, and appendix are common sites of involvement by Burkitt lymphoma, the terminal ileum most commonly involved due to a high concentration of lymphatic nodal tissue.[177] Common presenting symptoms range from a painless, palpable abdominal mass to abdominal pain with intestinal obstruction or perforation, followed by neck swelling.[178] Obstruction may be related to an intussusception with a pathologic lead point (see Fig. 108.7). Burkitt lymphoma is one of the most rapidly growing tumors, with a doubling time of approximately 24 hours, making prompt diagnosis important.[177]

***Imaging.*** Abdominal radiographs may show evidence of mass effect or obstruction related to an intussusception, or appear normal. US can demonstrate an intussusception with lymphoma seen as a lobulated, hypoechoic mass in the intussusceptum acting as a pathologic lead point. Prominent reactive lymphoid hyperplasia can be a mimicker.[153] In the absence of intussusception, a mass of low or heterogeneous echogenicity with a hyperechoic center may be seen when the lymphoma infiltrates the bowel wall (Fig. 104.21A). CT and MRI may show circumferential or asymmetric bowel wall thickening or focal masses (Fig. 104.21B and C) with dilatation of the bowel lumen from obstruction, luminal narrowing, or intussusception.[177,182] Ascites may also be present (see Fig. 104.21C). Careful evaluation of retroperitoneal organs, liver, and spleen is mandatory for disseminated disease. Burkitt lymphoma demonstrates high avidity on $^{18}$F-FDG PET/CT and PET/MRI in active disease at nodal and extranodal sites, useful in tumor staging and assessing treatment response.[182,183]

***Treatment.*** Although it grows rapidly, Burkitt lymphoma is also rapidly responsive to chemotherapy, with no need for radiation or surgery (unless complicated by intussusception or perforation).[181,184] Image-guided enemas can be attempted in this setting but should be done with caution and in consultation with the referring surgeon.[153]

## Neuroendocrine Tumor (Carcinoid Tumor)

***Overview.*** Neuroendocrine tumors (NETs) were previously known as *carcinoid tumors*. A 2011 consensus guideline redefined them as follows[185]: “neuroendocrine neoplasms” (NEN) for all low-, intermediate-, and high-grade tumors; “tumor” (NET) reserved for low- to intermediate-grade neoplasms (previously “carcinoid” or “atypical carcinoid”); and “carcinoma” (NEC) for high-grade neoplasms (previously “poorly differentiated carcinoma”). Additionally, mid and hindgut NETs are further classified by location: gastroduodenal, jejuno-ileal (SI-NEN), appendiceal, cecal, colonic, or rectal.[186]

NETs are rare neoplasms defined by the expression of neuroendocrine markers.[185] Second only to lymphoma in incidence of pediatric GI tract neoplasms, they occur in the digestive tract in up to 95% of cases.[187] Most commonly found in young adults, NETs are rare in children, with a reported prevalence of 0.08%.[188]

***Etiology.*** NETs arise from neuroendocrine enterochromaffin or Kulchitsky cells. Although most lesions arise de novo, NETs are associated with multiple endocrine neoplasia types 1 and 2 as well as NF1.[189]

***Clinical Presentation.*** Unlike the rapidly growing Burkitt lymphoma, NETs have a slow growth rate and indolent course, with a relatively long asymptomatic period.[186] Presentation may mimic acute appendicitis; patients otherwise come to medical attention with intermittent abdominal pain, vomiting, bleeding, and bowel obstruction. In adults, metastases are seen at diagnosis in approximately one-fourth of patients.[190] Metastases and the carcinoid syndrome are uncommon in children.[188]

***Imaging.*** NETs are not typically detectable on radiographs unless complicated by a secondary process such as intussusception with obstruction. Rarely, a calcified appendiceal NET may mimic a fecalith.[189] On cross-sectional imaging, associated mesenteric desmoplastic reaction, nodal, or hepatic metastases may be more readily identifiable than the primary tumor. CT and MR enterography/enteroclysis may aid in primary tumor detection.[186] On MRI, carcinoids may be seen as a subtle, asymmetric mural thickening that is isointense on T1- and mildly hyperintense on T2-weighted sequences.[189] Isotope imaging with $^{68}$gallium-DOTATOC PET/CT is preferred for detection and staging of NEN; $^{18}$F-FDG PET/CT or PET/MRI is not useful in lower-grade tumors.[186]

***Treatment.*** Locoregional surgical resection is the first line of treatment for NET (with tumor debulking if symptomatic); antiproliferative agents (e.g., somatostatin analogs and interferon-$\alpha$) and rarely peptide receptor radionuclide therapy are options in more advanced disease.[189] Tumors less than 2 cm in diameter at diagnosis have a favorable prognosis especially for incidentally detected appendiceal NET, where right hemicolectomy is no longer advocated.[187,188,191,192]

### KEY POINTS

- The most common causes of small bowel obstruction in older children are adhesions, hernias and omphalomesenteric duct remnants.
- Infectious gastroenteritis is most commonly caused by viruses, and imaging generally plays little or no role in the evaluation of the disease.
- ALARA (as low as reasonably achievable) principles, minimizing ionizing radiation exposure, should be followed with respect to imaging children with CD.
- US, CT, and MRI have largely replaced the fluoroscopic examination of the bowel in the assessment of IBD, and CT and MRI have comparable sensitivities and specificities.
- MRI is the imaging modality of choice for assessing perianal disease and fistulae in patients with CD.
- Burkitt lymphoma often involves the GI tract in children and is a common lead point for intussusception for older children.

# 105

# Congenital and Neonatal Disorders

Marta Hernanz-Schulman

## OVERVIEW

Congenital and neonatal abnormalities of the colon can be divided into those that present in the neonatal period, such as colonic atresia and stenosis, imperforate anus, and functional colonic abnormalities, such as small left colon syndrome and meconium plug. Entities such as Hirschsprung disease, anorectal stenosis, duplication cysts, and chronic intestinal pseudoobstruction (CIPO) are congenital abnormalities that can or even typically present later in life, while acquired entities, such as necrotizing enterocolitis, routinely affect the newborn, particularly the premature.

## COLONIC ATRESIA AND STENOSIS

***Overview.*** The colon is the least involved segment in intestinal atresias, with colonic atresia comprising between 1.8% and 15% of intestinal atresias, with an overall incidence of 1 in 1498 to 1 in 66,000 births.[1] The anatomic descriptive classification of intestinal atresias (as described in Chapter 102, Fig. 102.28) is applied to colonic atresias: type I membranous; type II blind ends separated by fibrous cord; type III mesenteric defect; and type IV multiple atresias.[2,3] Atresia involves the right colon in approximately half the cases, particularly type III lesions.[1]

Colonic atresia is associated with other colonic abnormalities, as well as extracolonic and extraintestinal comorbidities in as many as 47% of cases.[1] Approximately 22% of patients may have Hirschsprung disease or hypoganglionosis[4–6]; other associations include malrotation, abdominal wall defect, and other atresias.[1] Extraintestinal anomalies include the musculoskeletal system, heart, abdominal wall, eyes, and central nervous system (CNS).[6,7]

Congenital colonic stenosis is very rare, with less than 20 cases reported in the literature, typically consisting of stricture-like stenosis, although membranous stenosis has also been reported. Most cases of colonic stenosis in infants are acquired, particularly as sequela of conditions such as necrotizing enterocolitis.[8,9]

***Etiology.*** Similar to small bowel atresias, colonic atresias are thought to result from an ischemic event in utero leading to resorption of the involved bowel and discontinuity of the proximal and distal segments.[10] More recently, mutations in fibroblast growth factor 10 (FGF10) or its receptor have resulted in intestinal atresia in mice, even in the absence of vascular insult, suggesting that this genetic determinant may also play a role in the intrauterine development of intestinal atresias.[11,12] Most isolated cases are sporadic, but syndromic cases share a genetic basis. Hereditary multiple intestinal atresias, which include immune deficiencies and carries a very high mortality, is believed to be an autosomal recessive lesion, with mutations in the *TTC7A* gene.[13]

***Clinical Presentation.*** Polyhydramnios is uncommon, because the atresia is sufficiently distal to allow resorption of swallowed amniotic fluid. Infants with colonic atresia present with abdominal distension, vomiting, and failure to pass meconium. Because the obstruction is distal, the onset of vomiting may be delayed in comparison to more proximal atresias.[7,14]

***Imaging.*** Abdominal radiographs in patients with colonic atresia often show that the proximal colon is dilated far more than the other loops of bowel (Figs. 105.1A and B), and air-fluid levels and absence of gas in the rectum will be seen on prone cross-table lateral views (Fig. 105.1C). The disproportionate dilatation of the proximal colon is due to competence of the ileocecal valve, which allows intestinal contents forward into the atretic proximal colonic segment but does not allow decompression proximally. This finding is characteristic and highly suggestive of the diagnosis on plain films, although not always present. Contrast enema demonstrates a blind-ending microcolon, devoid of the filling defects that characterize meconium ileus (Fig. 105.1D).

***Treatment.*** Surgery is required. Because 15% to 20% of patients with colonic atresia will also have proximal intestinal atresia, the proximal bowel should be evaluated. Hirschsprung disease should be excluded before reestablishing intestinal continuity, and existing extraintestinal anomalies should be identified.[6,7] The size discrepancy between the markedly dilated proximal segment and the distal microcolon may necessitate resection of the dilated proximal segment.[15]

## ANORECTAL MALFORMATIONS

***Overview.*** Anorectal malformations (ARM) encompass the spectrum of anal atresia and stenosis, with an incidence estimated at approximately 1:5000 live births worldwide. Approximately one-third of patients have isolated lesions, whereas two-thirds are affected by other abnormalities in multiple organ systems as well as other portions of the gastrointestinal (GI) tract.[16] Approximately 95% of the patients have a fistula to the urethra (males), vagina (females), or the perineum; however, among patients with Down syndrome and ARM, approximately 95% have no fistula.[17]

ARM lesions were classified in 1953 by Gross as high and low, with respect to position of the atresia above or below the levator mechanism.[18,19] Two decades later, the concept of intermediate or translevator lesions was introduced to denote the more continuous spectrum of these lesions (Fig. 105.2). More recently Levitt and Peña have introduced a gender-inclusive classification that has prognostic implications as well as implications regarding optimal surgical management and outcome.[20] Under this framework, females with high lesions (high rectovaginal fistula) who later present with a persistent/unrepaired urogenital sinus abnormality represent girls with persistent cloaca, initially confused with high anal atresia; these are classified by the length of the persistent cloacal canal (Table 105.1).[20]

Rectal atresia and stenosis are discussed among the ARM lesions, although such patients have a normal anal canal and external physical findings. These lesions constitute approximately 1% of ARM lesions. In patients with rectal atresia, the rectum is atretic 1 to 2 cm above the anus.[20–22]

***Etiology.*** Anorectal atresia with rectourethral or rectovaginal fistulas may be the result of failure of the urorectal septum to descend to the cloacal membrane and the eventual site of the perineal body; if the cloaca is too small, the hindgut may then terminate anteriorly, entering either the urethra in the male or the vagina in the female. Rectoanal atresias are thought to be related to vascular accidents similar to those that occur in atresias of the small bowel and colon; imperforate anus is due to failure of breakdown of the anal membrane.[23]

## Abstract:

This chapter discusses congenital anomalies of the colon, and acquired abnormalities characteristic of the neonatal period.

Colonic atresia and stenosis are reviewed, including associations such as the Currarino syndrome. Anorectal malformations are discussed with respect to the level of termination, characteristics in males and females, and associated anomalies. Hirschsprung disease, its differential presentation in neonates and older patients, and diagnostic criteria, as well as complications such as Hirschsprung colitis are discussed.

Obstructive colonic lesions involving colonic dysmaturity and their relationship to Hirschsprung are also addressed, in conjunction with rarer entities such as the Berdon syndrome. The various types of colonic and rectal duplication cysts are discussed. Necrotizing enterocolitis, diagnosis, severity and Bell Criteria are also reviewed.

## Keywords:

Colon atresia
colon stenosis
congenital anomalies of colon
Currarino syndrome
Hirschsprung disease
Hirschsprung enterocolitis
Berdon syndrome
megacystis-microcolon-intestinal hypoperistalsis syndrome
chronic intestinal pseudoobstruction (CIPO)
colonic duplications
necrotizing enterocolitis (NEC)

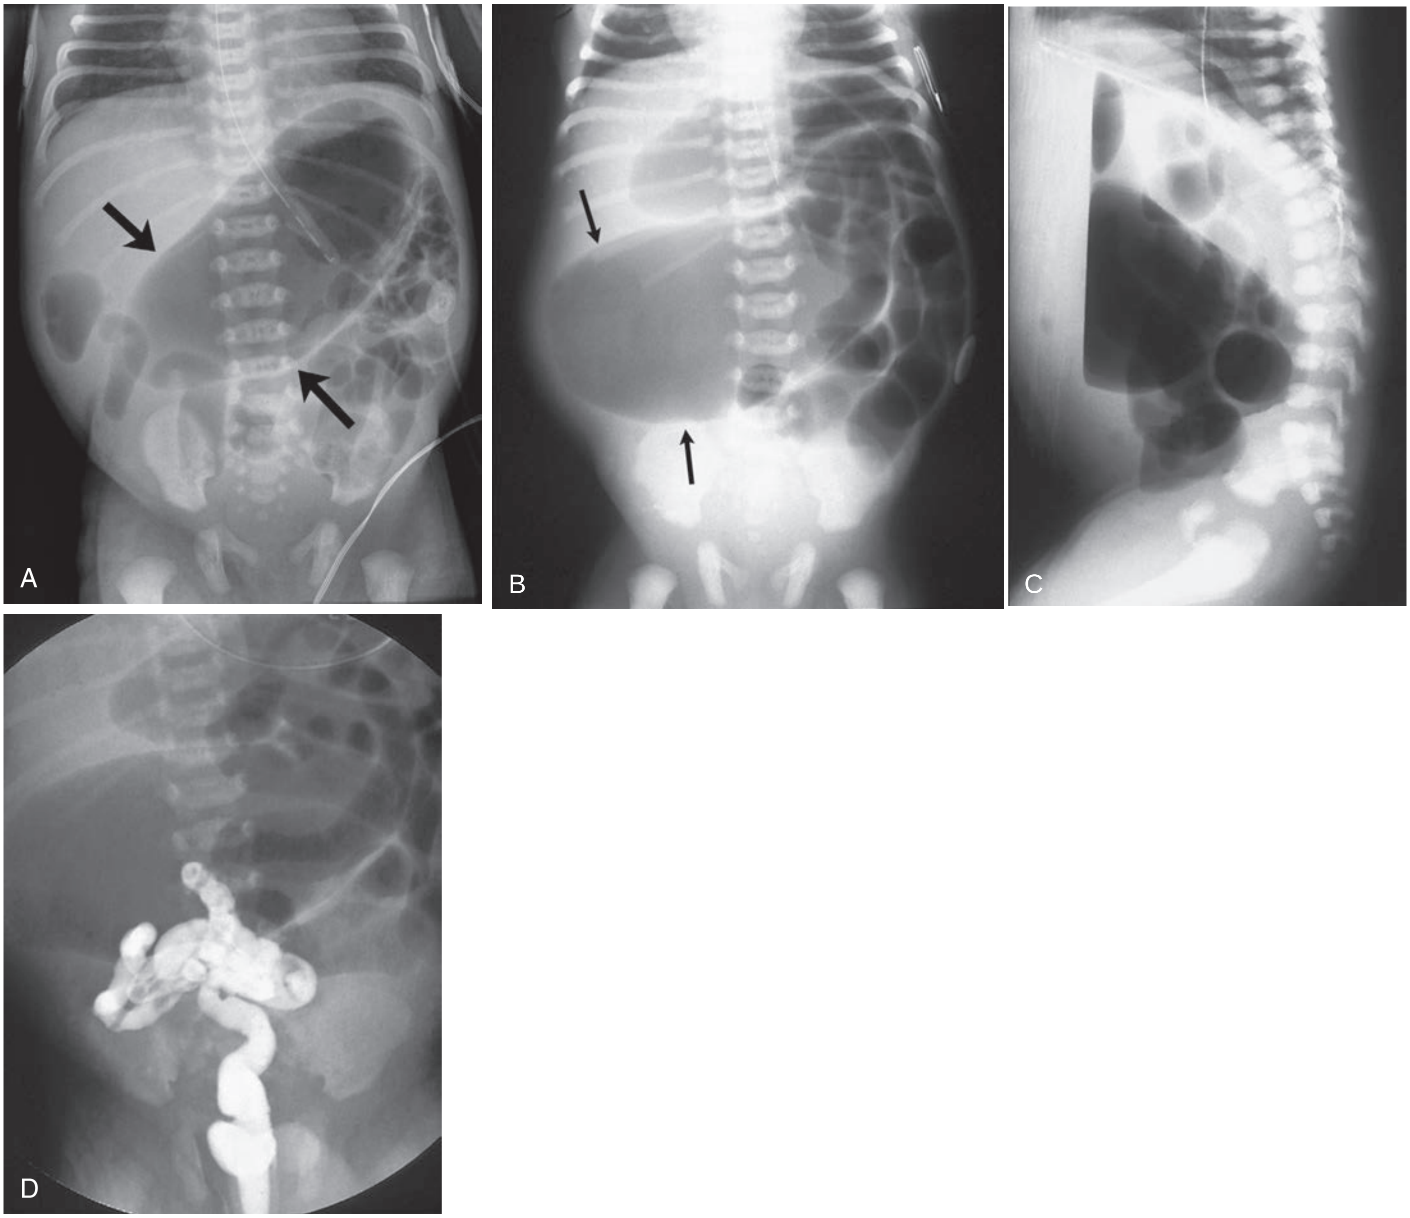

**Figure 105.1. Colonic atresia.** (A) Supine abdominal radiograph of neonate shows a markedly dilated proximal colonic segment *(arrows)* that could be mistaken for the stomach and also shows the relatively mild distension of the distal small bowel loops, despite the complete obstruction. Atresia of the ascending colon was found at surgery. (B) Supine abdominal radiograph of another infant with abdominal distension and bilious vomiting demonstrates protuberance of the flanks and elevation of the diaphragm. There are gas-filled dilated loops of bowel, but one loop is dilated far more than other loops; this represents the atretic proximal colonic segment *(arrows)*. Orogastric tube decompresses the stomach. (C) Prone cross-table lateral radiograph in same patient as shown in B. The large air-fluid level is located within the atretic proximal colonic segment. There is no gas in the rectum. (D) Contrast enema in same infant as shown in B and C shows a microcolon terminating blindly at the atretic segment.

No single genetic abnormality has been identified in association with ARM, but a genetic susceptibility is considered likely in many cases due to the increased risk in affected families, knock-out mice models, and the association of ARM with conditions that are part of chromosomal anomalies[24]; the most common chromosomal abnormalities are trisomy 21 and a microdeletion at chromosome 22q11.2, although abnormalities have been identified in multiple chromosomes.[16] Approximately 15% of patients with rectovestibular or rectoperineal fistulas indicative of low lesions have a positive family history for ARM. Genetic studies in both animals and humans have implicated defects in the sonic hedgehog, *Wnt5a*, and *Skt* genes. These studies suggest that the pathogenetic mechanisms of high and low fistulas differ and that it may be a genetic mutation, rather than obstruction, that leads to fistula formation in some cases.[16,24]

***Clinical Manifestations.*** Patients with ARM are clinically apparent by physical examination at birth, with the exception of patients with rectal atresia or stenosis, who are externally normal. The physical examination may reveal a perineal or vestibular fistula, although in both genders this is best evaluated after 24 hours, as

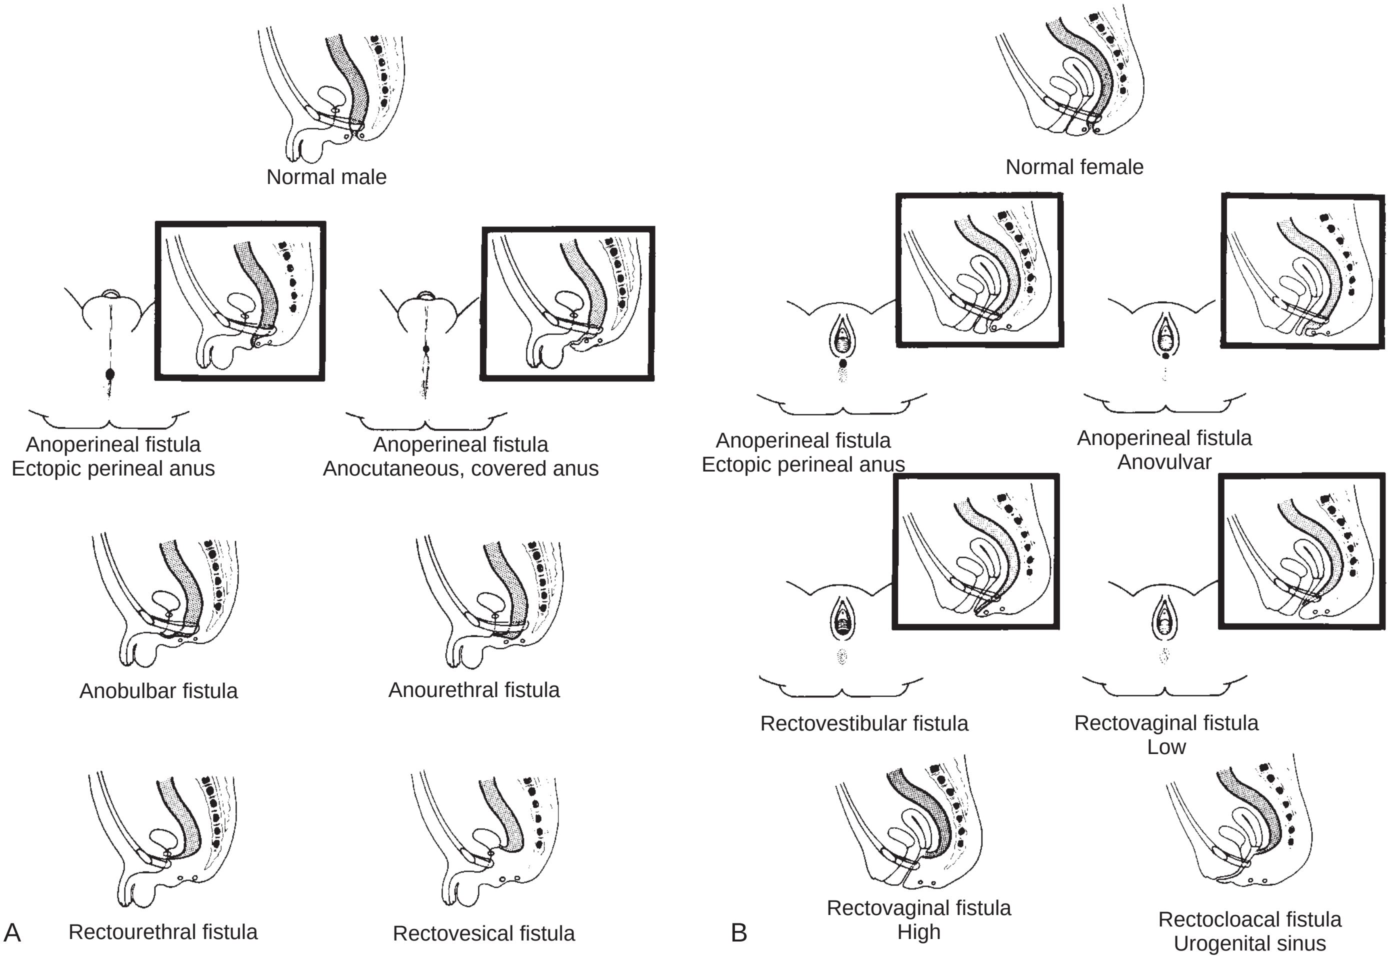

**Figure 105.2. Physical examination findings in boys and girls with anorectal malformations.** (A) Schematic diagram of normal and ectopic termination of the hindgut in the male. (B) Schematic diagram of normal termination and common sites of ectopic termination of the hindgut in the female. *(From Santulli TV. In: Mustard WT, et al, eds.* Pediatric Surgery. *2nd ed. **TABLE 105.1** Classification of Anorectal Malformations

| Males | Females |
|---|---|
| Perineal fistula | Perineal fistula |
| Rectourethral fistula | Vestibular fistula |
| Bulbar | Persistent cloaca |
| Prostatic | ≤3 cm common channel |
| Rectobladder neck fistula | >3 cm common channel |
| Imperforate anus without fistula | Imperforate anus without fistula |
| Rectal atresia | Rectal atresia |
| Complex defects | Complex defects |

*From Levitt M, Peña A. Anorectal malformations. In: Coran A, et al, eds.* Pediatric Surgery, *Philadelphia: CV Mosby, an Imprint of Elsevier; 2012.*

meconium may not appear in the perineum before this time.[20] The presence of a rectourethral fistula may be revealed by identification of fecal material in the urine. Patients who demonstrate a “flat bottom” (i.e., the buttock crease is not visible) have poor development of pelvic musculature, which typically implies a more guarded prognosis.[17] Girls with a single perineal orifice have a cloacal malformation.[20]

Other congenital anomalies are seen in greater than 50% of patients with ARM.[24] The best known group of anomalies associated with ARM is the VACTERL association, which includes *v*ertebral anomalies, *a*nal atresia, *c*ardiac abnormalities, esophageal atresia with or without *te* fistula, *r*enal and *l*imb abnormalities. Esophageal atresia complex is seen in approximately 10% of patients, and abnormalities affecting the duodenum, such as atresia or malrotation, are seen in 1% to 2%. Vertebral anomalies occur in approximately one-third of patients (Figs. 105.3A and B), and their severity may be correlated with the complexity of the anorectal lesion. Coronal clefts in particular are often seen in patients with imperforate anus and have been reported as being nine times more common in boys than in girls.[25] Genetic syndromes include trisomy 21, trisomy 8, and fragile X syndrome.[16] Cardiovascular abnormalities are seen in about one-third of patients and most commonly consist of atrial septal defect and persistent ductus arteriosus, followed by tetralogy of Fallot and ventricular septal defect.[17] Hirschsprung disease is rare, being seen in only 3 out of 2100 patients.[26] Genitourinary anomalies are common, presenting in one-third to one-half of cases, again correlated with increasing complexity of the defect. These range from reflux to renal dysplasia or agenesis, with cryptorchidism and hypospadias seen in male patients. Females may demonstrate Müllerian abnormalities, including duplications and obstructions, particularly in the setting of cloacal abnormalities.[17,20]

***Imaging.*** Patients with ARM undergo imaging to elucidate associated anomalies and to determine the fistulous anatomy. The

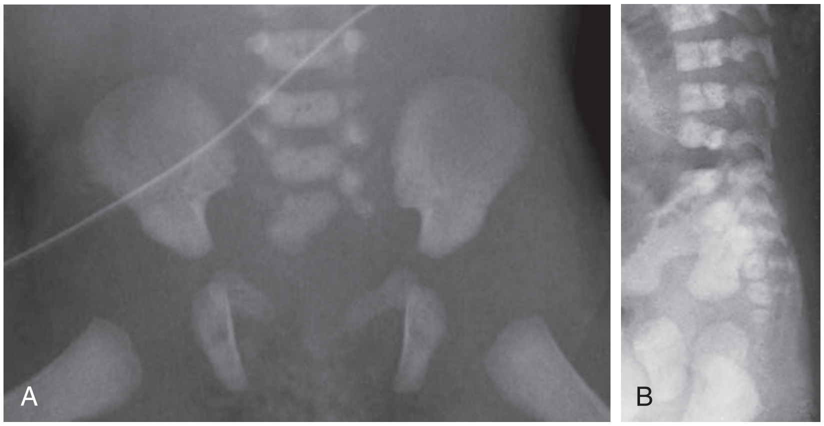

**Figure 105.3. Bony abnormalities in patients with anorectal malformations.** (A) Pelvic radiograph in a neonate shows an abnormal sacrum. (B) Lateral spine radiograph on another patient shows numerous lumbar coronal clefts.

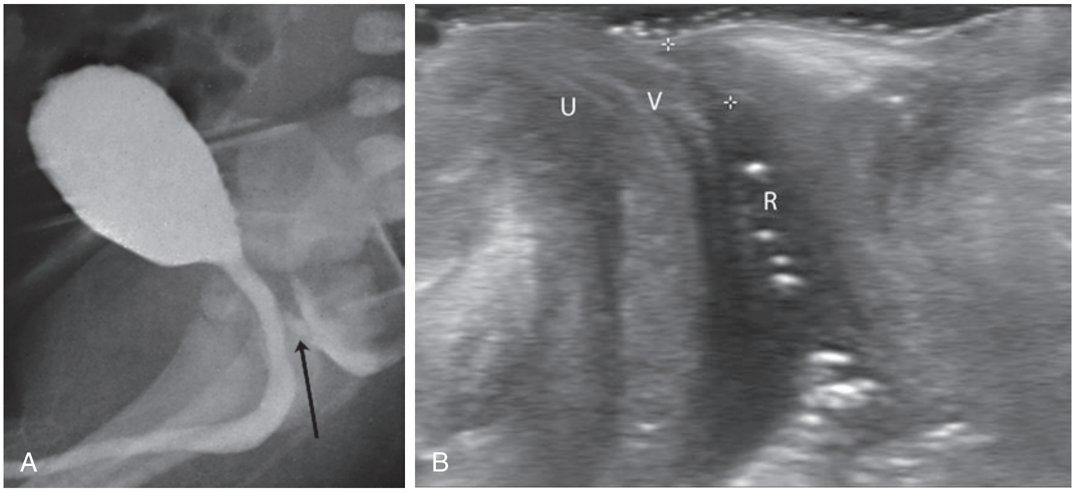

**Figure 105.4. Anorectal malformation: preoperative imaging.** (A) Voiding cystourethrogram in a male demonstrates a fistulous connection to the posterior urethra *(arrow)*. Note that the rectum bulges inferiorly below the level of the fistula. This could cause a spuriously short distance that might be seen on abdominal radiographs and transperineal sonography. (B) Sagittal transperineal ultrasound in a female infant shows the urethra *(U)*, vagina *(V)*, and rectum *(R)*; the latter contains multiple tiny gas bubbles. Calipers delineate the distance to the perineum. No fistulas were identified at imaging or subsequent repair.

sacral ratio[17] quantifies the degree of sacral hypoplasia by measuring the distance between the iliac crests and the inferior border of the sacroiliac joints (A–B) and the distance between the inferior border of the sacroiliac joints and the tip of the sacrum (B–C); the BC/CD ratio should be greater than 0.4. Increase in the ratio to approach 1.0 indicates better sacral development and better potential prognosis.

Imaging of these infants usually includes cardiac evaluation, radiographs of the spine, ultrasound of the kidneys and of the spinal canal, as well as ultrasound of the pelvis in girls, particularly those with cloacal anomaly, as uterine anomalies often exist. Perineal scanning is an important supplement to the imaging of these patients.[27]

In patients who do not have a perineal fistula, several imaging methods have been used for evaluation of the distal anatomy. One of the earliest methods, still in use by some,[17] is the lateral invertogram, or more recently the prone cross-table lateral view of the rectum, which relies on visualizing the gas-filled rectum and relating its termination to pelvic bony landmarks, particularly extension below the coccyx, which would classify it as part of a low lesion. However, problems such as meconium distal to gas, and movement of the rectum with infant straining and crying (Fig. 105.4A), render this examination often inexact and problematic, and it has been abandoned by many. Some investigators advocate performing a voiding cystourethrogram (VCUG) during initial evaluation, as it may reveal the fistulous connection (see Fig. 105.4A).[28] This procedure is not always successful because voiding pressure at the urethra may be insufficient to overcome blockage of meconium in the fistula.

Ultrasound is also used to evaluate the distal position of the rectum (Fig. 105.4B). The meconium in the pouch allows easy visualization of the distal rectum; however, changes in apparent position with straining make it somewhat challenging; measurements of 10±4 mm correlate with a low lesion, whereas measurements of 24±6 mm correlate with intermediate and high lesions. Other authors use 15 mm as the differentiator of low verus intermediate and high lesions.[27,29,30] Transverse rather than sagittal transperineal scanning can identify the puborectalis musculature; the presence of this musculature correlated with low-type lesions, whereas its absence correlated with high-type lesions.[31]

In patients without a perineal fistula who are initially managed with colostomy, evaluation after colostomy can be done through a colostogram, considered by many to be one of the most important anatomic imaging studies, outlining the presence and location of the fistula, the bowel that will be used in the pull-through procedure, and the bony pelvic anatomy (e-Figs. 105.5A and B).[32] The examination is performed under fluoroscopic control, and once the distal rectal vault has reached a rounded appearance, the examination should be considered complete.[33]

Magnetic resonance imaging (MRI) has also been used to identify the internal anatomy. High field strengths, small field of view, and sequences without fat suppression increase the conspicuity of the muscles of the pelvic floor and help visualize the position of the distal rectal pouch with respect to the levator mechanism.[34] Instillation of gadolinium can facilitate delineation of the anatomy. Magnetic resonance (MR) can also delineate Müllerian anomalies associated with cloacal malformation in girls with ARM. Three-dimensional (3D) reformats offer additional global information for the surgeon (e-Figs. 105.5C and D). MR is superior to colostogram in its ability to delineate the musculature of the pelvic floor, the levator group including the pubococcygeus, puborectalis, and iliococcygeus muscles, as well as the external anal sphincter (EAS).[29,35] This modality can also be used to evaluate the rectum and levator sling after definitive surgical repair (Figs. 105.6A and B).

Patients with rectal atresia who have normal-appearing external anal apparatus are imaged in the same manner as patients presenting with distal obstruction, by performing a contrast enema. The enema is diagnostic in that it demonstrates a very short distal rectum that terminates blindly (e-Fig. 105.7).

***Treatment.*** The treatment is surgical but varies with the level and complexity of the lesions. Most boys can be repaired with a posterior sagittal approach alone, although some with a high lesion will require an additional abdominal surgical component to mobilize a very high rectum. In girls, operative repair of the cloacal anomaly can be extremely challenging when there is a long channel.[32] Babies with rectal atresia typically undergo initial colostomy, with subsequent anastomotic repair of the atretic rectum with the anal canal.[20]

## CURRARINO ASSOCIATION

***Overview.*** This entity was initially described in 1981 as a triad of anorectal stenosis or other type of low anorectal malformation: anterior sacral defect such as scimitar, crescent or sickle deformity, and a presacral mass such as meningocele, teratoma, or enteric cyst.[36] Since that time, our understanding of this abnormality has undergone an evolution, with recognition of a much wider spectrum of phenotypic abnormalities and of an underlying genetic defect.

***Etiology.*** Currarino syndrome is an autosomal dominant disorder with variable penetrance; approximately 50% of the cases are sporadic. A mutation located at 7q36 encoding for the *HLXB9* (*MNX1*) gene that encodes for nuclear transcription factor HB9, which plays a role in the dorsoventral separation of the caudal embryo. Other genes related to the same differentiation pathway may be involved in cases that are negative for *HLXB9* mutations.[37–39] A phenotype has been described that includes abnormal facies and development, associated with a normal *MNX1* gene and a larger distal 7q deletion.[40]

***Clinical Presentation.*** Age at presentation is a spectrum that spans the fetal and adult age groups. A fetus may present with a presacral mass, a neonate with anal atresia, and an older child and adult with constipation, meningitis, or presacral malignancy. The spectrum of presacral masses includes teratoma, rectal duplication cyst, anterior meningocele, leiomyosarcoma, and ectopic nephroblastoma.[38,39,41–43]

Other features of the full spectrum of the syndrome include Hirschsprung disease, dysganglionosis, bladder motility abnormalities, vesicoureteral reflux, rib anomalies, urinary and gynecologic abnormalities, cord tethering, and intraspinal lipomas.[42,44]

***Imaging.*** Radiographs of the sacrum may reveal the typical scimitar-shaped sacral abnormality (Fig. 105.8A); however, other sacral defects, typically deletion abnormalities, may be present. In a minority of patients, the sacrum is normal.[39]

Patients with anorectal stenosis may have a rectoperineal fistula or an anteriorly placed anus, and present with constipation, sometimes in early adulthood. Contrast enema shows marked narrowing of distal rectum, with excessive stool proximally (Fig. 105.8B). If of sufficient size, the presacral mass will exert a visible mass effect upon the posterior wall of the distal rectum.

MRI demonstrates the presacral mass and images the spinal canal well (Fig. 105.8C). In young infants, the presacral mass is often visible sonographically (Fig. 105.8D).

***Treatment.*** Surgical treatment depends on the specific phenotypic manifestations, and each is treated accordingly, involving general surgeons, neurosurgeons, and oncologists.

## HIRSCHSPRUNG DISEASE

***Overview.*** This condition that bears his name was first recognized as a distinct entity by Hirschsprung, who in 1887 carefully described and published a detailed description of two infants who had died before 1 year of age.[46,47] Once uniformly

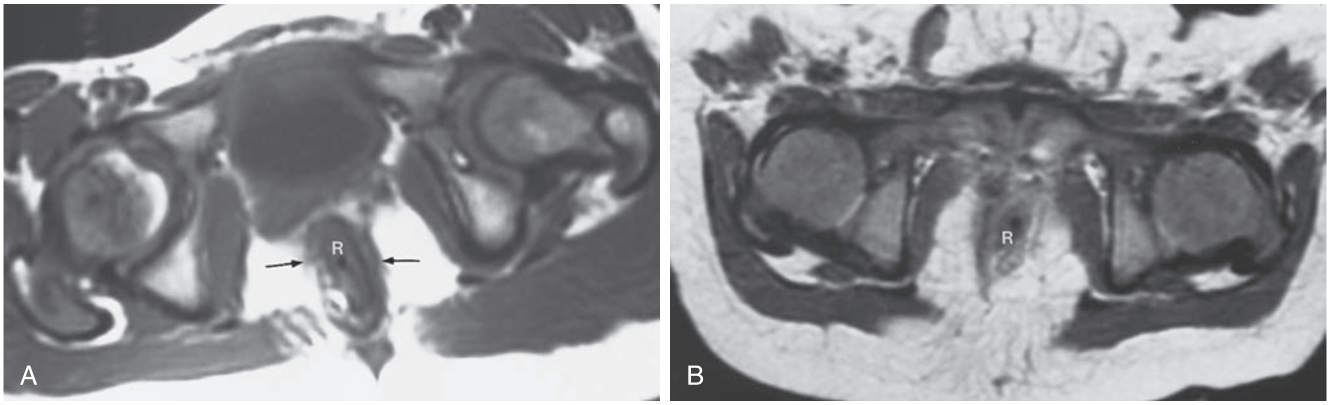

**Figure 105.6. Anorectal malformation after definitive repair.** (A) Axial T1-weighted MR image at the level of the pubic bone shows the rectum *(R)* contained within the puborectalis muscle *(arrows)*. (B) Axial T1-weighted MR image through the region of the pubic bone on another postoperative child shows that the rectum *(R)* is not enclosed by muscle on the left side. There is little puborectalis muscle on the left.

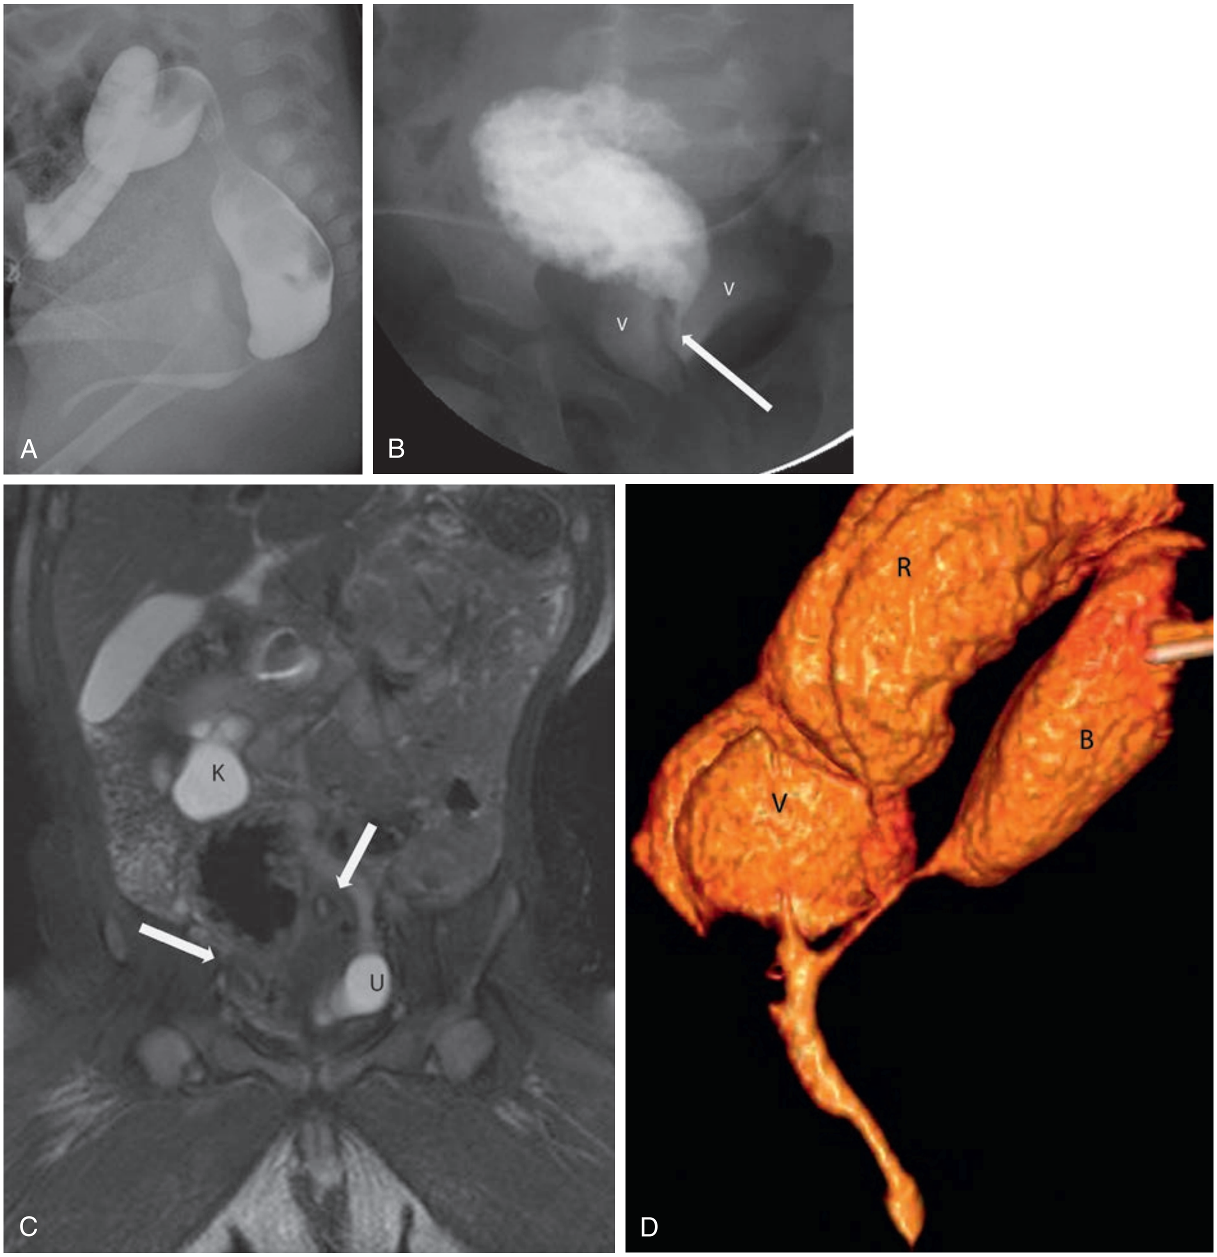
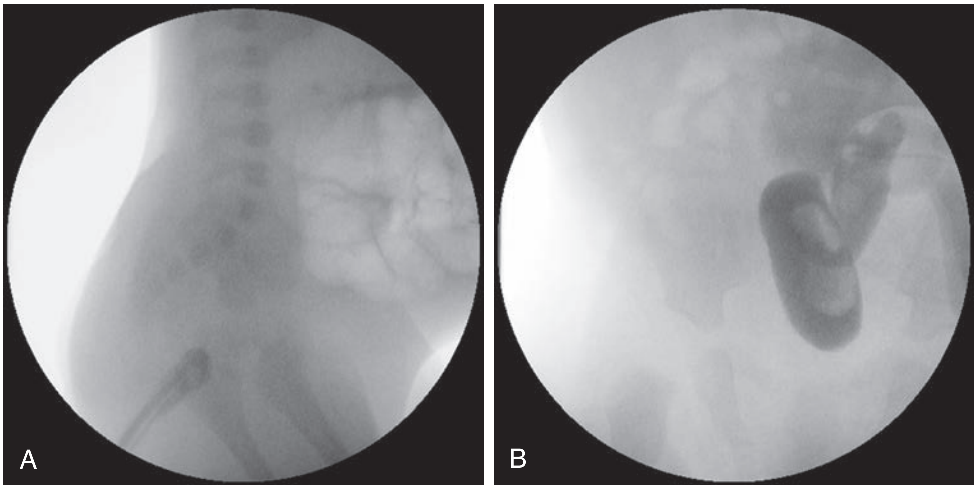


**e-Figure 105.5. Anorectal malformation (ARM).** (A) Colostogram in a male infant demonstrates a fistula from the atretic rectal segment to the posterior urethra. (B) Colostogram in a female infant with ARM, cloaca, and uterovaginal duplication. Contrast outlines the fistulous connection *(arrow)* between the atretic colonic segment and the left-sided vagina (*V*, Right and left vaginal canals). (C) Coronal T2-weighted MR image on same infant as shown in (B) shows the two uterine horns *(arrows)*. *K*, Partly visualized renal pelvis of a pancake kidney with dilated left ureter *(U)*. (D) Sagittal 3D reformat of ARM and cloacal anatomy in same patient as shown in (B) and (C). Vaginal canal and urethra unite into a common channel that terminates in a single orifice at the perineum. *B*, Bladder; *R*, atretic rectum; *V*, one of two superimposed vaginal canals, shown to communicate with vagina on other images and in (B).



**e-Figure 105.7. Rectal atresia.** (A) Initial lateral image of attempted contrast enema in neonate with distal obstruction. Note the dilated loops of bowel and the lack of air in the rectum. The catheter and the contrast could not advance further than 2 cm. (B) Colostogram before definite repair shows the termination of the colon proximal to the atresia. Compare with the location of the catheter outlining the distal segment in (A).

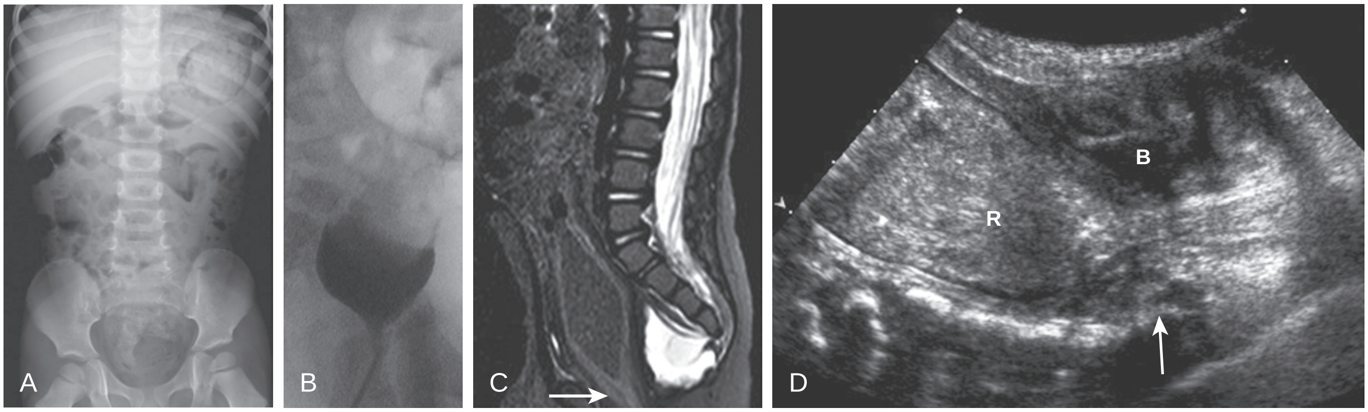


**Figure 105.8. Currarino syndrome.** (A) Supine abdominal radiograph in 23-month-old boy with history of constipation demonstrates increased amount of stool in the colon, and a bony deletion anomaly, resembling a scimitar, along the left side of the sacrum. (B) Contrast enema demonstrates narrowing of the distal rectum. (C) Sagittal T2-weighted MR image demonstrates a cystic presacral mass that proved to represent an anterior meningocele. Note the narrowing of the distal rectum *(arrow)*. (D) Anterior sagittal pelvic sonogram of a different male neonate shows a dilated proximal rectum *(R)* with distal narrowing, and a retrorectal hypoechoic mass *(arrow)*, which proved to represent a mature teratoma. *B*, Bladder.

lethal, Hirschsprung disease remains a serious condition with potential mortality and morbidity. It is a familiar condition to most pediatricians, occurring in approximately 1 per 5000 live births.[45] Hirschsprung disease is responsible for approximately 15% to 20% of cases of neonatal bowel obstruction, presenting in the newborn period in approximately 80% of cases. The transition point between normal and abnormal bowel can occur at any point and can extend through a variable length of the small bowel, to rarely include the entire bowel as total intestinal aganglionosis.[45] When the transition point is located at the rectosigmoid, it is termed *short-segment aganglionosis* and occurs in approximately 80% to 90% of cases. Males predominate in short-segment aganglionosis (4:1 boy:girl ratio); however, male preponderance diminishes in longer segment involvement.

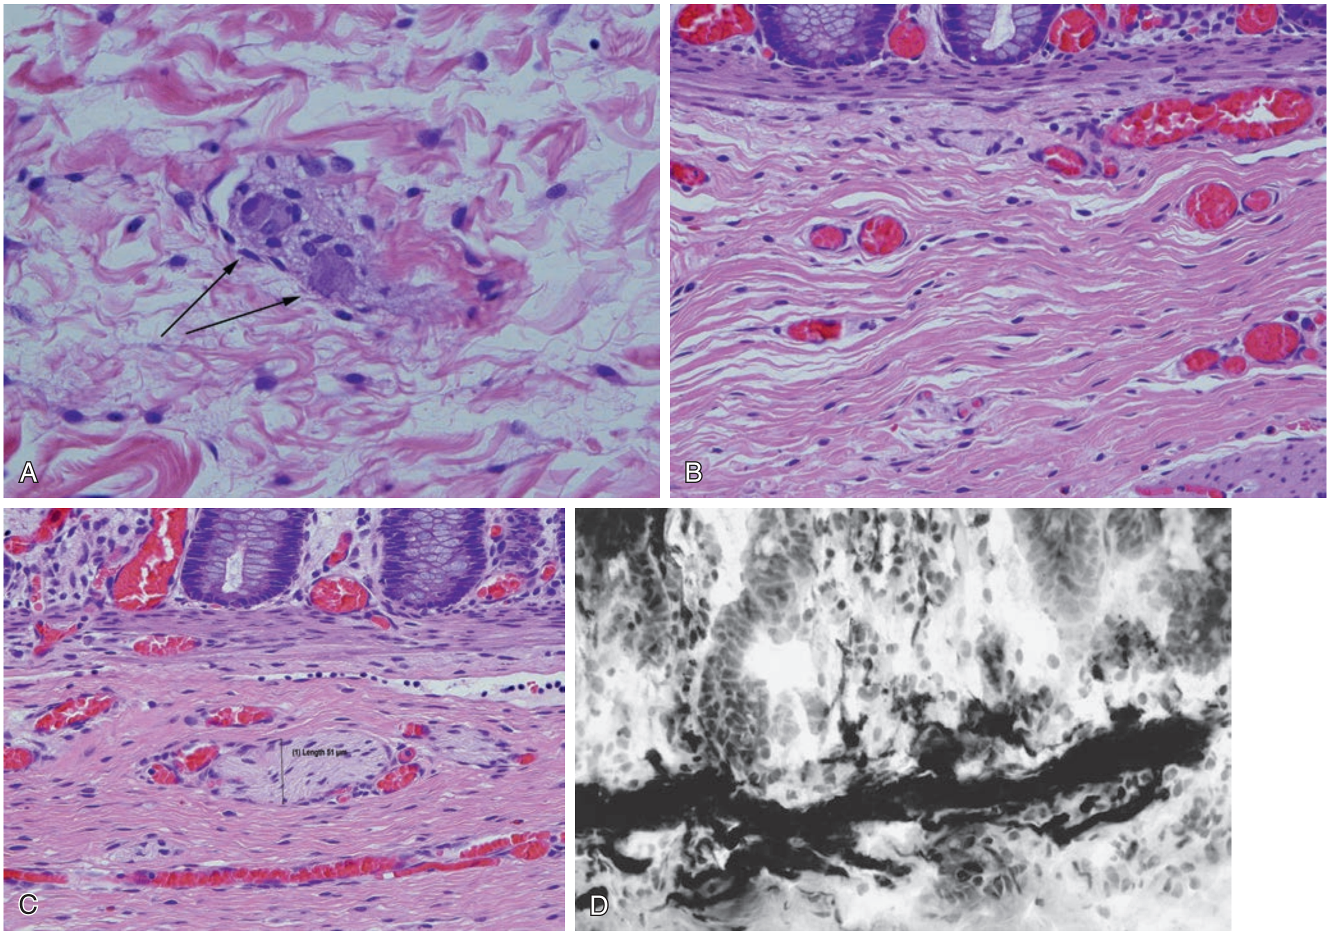
Hirschsprung disease is the result of failure of propagation of normal innervation of the bowel, due to arrest of the proximal to distal migration of vagal neural crest cells, and is therefore considered a neurocristopathy. As a result of abnormal arrest of migration, a variable length of distal bowel lacks parasympathetic Auerbach (intermuscular) and Meissner (submucosal) plexuses, and is unable to participate in normal peristaltic propulsion of the colonic contents, resulting in failure of relaxation and functional obstruction. In addition to absence of ganglion cells, histologic evaluation of the abnormal bowel also shows abnormal acetylcholinesterase staining and hypertrophied nerve fibers (e-Fig. 105.9).

***Etiology.*** The etiology of the absence of ganglion cells from the involved segments in Hirschsprung disease is not known, but the migration is controlled by a hierarchical gene regulatory network.[51] One of the theories is that the migrating ganglion cells do not reach the distal segment because they are fewer in number, or mature prematurely; on the other hand, it is also possible that the ganglion cells reach the distal segment but perish or are unable to proliferate because of a deficient microenvironment.[52] A variety of gene mutations have been found, suggesting that this may be a multifactorial disease. The most commonly identified abnormality is in the *RET* proto-oncogene located at 10q11, found in approximately 15% to 35% of sporadic cases and 50% of familial cases. *EDNRB* located at 13q22 is identified in approximately 5% of cases.[53–55] A positive family history is encountered in a minority of patients (<10%), but this increases to nearly 25% in patients with total aganglionosis, with the degree of risk proportional to the length of the affected segment and degree of consanguinity.[56,57]

***Clinical Presentation.*** The clinical presentation of Hirschsprung disease in the neonate is one of distal obstruction, including abdominal distension and bilious vomiting, as well as failure to pass meconium beyond the first 24 hours, seen in up to 90% of patients.[52] Rarely perforation of the cecum or appendix can occur in neonates, typically those with long-segment disease.[58,59] In patients with total colonic aganglionosis, ganglion cells tend to be absent from the appendix as well.[60] In older children, Hirschsprung disease presents with constipation, with abdominal distension, vomiting, and failure to thrive in more severe cases. In late presentation, the zone of transition is typically low-segment, as longer segment disease usually presents early.[52] Among infants diagnosed with Hirschsprung disease, 6% to 19% have been premature; in these patients the presentation can be confusing due to comorbidities and overlap with findings of immature enteric nervous system.[61,62]

Hirschsprung disease is associated with multiple other conditions in up to 30% of cases.[63] It is most commonly associated with Down syndrome, which is present in approximately 2% to 10% of patients with Hirschsprung disease, in a 5:1 boy:girl ratio.[45] Other associated syndromes include Waardenburg syndrome (pigmentary anomalies and sensorineural hearing loss), Goldberg-Shprintzen syndrome (mental retardation, cleft palate, and Hirschsprung disease), McKusick-Kaufman syndrome (hydrometrocolpos, polydactyly, congenital heart disease), Bardet-Biedl syndrome (pigmentary retinopathy, obesity, hypogonadism), the Currarino association, and central hypoventilation syndrome (Ondine curse).[45,64,65] Patients with longer segment aganglionosis are more likely to demonstrate central hypoventilation syndrome than those with short-segment disease.[66] Other isolated abnormalities include malrotation, limb, skin, CNS, kidney, cardiac, and other malformations.[52,64,67,68]

Enterocolitis, also known as *Hirschsprung-associated enterocolitis*, is a major cause of morbidity and mortality in Hirschsprung disease, affecting approximately 10% to 50% of patients.[52,69] Clinically, it can present insidiously or abruptly, with diarrhea, fever, abdominal distension, colicky abdominal pain, and hematochezia, and may occur before or after surgery. If the child is not known to have Hirschsprung disease at the time of enterocolitis onset, the clinical situation can be confusing, as the expected clinical finding in patients with Hirschsprung is constipation rather than diarrhea. A Hirschsprung-associated enterocolitis score, which incorporates clinical, laboratory, and radiologic findings, may prove helpful in



**e-Figure 105.9. Pathologic findings in Hirschsprung disease.** (A) Normal newborn hematoxylin and eosin staining reveals submucosal ganglion cells *(arrows)*. (B and C) Newborn with Hirschsprung disease. Biopsy shows no ganglion cells (B) and hypertrophic nerve (C) outlined by linear caliper measurement. Acetylcholinesterase stain of biopsy reveals abnormal stain of twiglike nerve processes in the lamina propria.

establishing the diagnosis and determining the severity of this condition.[70] Pathogenesis is unknown, but implicated mechanisms include abnormal epithelial lining, abnormal mucin production, abnormal local immune mechanisms, and viral and bacterial pathogens, notably *Clostridium difficile*, promoted by intestinal stasis. Studies in mice have implicated abnormal goblet cell differentiation and splenic lymphopenia.[71,72] Incidence of enterocolitis increases with delayed diagnosis, long-segment disease, and comorbid conditions, such as found in patients with Down syndrome.[69] Implicated postoperative risk factors include development of postoperative intestinal obstruction secondary to anastomotic stricture or adhesions, or development of anastomotic leak.[69]

***Imaging.*** In neonates, the abdominal radiographs demonstrate evidence of distal bowel obstruction (Fig. 105.10A). On prone cross-table lateral radiographs, there is usually gas in the rectum, unlike with small bowel or colonic atresias; however, the caliber of the air-filled rectum is clearly smaller than that of more proximal bowel, and a zone of transition may be identifiable if located at the rectosigmoid junction. In older patients, a retained rectal foreign body may provide an initial clue to the diagnosis (Fig. 105.10B).

Radiologic diagnosis is made with contrast enema, which is geared toward identification of the zone of transition (Figs. 105.10C–E). Routine enemas before the diagnostic procedure should be avoided. The study is done with a small catheter, which should be placed as close to the sphincter as possible in neonates. In neonates, water-soluble iso-osmolal agents are preferred, as hyperosmolal media will lead to increased bowel distension. Barium is not optimal if there is another cause of obstruction, such as meconium ileus, and undesirable in case of perforation. In older patients being evaluated for constipation, barium is the usual contrast agent. Initial images must be obtained in the lateral projection, as soon as the contrast begins to enter the colon, before any potential obliteration of the zone of transition has occurred. Multiple fluorostore images are used to document the flow of contrast and the caliber of the colon, as they offer a temporal documentation of the findings without additional radiation exposure. The enema is terminated when the zone of transition is identified.

The distal, aganglionic colon is typically normal in caliber, with a variably abrupt transition to dilated proximal colon. The aganglionic segment may exhibit a changing, serrated appearance, due to aperistaltic contractions of the abnormally innervated bowel. A rectosigmoid diameter ratio less than 0.9 will typically be present in patients with low-segment Hirschsprung disease. However, the rectosigmoid ratio is rarely needed to identify the zone of transition, and it can be misleading in cases of more extensive aganglionosis; it is only helpful when the zone of transition is located at the rectosigmoid junction and can be misleading if the zone of transition is located elsewhere. This is the opposite of patients with functional constipation, where there will be greater distension of the rectum, or of the rectum and sigmoid, in comparison with the more proximal colon. Postevacuation and delayed films are helpful in the neonate, particularly in patients with total colonic aganglionosis in whom the colon may have normal or nonspecific appearance.[73]

In older patients, retained stool may distend the aganglionic segment. However, a caliber difference may be maintained, and coupled with an appropriate index of suspicion, can lead to recognition of the diagnosis (Figs. 105.10F–H).

In patients with total colonic aganglionosis, the findings are variable and the diagnosis can be problematic; as with the older patient, an appropriately high index of suspicion is needed. The colon in these infants may present a normal or near-normal appearance with normal and uniform caliber. Although often relatively featureless, there can be a pseudotransition zone, sometimes at the splenic flexure, or the patient may demonstrate a microcolon,

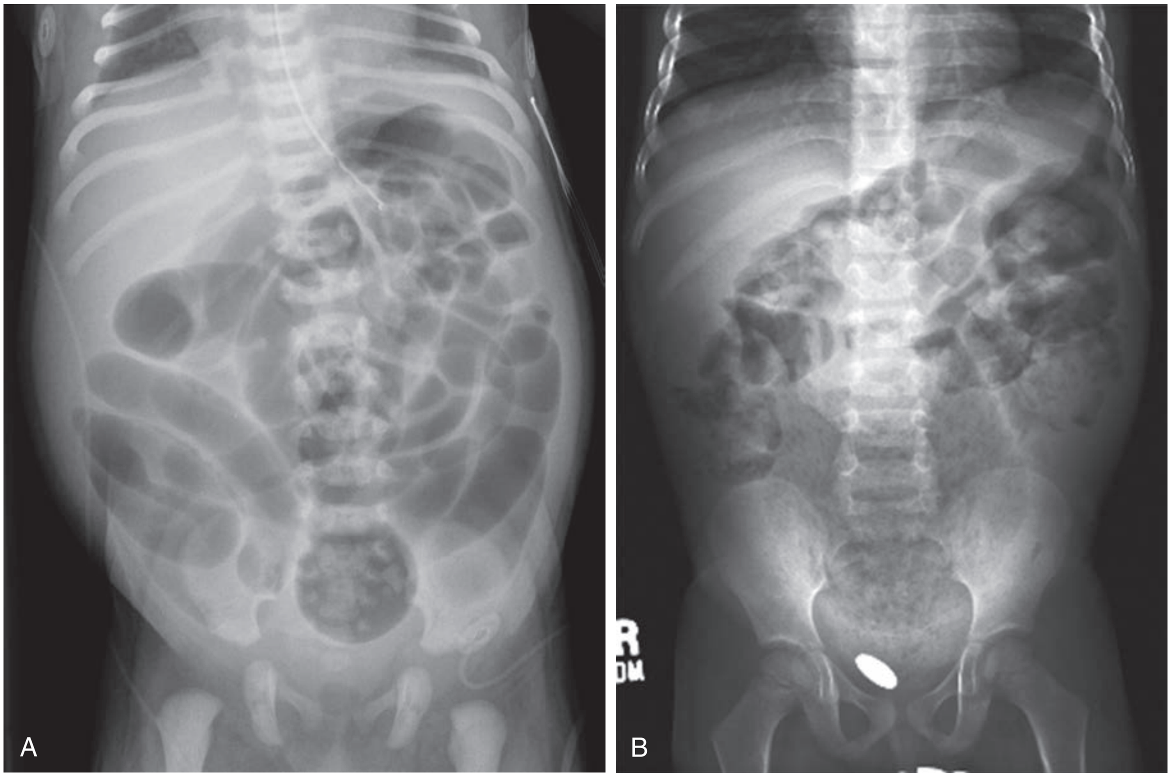


**Figure 105.10. Hirschsprung disease: early and late diagnosis.** (A) Supine abdominal radiograph on 3-day-old baby with abdominal distension reveals multiple dilated loops of bowel, indicating a distal obstruction. (B) Abdominal radiograph in a 4-year-old status-post repair of interrupted aortic arch, who presented with constipation and retained coin within the rectum for several months. There is marked fecal dilatation of the sigmoid, which does not extend into the rectum; the rectum contains a retained coin.

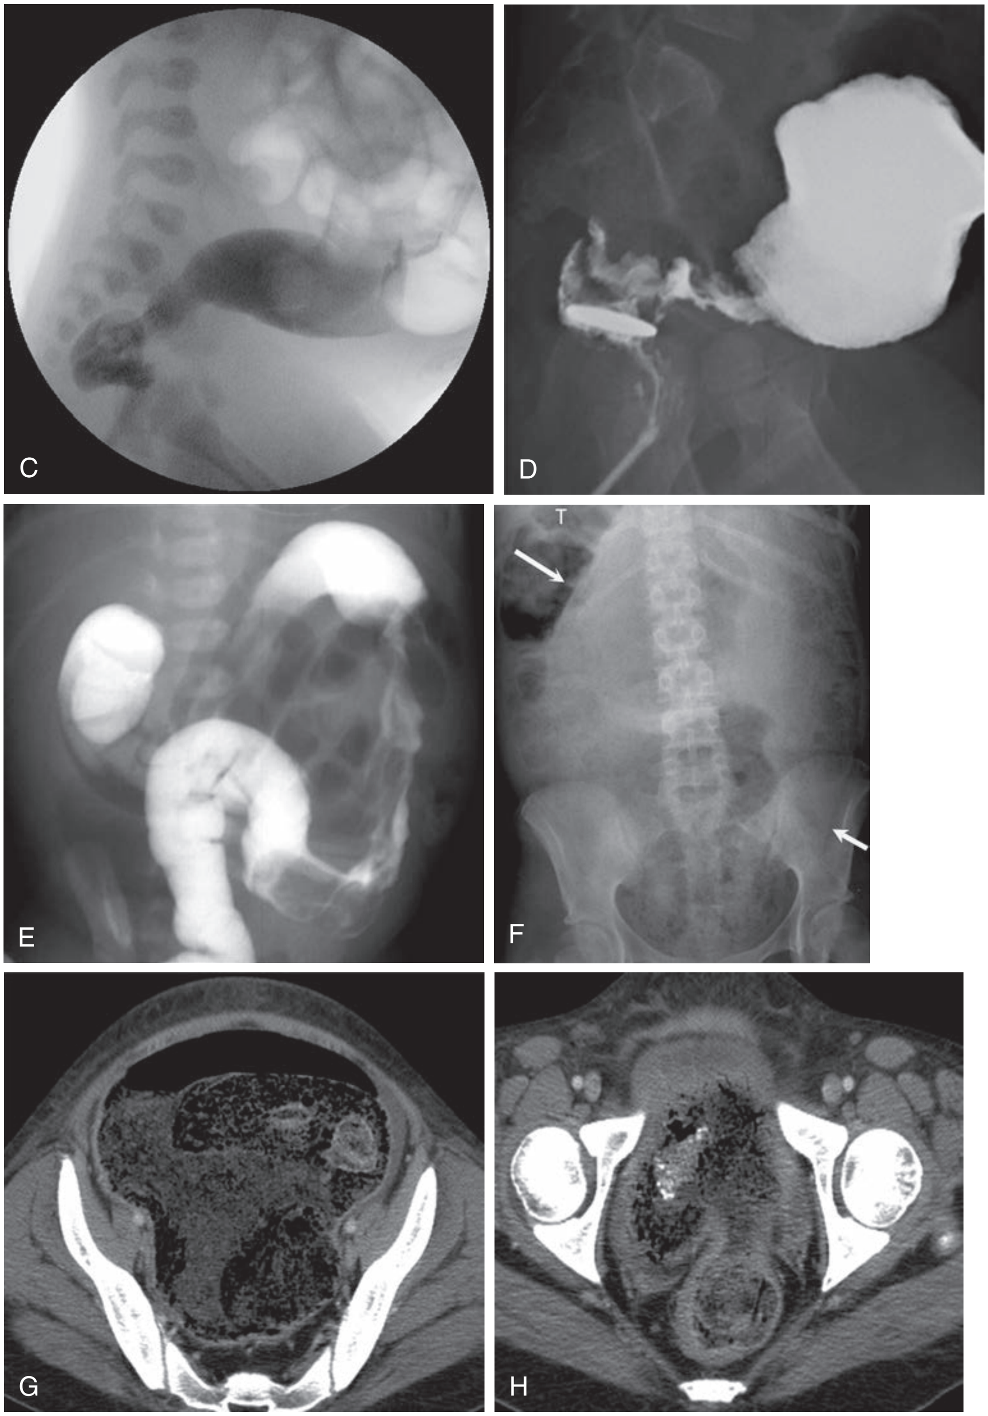

**Figure 105.10, cont'd.** (C) Contrast enema in a lateral projection on same patient as shown in (A) shows a caliber change at the rectosigmoid junction consistent with a rectosigmoid transition zone. (D) Lateral view of contrast enema in same patient as shown in (C) clearly shows the zone of transition, and the retained coin. (E) Abdominal image during contrast enema in a 2-day-old girl with positive family history of Hirschsprung disease and signs of distal bowel obstruction. Note the multiple dilated loops of bowel. The examination shows an abnormal distal descending colon, with irregular wall resulting from disordered contraction, and an apparent transition at the splenic flexure. At surgery, Hirschsprung was confirmed, with transition at the splenic flexure. (F) Abdominal radiograph of 15-year-old girl with diabetes and history of intermittent diarrhea, who presented acutely to the emergency department with diarrhea and abdominal distension. The abdominal radiograph shows marked stool burden and colonic dilatation. The sigmoid colon *(arrows)* extends into the abdomen, and displaces transverse colon *(T)* cephalad. (G) CT on same patient as shown in (F) was requested for clinical concern of appendicitis. CT at upper pelvis shows dilated sigmoid entering the pelvis. (H) CT lower in pelvis shows the zone of transition.

at times with the development of a meconium ileus pattern (e-Figs. 105.11A–F).

Newborns with Hirschsprung disease can initially present as meconium plug (e-Figs. 105.11E) or small left colon syndrome; such patients should be carefully monitored, and if normal bowel function does not return, further evaluation such as suction biopsy should be considered.

Definitive diagnosis is made by characteristic biopsy findings, showing absence of ganglion cells and abnormal acetylcholinesterase staining and hypertrophied nerve fibers. Manometric studies, with failure of relaxation of the internal sphincter with rectal distension, are helpful after the immediate neonatal period, and therefore helpful in older children.

Abdominal radiographs of patients with Hirschsprung-associated enterocolitis may show dilatation of bowel loops, with irregular outline consistent with spasm and mucosal disruption and ulceration (Fig. 105.12A). Contrast enemas are not indicated but if performed will show ulceration and spasm (Fig. 105.12B).

***Treatment.*** Surgical repair of Hirschsprung disease involves resecting the denervated bowel and bringing normally innervated bowel distally through the sphincteric mechanism. Swenson devised and performed the first successful surgical repair; his procedure consists of resection of the aganglionic segment and anastomosis of normal, ganglion-containing bowel to the sphincteric mechanism. The Duhamel procedure involves leaving the anterior portion of the aganglionic rectum in place and anastomosis of ganglion-containing bowel to its posterior wall. The Soave or endorectal pull-through involves resection of the mucosa and submucosa of the aganglionic bowel, and pulling the normal ganglion-containing bowel through the muscular rectal sleeve.[20] The Duhamel and Soave procedures are modifications of the Swenson, designed to minimize risk of injury to the sphincteric mechanism. Complications include postoperative leaks, strictures, and delayed bowel control. Residual obstruction predisposes to stasis and the consequent risk of enterocolitis. Postoperatively, some narrowing may be seen at the distal muscular sleeve, or the barium enema may appear normal, except for the double-density from the retained rectal pouch in patients treated with the Duhamel procedure (e-Figs. 105.13A and B). Strictures and the appearance of a zone of transition are not normal postoperative findings.

More recently there has been work investigating the possibility of introducing stem cells to populate the aganglionic bowel; although promising, these investigations are in the early stages of animal testing.[74–76]

## COLONIC DYSMOTILITY: MECONIUM PLUG, SMALL LEFT COLON, AND DYSMOTILITY OF PREMATURITY

***Overview.*** Meconium plug and small left colon syndromes refer to conditions of colonic dysmotility, which present as distal bowel obstruction in neonates, and which overlap with each other as well as with Hirschsprung disease. In meconium plug syndrome, a plug of meconium is identified within the colon, which, when evacuated, has a characteristic "white head" (Fig. 105.14A). The colon in patients with the small left colon syndrome may also contain meconium plugs but, in addition, a variable portion of the left colon, typically encompassing the descending colon and sigmoid, have a characteristically small caliber resembling a microcolon. In these patients, the rectum is typically of normal caliber. These conditions also overlap with the failure to pass meconium and, at times, obstructive symptoms that may be seen in very low or extremely low birth weight infants (<1500 and <1000 grams birth weight, respectively).

***Etiology.*** The etiology of these conditions is believed to be a delayed maturation of effective peristalsis in these patients and/or abnormally increased water absorption by the colon leading to a more tenacious meconium. Approximately 40% to 50% of small left colon syndrome cases occur in conjunction with maternal diabetes; conversely, small left colon syndrome has been cited to occur in approximately 4.7% of infants with history of maternal diabetes.[77] An increased viscosity of exocrine secretions and an immature intestinal nervous system are thought to be responsible for the obstructive symptoms seen in some low birth weight infants.[78,79]

***Clinical Presentation.*** Patients present with abdominal distension and bilious vomiting, typically in a term infant. Meconium

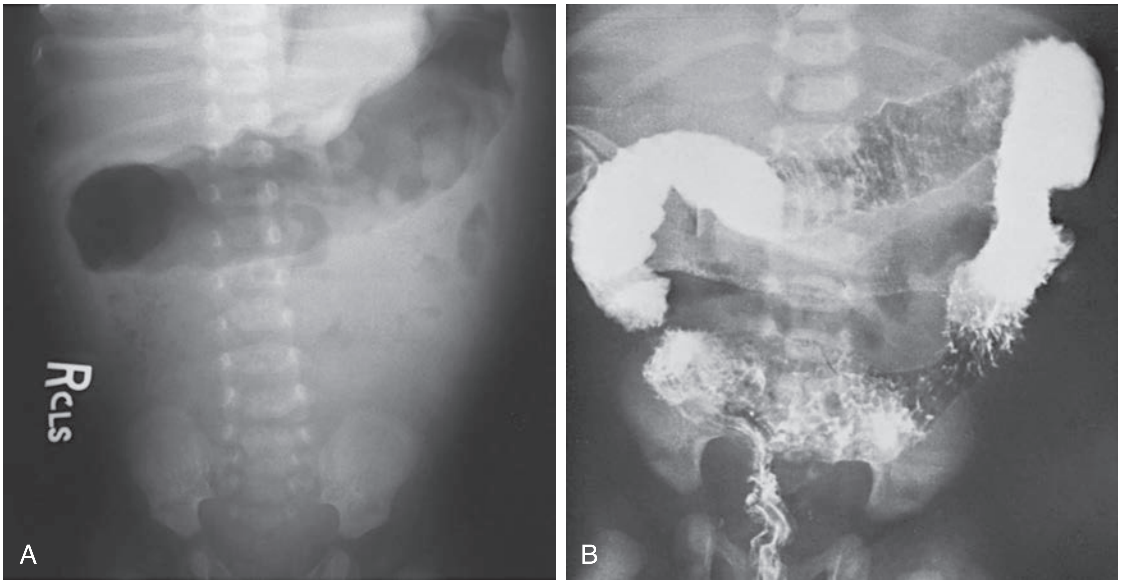

**Figure 105.12. Hirschsprung enterocolitis.** (A) Abdominal radiograph of a child who developed Hirschsprung-associated enterocolitis shows the irregular wall and thumb printing in the gas-filled transverse colon. (B) Lethal enterocolitis in a 12-day-old boy who presented with fever, foul diarrhea, and shock. Contrast enema shows extensive edema, ulceration, and spasm. The patient expired on arrival at the referral institution.

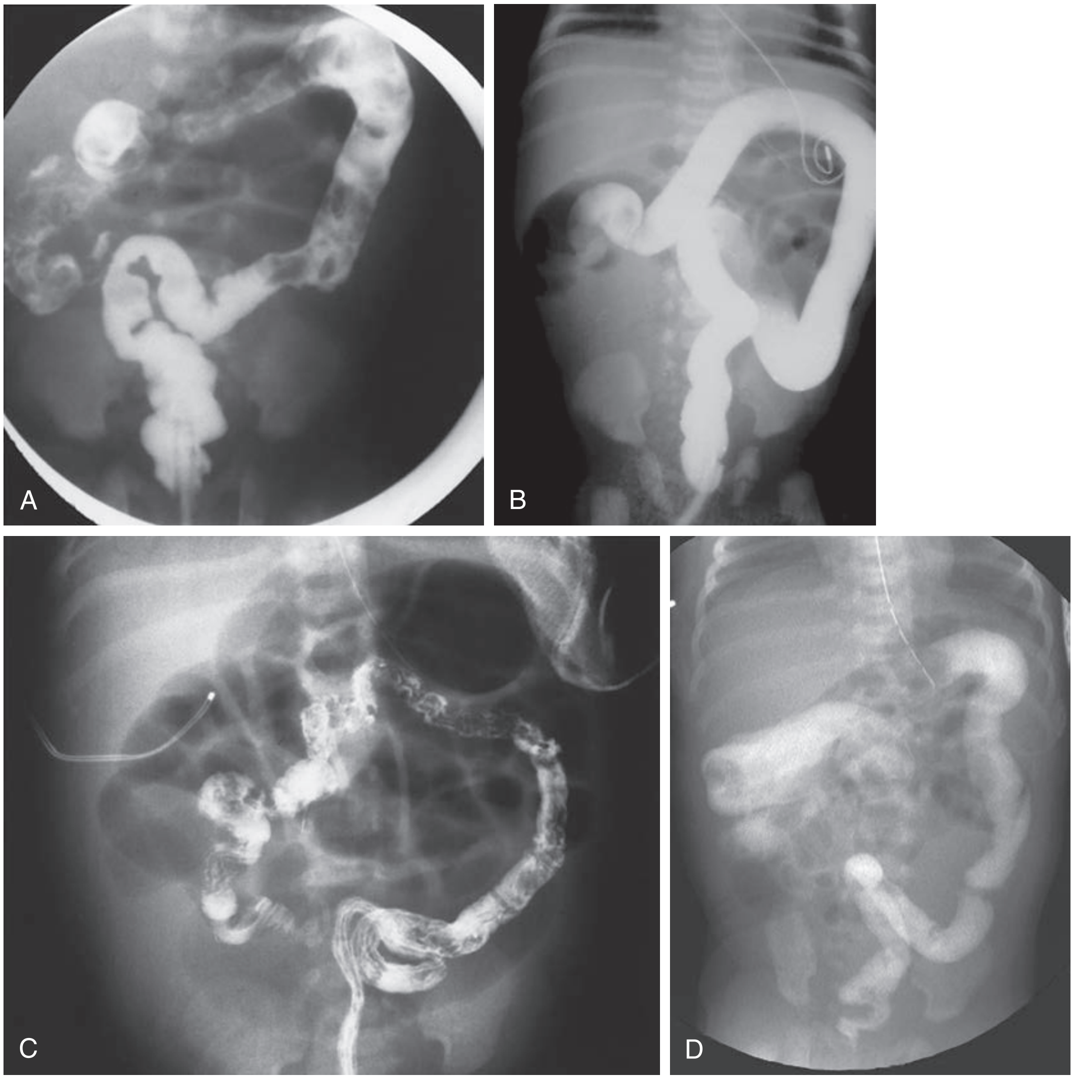
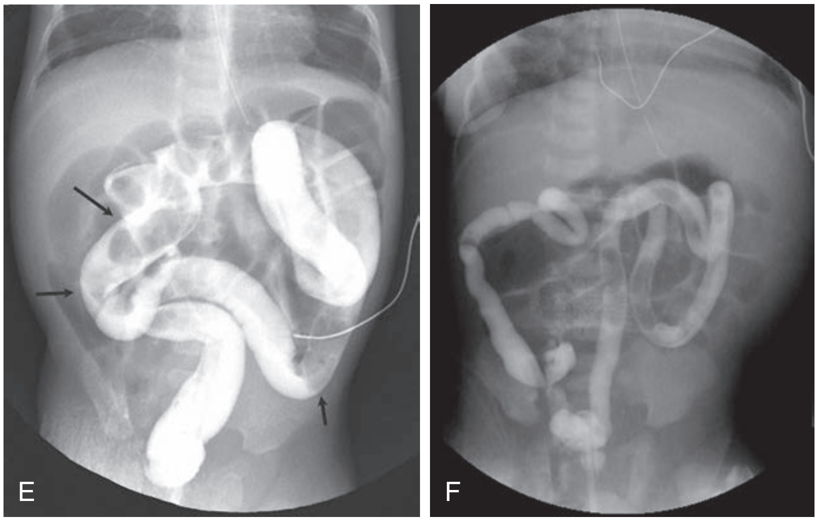
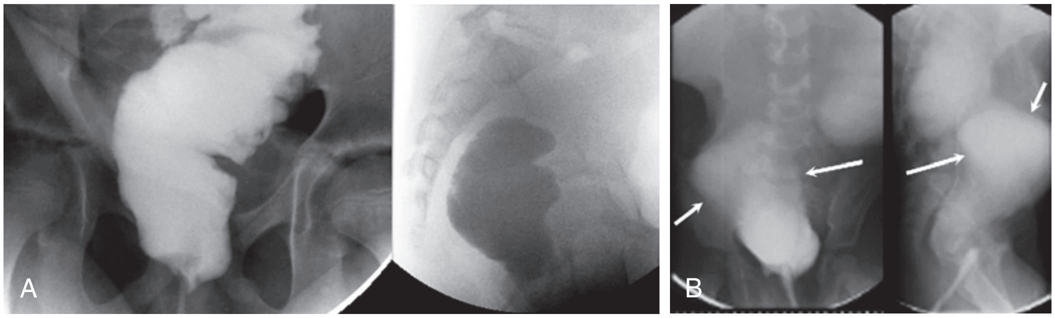


**e-Figure 105.11. Hirschsprung disease: contrast enema in total colon and small bowel aganglionosis.** (A) Anteroposterior image of contrast enema of neonate with distal bowel obstruction; the colon shows a normal and uniform caliber, without evidence of zone of transition, although it is somewhat featureless and contains multiple filling defects; note the dilated loops of small bowel in the background. Total colonic aganglionosis was documented at surgery. (B) Anteroposterior image of contrast enema of a neonate with Down syndrome. The examination shows a colon of uniform caliber, although less redundant than typical. Total colonic aganglionosis was found at surgery. (C) Image from contrast enema in another neonate with total colonic aganglionosis, demonstrating the appearance of a microcolon. (D) Image from contrast enema in a 6-day-old girl with distal obstruction. The examination shows a gradual caliber change, with a questionable transition point at the distal transverse colon. Total colonic aganglionosis was documented at surgery.

*Continued*



**e-Figure 105.11, cont'd.** (E) Image from contrast enema in neonate with distal bowel obstruction demonstrates a uniform caliber colon with multiple filling defects *(arrows)* suggesting meconium plugs. At surgery, Hirschsprung was identified involving the entire colon and the distal 20 cm of ileum. (F) Image from contrast enema in a 1-day-old infant with distal obstruction. The examination shows a colon only slightly larger than a typical microcolon. At surgery, there was aganglionosis of the entire colon, and of the small bowel to the jejunum, 51 cm from the ligament of Treitz. Because of the short length of his normal bowel, the child became TPN-dependent.



**e-Figure 105.13. Hirschprung disease after pull-through surgery.** (A) Frontal and lateral radiographs of contrast enema in child after Soave procedure. Note the smooth appearance of the colon through the pull-through sleeve. (B) Frontal and lateral radiographs of contrast enema in child after Duhamel procedure. Note the double density appearance of contrast within the wider Duhamel pouch *(arrows)*.

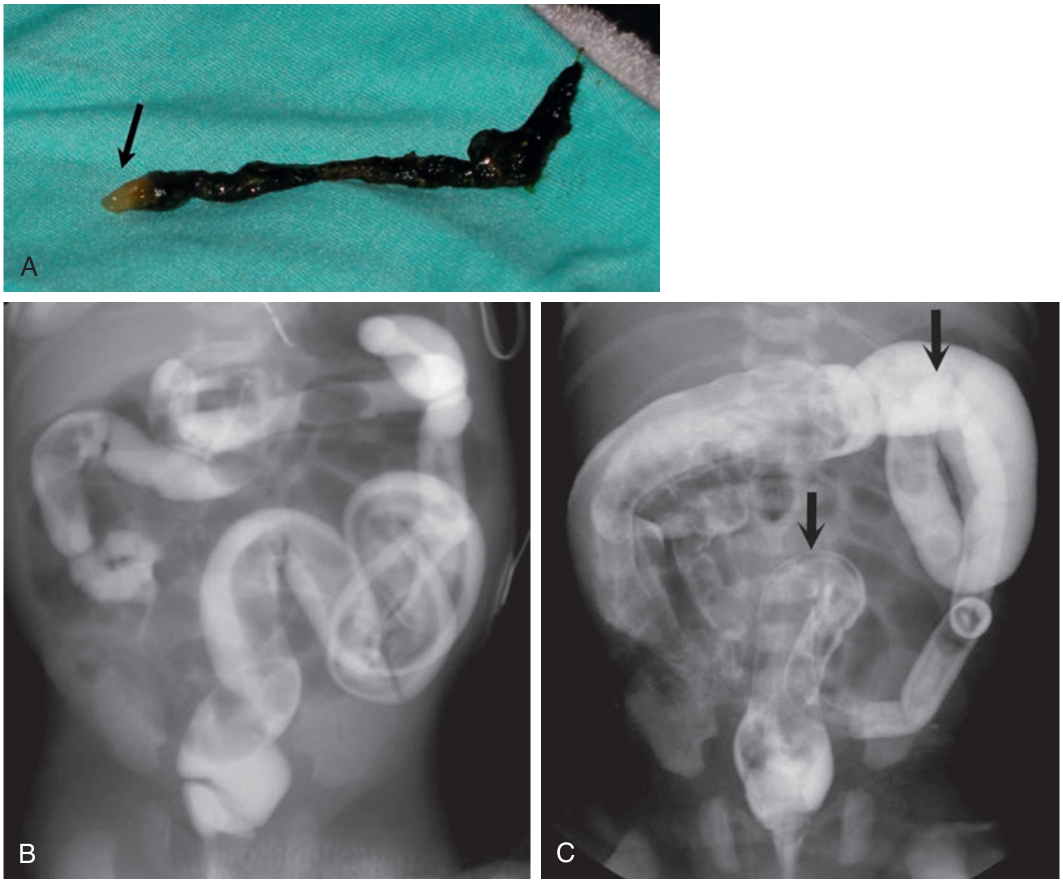


**Figure 105.14. Colonic dysmotility.** (A) Photograph of a meconium plug evacuated after diagnostic contrast enema, demonstrating the distinctive white tip *(arrow)*. (B) Water-soluble enema in infant with meconium plug. Note the long plug outlined as a filling defect within the contrast column in the distal colon. After this examination, the patient did well, relieved of the obstruction. (C) Water-soluble enema in infant with small left colon. Note the normal caliber rectum, and the small diameter of the colon, beginning in the sigmoid, and continuing along the left colon (outlined by distal and proximal *arrows*). Meconium plugs are also evident. This infant also did well after this examination, relieved of the obstruction.

plug and small left colon syndromes could be the presenting findings in patients with Hirschsprung disease. It is important to monitor these patients closely after initial relief of obstruction; if symptoms recur or do not abate, biopsy is necessary to evaluate for Hirschsprung disease.[80]

The very low and extremely low birth weight patients typically present around 10 to 14 days of age, with increasing abdominal distension and failure to pass meconium.[78] Abdominal examination is usually benign, but complications such as bowel perforation can occur.

***Imaging.*** Radiographs show typical findings of distal obstruction with multiple dilated loops of bowel, although the degree of dilatation tends to be less than that seen in other causes of distal obstruction, such as distal atresias or meconium ileus.[81] As with other cases of distal bowel obstruction, a diagnostic contrast enema with water-soluble contrast material with a near-iso-osmolal concentration should be performed. In cases of meconium plug, the enema demonstrates a colon of normal caliber, with a typically long filling defect caused by the meconium plug (Fig. 105.14B), which the patient may evacuate at the conclusion of the radiographic examination. Patients with small left colon syndrome will show a small caliber colon involving a variable length of sigmoid and descending colon, with a typically normal caliber rectum (Fig. 105.14C). Low birth weight infants typically do not come to diagnostic contrast enema; if the infants have obstruction secondary to other causes as outlined in this chapter, findings may be diagnostic.[78]

***Treatment.*** Patients with meconium plug and small left colon syndrome typically do well after the enema examinations. In patients with a protracted recovery or in whom there is recurrence of symptoms, biopsy for Hirschsprung disease should be performed. Premature infants with obstruction may be treated with enemas,[78] although it carries more risk in these much more labile, very small infants; guidance with ultrasound has also been reported.[82]

## CHRONIC INTESTINAL PSEUDOOBSTRUCTION

***Overview.*** CIPO refers to a characteristic, chronically recurring, and at times massive dilatation of the intestinal tract without identifiable mechanical cause. The term encompasses a heterogeneous group of disorders that affect the enteric nervous system and intestinal smooth muscle, resulting in failure of normal intestinal motility. The condition can be primary or secondary. Secondary disease is associated with multiple conditions, including scleroderma, dermatomyositis, and muscular dystrophies; infiltrative diseases such as amyloidosis; nervous system diseases such as myotonic dystrophy and familial dysautonomia; postviral syndromes such as Epstein-Barr, cytomegalovirus (CMV), herpes zoster and rotavirus; fetal alcohol syndrome; and mitochondrial disorders.[83]

In the pediatric population, primary disease predominates and is subdivided into neuropathic or myopathic forms; patients with the myopathic form of primary disease tend to have involvement of other systems, particularly the urinary system.

Approximately 40% of patients become symptomatic within the first month and 65% within the first year of life. Chronicity is defined as either congenital disease persisting during the first 2 months of life or as persistence for greater than 6 months. Histopathology may demonstrate diverse findings, such as hypoganglionosis, degenerative changes in smooth muscle fibers, additional muscle layer, collagen deposition, degeneration of neurons and axons, and proliferation of neurons, nerve fibers, or glial cells.

Neuronal intestinal dysplasia (NID) constitutes a form of primary disease with two subtypes and is a disorder of intestinal innervation that can be diffuse or localized.[84] Type A consists of aplasia or hypoplasia of sympathetic innervation of the intestine and constitutes less than 5% of cases. Type B accounts for approximately 95% of cases and affects the parasympathetic system with hyperplasia of the submucosal and myenteric plexus with dysplastic and ectopic ganglion cells and increased acetylcholinesterase staining.[51] Type B NID has been found in the proximal intestine of patients with Hirschsprung disease.[85–87]

***Etiology.*** The enteric nervous system generates rhythmic enteric activity and includes the interstitial cells of Cajal, neurons, and glial cells. The network of interstitial cells of Cajal has been found to be abnormal in some patients with CIPO, and delayed maturation of these cells has been reported in neonates with transient CIPO. Ganglion cells containing nitric oxide synthase, which mediates sphincteric relaxation, have been found to be increased in some patients with CIPO.[83] Animal models targeting the *Hox11L1* gene and the endothelin B receptor develop phenotypic and histologic findings similar to NID type B, with hyperplasia of myenteric ganglia. However, genetic investigation in humans with NID has been unproductive.[51,85] Most cases of this disease are sporadic, and although a genetic locus in humans has not been isolated, familial clusters with autosomal dominant inheritance have been reported.[44] More recently, mutations in *RAD21* disrupting regulation of apolipoprotein B have been found in patients with CIPO, with animal experiments suggesting a role in transit and development of intestinal neurons.[88]

***Clinical Findings.*** Children present with periodic vomiting, diarrhea, abdominal distension, constipation, pain, and weight loss. Patients with NID type A present in the neonatal period with acute episodes of intestinal spasticity, diarrhea, and hematochezia. Patients with NID type B present with chronic constipation and/or pseudoobstruction, typically in the first 3 years of life.[44] Patients who develop small bowel bacterial overgrowth secondary to intestinal stasis may develop diarrhea, weight loss, and macrocytic anemia.[83]

Multiple anomalies have been documented in patients with primary disease, in addition to Hirschsprung disease, which occurs in as many as 10% of cases.[44] Related associations include multiple endocrine neoplasia type IIb and neurofibromatosis.[89] Other associations include malrotation, ARM, congenital short small bowel, and intestinal atresia, as well as extraintestinal problems such as vesical dysfunction, Down syndrome, and histiocytosis.[44]

***Imaging.*** Imaging demonstrates dilated loops of bowel, particularly the colon, with air-fluid levels suggestive of obstruction but which really represent severe adynamic ileus. Megacolon is typically found with contrast enema, without the diagnostic transition zone findings of Hirschsprung disease. Contrast small bowel and enema studies show poor motor activity in affected parts of the bowel, but otherwise are nonspecific. Gut dilatation is common in the colon, the stomach, and the small bowel, and can assume massive proportions (e-Fig. 105.15).

***Treatment.*** Gastrostomy may be used for feeding (although is often not tolerated) and for venting. Enteral feedings through a jejunostomy are sometimes tolerated. Medical management includes prokinetic agents and antiemetics. Management of patients who develop small bowel bacterial overgrowth includes vitamins, antibiotics, and possibly probiotics.[83] Some patients may need intestinal transplantation, or combined hepatic and intestinal transplantation if liver disease secondary to total parenteral nutrition supervenes.[83] Stem cell transplantation may have a future role in treatment of these conditions.

## MEGACYSTIS-MICROCOLON-INTESTINAL HYPOPERISTALSIS SYNDROME

***Overview.*** The megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS or Berdon syndrome) was first described by Berdon and colleagues in 1976[90] and is a well-recognized clinical entity[51,85] with an approximately 2:1 female predominance.[91] Malrotation is present in many patients.[90,91] This syndrome is considered one of the most severe forms of functional intestinal obstruction in the newborn and is often fatal[91]; without treatment, most patients succumb within the first 6 months of life.[92]

***Etiology.*** Approximately 20% of reported cases are familial, with a pattern suggesting autosomal recessive inheritance.[93] *nAchR* genes on chromosome 15 affecting the nicotinic acetylcholine unit have been implicated.[51,93] Histologic evaluation shows normal ganglion cells in most patients, but these are decreased in some patients and increased in others, who show hyperganglionosis as well as giant ganglia.[91] Interstitial cells of Cajal are responsible for generating coordinated peristaltic activity, and abnormalities in the interstitial cells of Cajal in the urinary bladder[94] and in the intestinal myenteric plexus[95] have been found in patients with MMIHS. In addition, abnormalities of the smooth muscle cells have been found, with evidence of thinning, vacuolar degeneration, and increased connective tissue in both the bowel and bladder.[95–97]

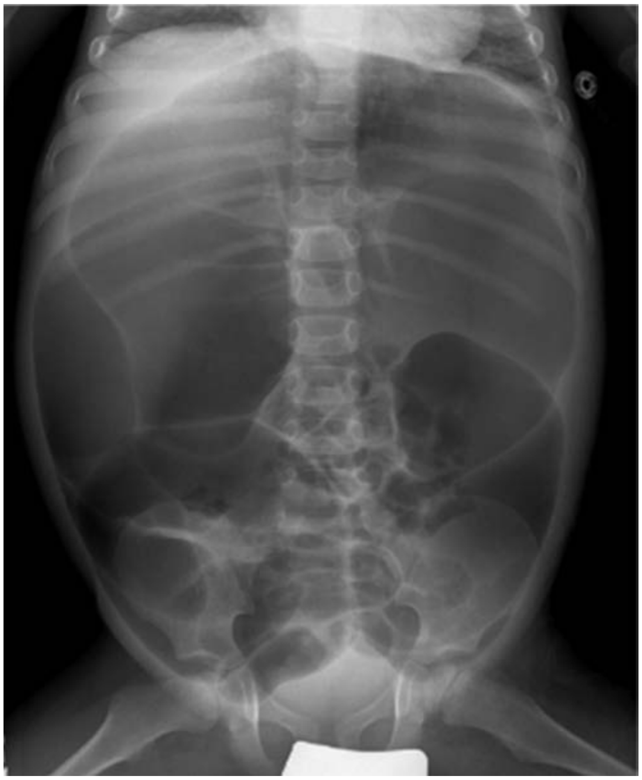
***Clinical Presentation.*** These infants present with abdominal distension and bilious vomiting secondary to obstruction; abdominal distension is exacerbated by urinary bladder dilatation. Bowel sounds are decreased or absent.

***Imaging.*** Radiographs show marked abdominal distension, a largely gasless abdomen with the markedly distended urinary bladder displacing bowel loops. Ultrasound demonstrates the markedly distended urinary bladder, typically in association with hydroureteronephrosis. Upper GI demonstrates hypo- or aperistalsis of stomach, duodenum, and small bowel. Contrast enema demonstrates a microcolon. Malrotation is seen in more than one-half of cases (Fig. 105.16).[85]

***Treatment.*** This condition carries a poor prognosis, with one series reporting only 7 of 44 patients surviving.[93] Medical treatment with prokinetics and GI hormones is most often unsuccessful, and total parenteral nutrition becomes necessary to maintain the infants.[85] Patients who develop hepatic disease become candidates for multivisceral transplantation.[92]

## COLONIC DUPLICATIONS

***Overview.*** GI duplications are also discussed in Chapters 96, 99, and 102, with the specific associated gut segments; this chapter will address findings characteristic of colonic duplications. Approximately 17% of GI duplications are colonic,[98] and 5% are rectal. Colonic duplications can be cystic or tubular. Cystic duplications consist of a short duplicated segment typically not communicating with the adjacent lumen. Tubular duplications typically connect with the GI tract and often drain into a single or duplicated anal orifice or into the perineum via a fistula. The colon proper is that portion ending in a perineal anus; the duplicated colon is that portion ending at a perineal fistula, at a communication with the colon proper, or blindly. In some cases, both colons end in a duplicated perineal anus or in perineal fistulae.[99] The duplications are of variable length and can be classified as extending above or below the peritoneal reflection. If the duplication does extend



**e-Figure 105.15. Chronic intestinal pseudoobstruction.** Abdominal radiograph of a 5-year-old boy with myopathic type pseudoobstruction, largely dependent on total parenteral nutrition due to prolonged episodes of feeding intolerance. During this acute presentation, the radiograph demonstrates massive dilatation of the colon.

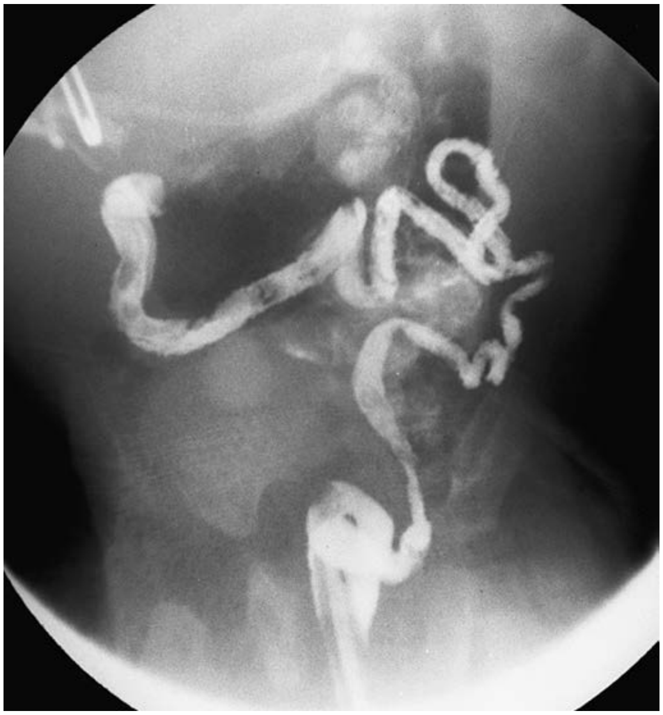


**Figure 105.16. Megacystis-microcolon-intestinal hypoperistalsis syndrome.** Single frontal view of newborn female reveals the microcolon characteristic of this entity. Note the malposition of the cecum, consistent with the malrotation that is common in these patients. Soft tissue density in the pelvis is consistent with a distended urinary bladder.

below the peritoneal reflection, and therefore does not have a perineal opening, communication with the lumen can be at one or both ends. They can extend proximally to involve the cecum, appendix, and terminal ileum.

Approximately 75% of tubular colonic duplications are associated with multiple other anomalies, including renal anomalies. When associated with duplication of the genitourinary tract (uterus, bladder, urethra, penis), and vertebral and cord abnormalities, it is termed *caudal duplication anomaly* (e-Fig. 105.17).[100,101] Although anterior rectal duplications have been reported,[98] cystic rectal duplications are typically located in the presacral space (e-Fig. 105.18).

***Etiology.*** The partial or abortive twinning theory invokes a split in the primitive streak during the embryonic period, with a relatively late split resulting in duplications of the colon. In cases of caudal duplication anomaly, a mechanical cause may interfere by dividing developing precursor structures leading to duplication.[102]

***Clinical Findings.*** The presentation of colonic duplication varies with the type and location. The incidence of gastric mucosa within colonic duplications is reportedly less than in other types, and they can therefore remain asymptomatic and discovered incidentally in late childhood or adulthood. Cystic duplications may be complicated by bowel obstruction due to volvulus, intussusception with the duplication cyst as a leading point, or as an acutely enlarging mass. Duplications may also become symptomatic secondary to inflammation and ulceration; nausea, vomiting, abdominal pain, and identification of a mass on physical examination or imaging are common presentations. Rectal duplications, when large or enlarging, can present with constipation as well as urinary obstruction; because they are located behind the rectum, they may also mimic presacral meningoceles or cystic teratomas.[98,99] Colon and rectal duplications may present as a second opening in the perineum. In girls in whom the duplication terminates in a perineal/vaginal opening, the duplication may simulate a rectovaginal fistula.[104]

***Imaging.*** Initial suspicion on physical examination or on plain films can be followed up with sonography, fluoroscopy, computed tomography (CT), or MRI. Tubular duplications with a perineal fistula are best diagnosed with contrast enema via both perineal orifices, outlining both lumina; antegrade contrast studies may also be diagnostic. CT and MRI will likely be diagnostic, but at the present time their exact role in the workup of these lesions remains undefined. Rectal duplications can be identified in plain films and contrast enemas via a mass effect upon the rectum, and upon the adjacent genitourinary structures if sufficiently large. Sonography and MRI are likely the best modalities to evaluate noncommunicating cysts (see e-Fig. 105.18). A search for other system anomalies should also be undertaken, with the appropriate imaging modality.

***Treatment.*** Symptomatic simple cystic duplications can be resected. If a presacral rectal duplication presents as an abscess, drainage is advocated as initial treatment.[98] Long colonic duplications can be treated by extensive fenestration between the two lumina, with resection of the perineal fistula.

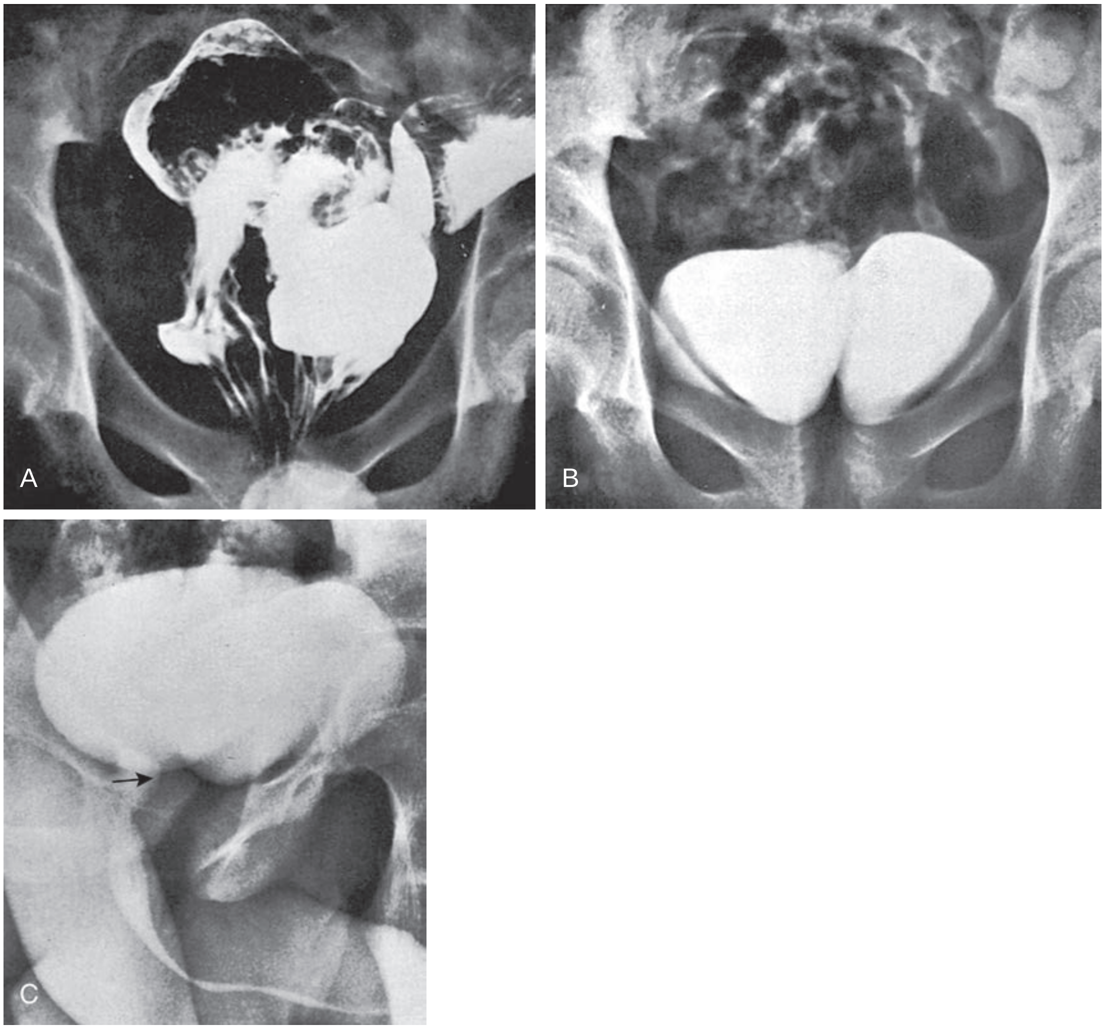
## NECROTIZING ENTEROCOLITIS

***Overview.*** The term necrotizing enterocolitis (NEC) was coined in 1952[105] to describe an inflammatory condition affecting the GI tract of neonates, most commonly premature infants surviving the first few days of life who were receiving enteral nutrition. Today, necrotizing enterocolitis is considered the most common newborn surgical emergency, with greater morbidity and mortality than all other surgical GI conditions in this age group combined.[106] Approximately 90% of cases of NEC occur in premature infants; the incidence of NEC is inversely proportional to gestational age, with the majority of cases occurring in infants weighing between 500 and 750 grams, and only approximately 7% to 13% of cases occurring in full-term infants.[106] NEC affects up to 11.5% of infants weighing less than 750 grams and 4% of infants weighing between 1250 and 1500 grams.[107,108] Risk factors for NEC in term infants include congenital heart disease and other conditions that affect splanchnic blood flow, such as maternal cocaine use and decreased prenatal umbilical blood flow.

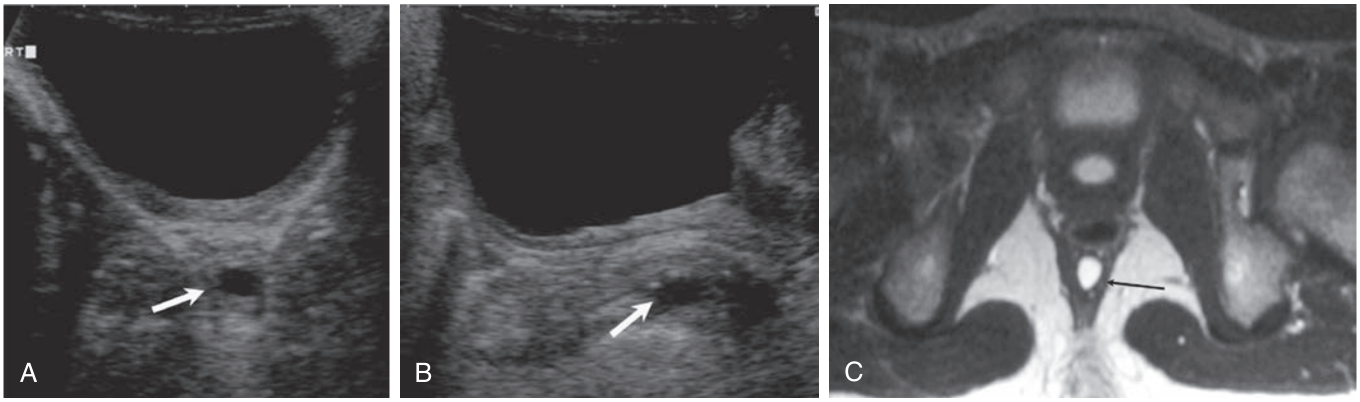
The Bell classification of enterocolitis severity, introduced in 1978,[109] is still used with modifications today (Table 105.2).[110,111] Stage I is sensitive but nonspecific, as it includes infants in whom NEC is suspected, but not definitely diagnosed; stage IIA is mild but definite NEC; stage IIB is NEC of moderate severity, while stage IIIA refers to advanced NEC, and stage IIIB refers to NEC that has advanced to perforation. Some investigators suggest excluding stage I, which is relatively nonspecific and may include patients without true NEC and suggest grouping NEC by suspected etiologies.[113]

***Etiology.*** Ischemia leading to intestinal mucosal injury, prior feedings, and a substrate of intestinal flora have been recognized for decades as central to the pathophysiology and development of NEC.[106,112] A complex process involving cytokines and growth factors initiates an inflammatory cascade leading to intestinal injury, cellular apoptosis, breach of the mucosal barrier, and bacterial translocation in susceptible infants.

The most important risk factors for the development of NEC are prematurity and enteral feedings, which have been instituted in 90% of infants who develop NEC. The premature neonate has poorly developed intestinal motility leading to stasis, altered ability to maintain homeostasis between proinflammatory and antiinflammatory compounds, to regulate splanchnic vasoconstriction and blood flow, and to maintain mucosal integrity. Proinflammatory compounds are upregulated in NEC, including platelet activating factor, tumor necrosis factor, and certain types of interleukins, leukotrienes, and oxygen free radicals. Toll-like receptor 4 (TLR4)



**e-Figure 105.17. Duplication of the entire colon and bladder.** (A) Contrast enema of the pelvis after excretory urography in a 15-year-old boy who had been treated in the newborn period for anal atresia, demonstrates two rectums. Surgical exploration revealed duplication of the entire colon, from appendix to rectum. (B) Frontal radiograph of the pelvis after excretory urography shows two bladders. Each upper urinary tract emptied into the bladder on its respective side. (C) Voiding urethrogram demonstrates a single urethra *(arrow)* originating from the right side.



**e-Figure 105.18. Rectal duplication.** (A) Transverse sonogram in a 6-year-old girl who presented with abdominal pain shows an incidental finding of a small cyst *(arrow)* inseparable from the rectal wall. (B) Sagittal sonogram demonstrates the retrorectal location of the cyst *(arrow)*. (C) Axial T2-weighted MR image confirms the small cystic lesion *(arrow)* and better demonstrates its retrorectal location.

**TABLE 105.2** Modified Bell Staging Criteria

| Stage | Systemic Findings | Abdominal Findings | X-rays |
|---|---|---|---|
| IA, B – Suspected | Apnea, bradycardia, temperature instability | Distension, blood in stools | Mild ileus |
| IIA – Definite, mild severity | Apnea, bradycardia, temperature instability | Absent bowel sounds +/– abdominal tenderness | Ileus, pneumatosis |
| IIB – Definite, moderate severity | Metabolic acidosis, thrombocytopenia | Abdominal tenderness +/– cellulitis, RLQ mass | Ileus, pneumatosis, ascites |
| IIIA – Definite, severe | Apnea, hypotension, bradycardia, metabolic and respiratory acidosis, neutropenia, DIC | Abdominal distension, abdominal tenderness, signs of peritonitis | Ileus, pneumatosis, ascites |
| IIIB – Definite, severe, bowel perforation | Apnea, hypotension, bradycardia, metabolic and respiratory acidosis, neutropenia, DIC | Abdominal distension, abdominal tenderness, signs of peritonitis | Pneumoperitoneum |

*Adapted from Sylvester K, Liu G, Albanese CT. Necrotizing enterocolitis. In: Coran A, et al, eds.* Pediatric Surgery, *Philadelphia: CV Mosby, an Imprint of Elsevier; 2012.*

senses lipopolysaccharide, and its expression is associated with increased severity of NEC; its concentration falls precipitously at birth, but its expression is attenuated by breast milk.[113] Accelerated apoptosis resulting from overproduction of inflammatory compounds has been shown to result in a break at the villus tip of the intestinal mucosal barrier, facilitating bacterial translocation and the inflammatory cascade.[106,107,114]

***Clinical Findings.*** The clinical findings reflect the severity and evolution of the disease. In Bell stage I disease, the infant exhibits relatively nonspecific symptoms, including systemic signs such as apnea, bradycardia, and temperature instability, and abdominal signs consisting of abdominal distension, hemoccult positive stools, and increased gastric residuals. These signs could also be present in other conditions, such as sepsis, and therefore are sensitive, but relatively nonspecific. By stage IIA, the diagnosis of NEC can be made, and clinical findings include abdominal tenderness and grossly bloody stools; by stage IIB, the child has progressed to thrombocytopenia and mild acidosis, as well as abdominal wall edema and tenderness. Infants in stage IIIA have severe disease with metabolic and respiratory acidosis requiring intubation, signs of disseminated intravascular coagulation, with worsening abdominal wall erythema, edema, and induration. Patients with stage IIIB disease show clinical evidence of shock and gut perforation.

Complications of NEC in survivors relate to whether the patients have developed short bowel syndrome, with dependence on total parenteral nutrition and its attendant complications. Strictures occur in 9% to 36% of survivors of NEC, most often in the colon (70%–80%), and 21% of these occur at the splenic flexure. Strictures develop most often in patients who have been managed medically and present with failure to gain weight, rectal bleeding, or signs and symptoms of obstruction.[7,106]

***Imaging.*** Abdominal radiographs have been the mainstay of imaging evaluation of infants with NEC, and the Bell criteria therefore have corresponding radiographic findings.

The radiographs of infants with Bell stage I disease, similar to the physical findings, are nonspecific, demonstrating a bowel gas pattern that is within normal limits or shows a mild ileus. Stage IIA disease is specific, because in addition to an ileus pattern, focal pneumatosis can be seen. As NEC progresses to stage IIB, radiographs show extensive pneumatosis ± portal venous gas and early ascites (Figs. 105.19A and B). Stage IIIA demonstrates more prominent ascites and persistent bowel loops; pneumoperitoneum is the hallmark of stage IIIB disease (Fig. 105.19C). Periodic imaging is important and is employed more frequently in patients who have more advanced disease.

Ultrasound is a useful and often complementary modality to abdominal radiographs.[115,116] In stage IIA disease, intramural gas has a characteristic appearance as it wraps around the subserosa of the involved bowel loops (Fig. 105.20A); absent peristalsis correlates with the clinical absence of bowel sounds. In stage IIB disease, ultrasound identifies ascites more easily than radiographs, while the pneumatosis and portal venous gas are also seen (Fig. 105.20B). In stage IIIA disease, thinning of the bowel wall can be evident. The hallmark of stage IIIB disease, pneumoperitoneum, is seen on ultrasound, most easily as gas anterior to the liver. However, pneumoperitoneum may not be present in as many as 37% of infants with perforation[106]; when there is perforation, ultrasound can demonstrate complex ascites, which has been correlated with bowel perforation and need for surgery.[117] Several sonographic findings are associated with an adverse outcome, particularly focal fluid collections, and three or more of these additional findings: abnormal bowel wall echogenicity, bowel wall thickening or thinning, free fluid with internal echoes, absent bowel wall perfusion, and intramural gas.[118]

Patients who develop strictures may be evaluated with fluoroscopic examinations, typically contrast enema, as 80% of strictures develop in the colon, and 15% in the terminal ileum (Fig. 105.21).[106]

***Treatment.*** Initial medical treatment consists of fluid resuscitation, antibiotics, and total parenteral nutrition. Surgical intervention is required to remove bowel that has become gangrenous, while preserving intestinal length. Optimal surgical timing, when the bowel is gangrenous but before perforation, is difficult to define clinically or by imaging.[106] Pneumoperitoneum in infants with surgically proven perforation is present in only approximately 63% of cases.[106] Criteria that suggest gangrene before perforation include abdominal wall erythema, fixed appearance of intestinal loop(s) on radiography or ultrasound, and clinical deterioration while receiving medical therapy.[106,119] Patients with perforation who are deemed very poor surgical candidates may undergo initial peritoneal drainage.[106,119]

## KEY POINTS

- Colonic atresia is uncommon, representing between 1.8% and 15% of all intestinal atresias.
- Approximately 95% of patients with ARM have a fistula to the urethra, vagina, or perineum; however, fistulae are much less common in patients with Down syndrome and ARM.
- The Currarino association was initially described as a triad of ARM, presacral mass, and sacral anomaly, but current understanding recognizes a much wider spectrum of phenotypic abnormalities and an underlying genetic defect.
- Hirschsprung disease histopathology includes absent ganglion cells, hypertrophied nerve fibers, and increased acetylcholinesterase staining.
- Diagnostic findings at contrast enema in patients with Hirschsprung disease include a zone of transition between normal caliber aganglionic bowel distally and dilated bowel proximally; irregular outline of the aganglionic segment may be present due to nonperistaltic contractions.

*Continued*

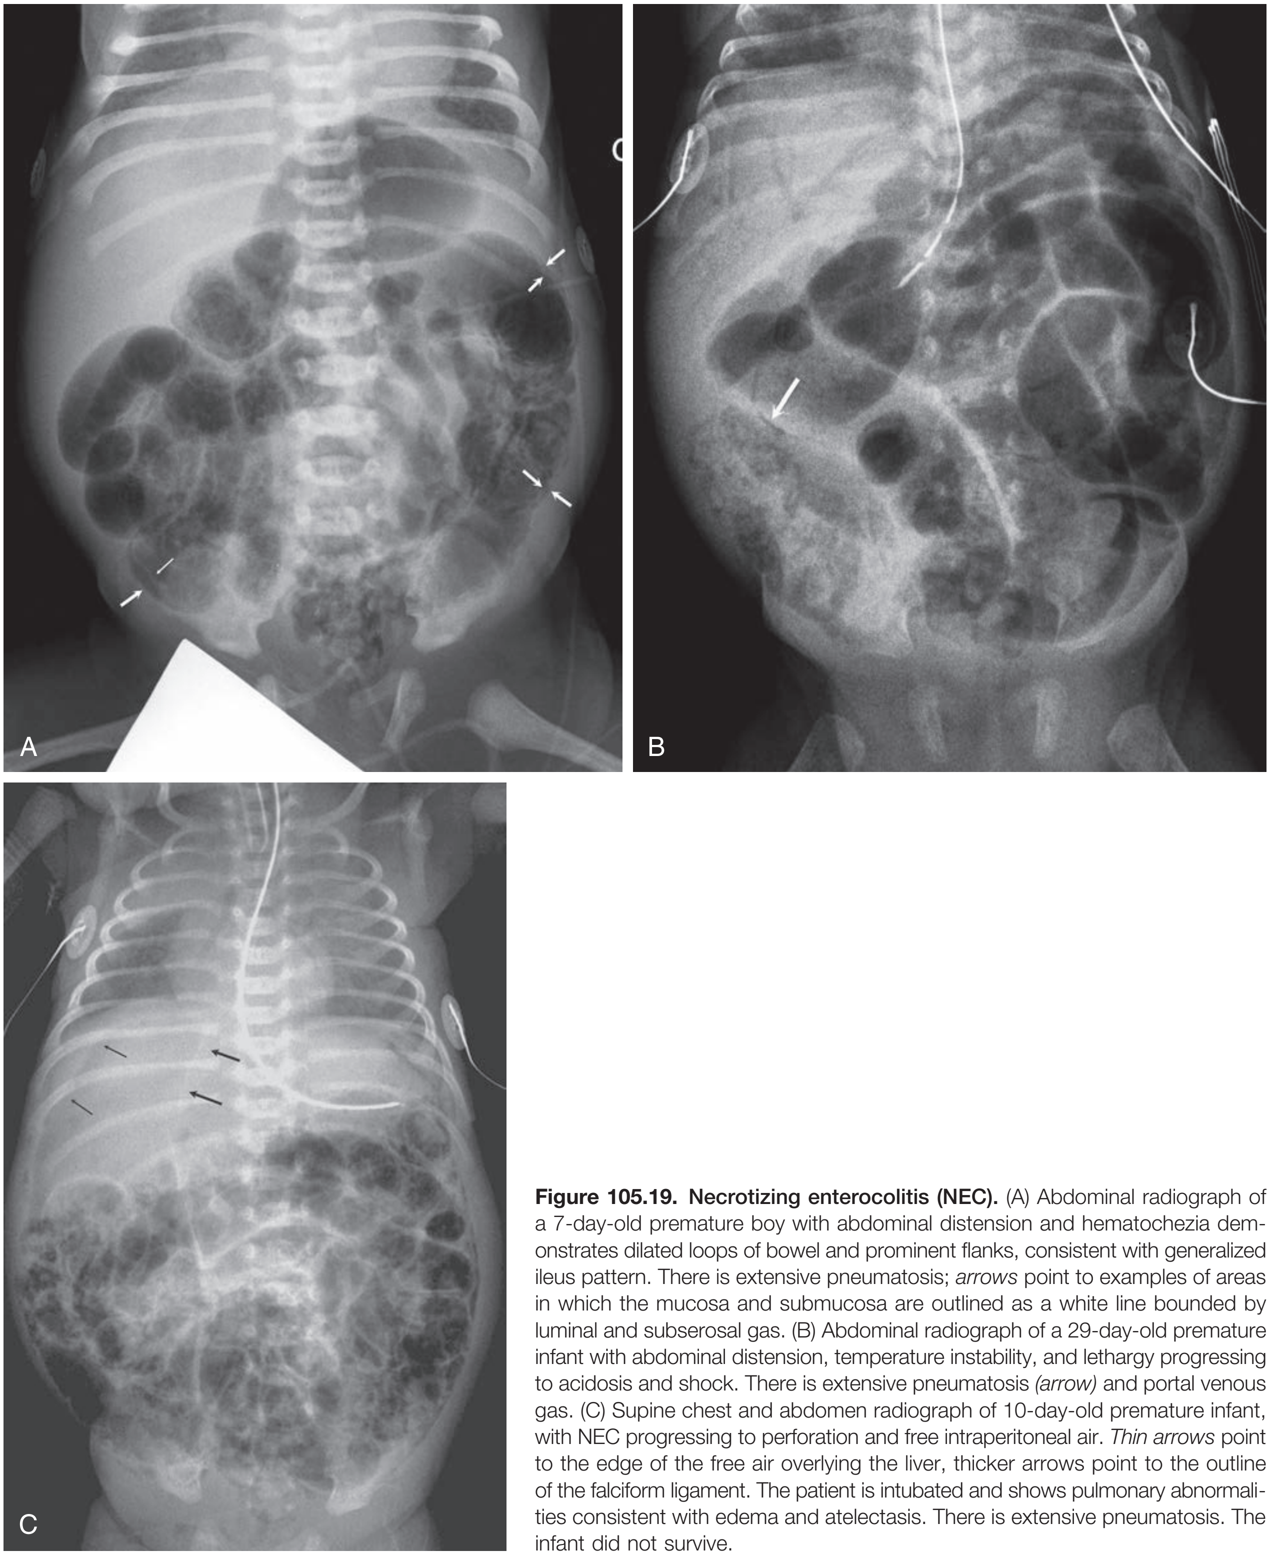


**Figure 105.19. Necrotizing enterocolitis (NEC).** (A) Abdominal radiograph of a 7-day-old premature boy with abdominal distension and hematochezia demonstrates dilated loops of bowel and prominent flanks, consistent with generalized ileus pattern. There is extensive pneumatosis; *arrows* point to examples of areas in which the mucosa and submucosa are outlined as a white line bounded by luminal and subserosal gas. (B) Abdominal radiograph of a 29-day-old premature infant with abdominal distension, temperature instability, and lethargy progressing to acidosis and shock. There is extensive pneumatosis *(arrow)* and portal venous gas. (C) Supine chest and abdomen radiograph of 10-day-old premature infant, with NEC progressing to perforation and free intraperitoneal air. *Thin arrows* point to the edge of the free air overlying the liver, thicker arrows point to the outline of the falciform ligament. The patient is intubated and shows pulmonary abnormalities consistent with edema and atelectasis. There is extensive pneumatosis. The infant did not survive.

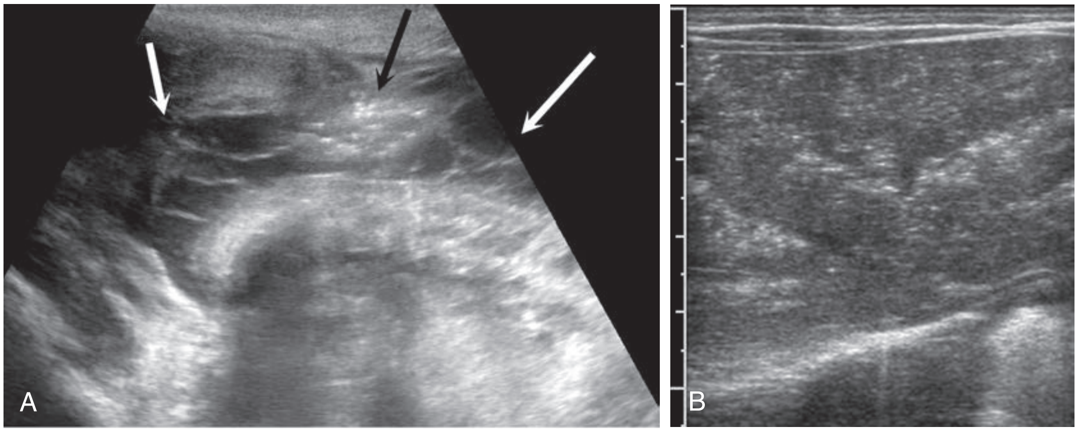

**Figure 105.20. Necrotizing enterocolitis (NEC).** (A) Ultrasound of an infant with severe NEC and perforation. *Black arrow* outlines bowel loop with circumferential punctate echoes consistent with pneumatosis. *White arrows* point to complex fluid collection. (B) Transverse sonogram of the liver in infant with portal venous gas demonstrates the multiple intrahepatic echoes along the vascular distribution.

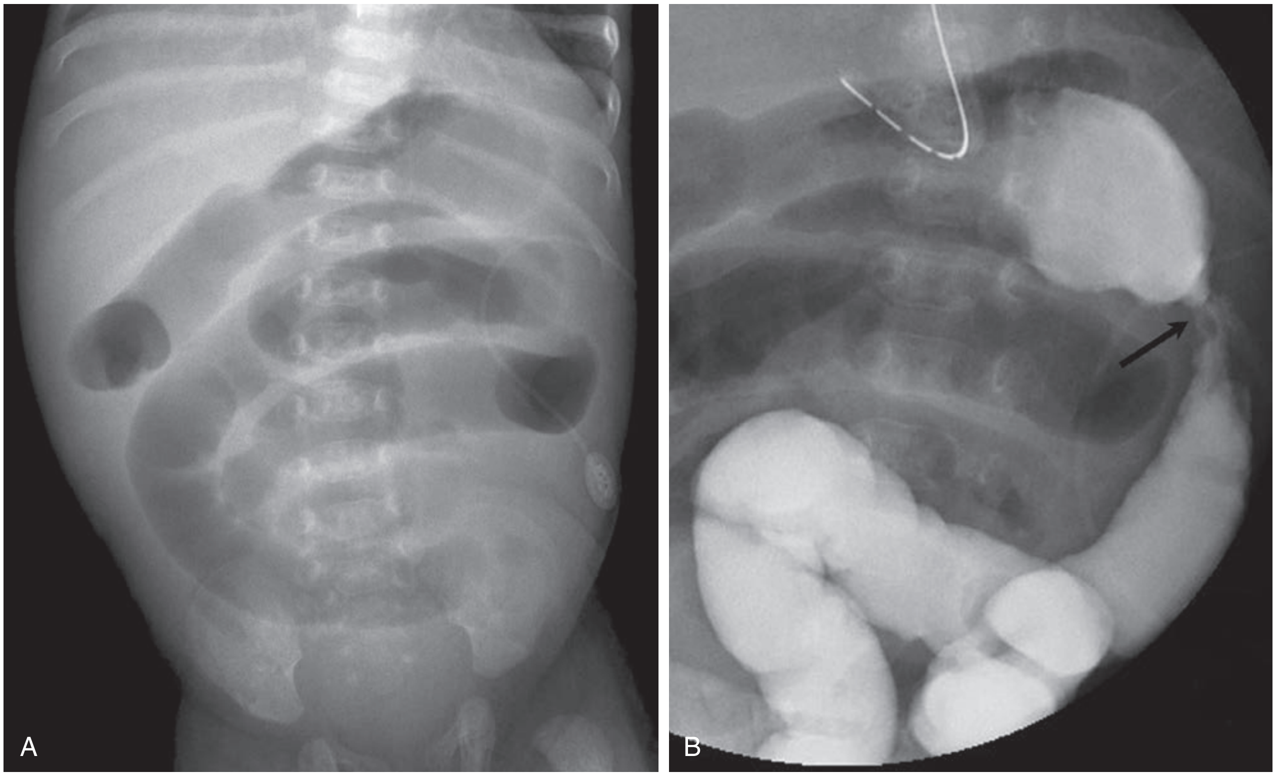

**Figure 105.21. Necrotizing enterocolitis (NEC): development of strictures.** (A) A 7-week-old premature infant with past history of NEC presents with increasing residuals, vomiting, and abdominal distension. Abdominal radiograph shows dilated loops of bowel consistent with a distal, partial obstruction. (B) Spot image from contrast enema demonstrates an area of narrowing in the proximal descending colon, consistent with a stricture *(arrow)*.

- Meconium plug and small left colon syndrome are considered functional obstructions and are usually transient; failure to resolve requires exclusion of Hirschsprung disease.
- Chronic intestinal pseudoobstruction may be primary or secondary. The primary form is most common in children and is, in turn, subdivided into neuropathic and myopathic forms.
- Megacystis-microcolon-intestinal hypoperistalsis syndrome presents within the first 6 months of life, is associated with malrotation, and has a poor prognosis.
- Tubular colonic duplications of the colon often drain to the perineum; typically, although not invariably, they connect to the gastrointestinal tract.
- NEC is most commonly seen in premature infants, with a triad of intestinal ischemia, oral feedings, and luminal bacteria. Bell criteria differentiate the level of severity of the condition, which correlates with clinical and imaging findings.

# 106 Inflammatory and Infectious Diseases

*Mary-Louise C. Greer and Tahani M. Ahmad*

Colitis encompasses a spectrum of infectious and noninfectious inflammatory conditions. Infectious colitides, with etiologies often overlapping with enteritis (see Chapter 104), are typically acute in onset and may be localized as in acute appendicitis. The causative agent may not be known in inflammatory colitis. Some patients with hemolytic uremic syndrome (HUS) or inflammatory bowel disease (IBD) are recognized as having altered immune regulation,[1,2] and more often this form of colitis is chronic. Etiologies, clinical manifestations, imaging, and treatment options of these colitides, and others including treatment-related colitis (e.g., pseudomembranous and radiation-induced colitis), will be discussed. For some, such as IBD, this will be expanding on the discussion from Chapter 104.

## INFLAMMATORY BOWEL DISEASE

IBD includes Crohn disease (CD), ulcerative colitis (UC), and unclassified IBD. For the incidence, etiology, pathophysiology, and clinical presentation of IBD in the pediatric population, including very early onset IBD, please refer to Chapter 104. In this chapter, we will be addressing imaging of CD and UC, including perianal disease, and treatment where it differs from IBD of the upper gastrointestinal (GI) tract.

### Imaging

A summary of the diagnostic performance of various modalities in diagnosing features of IBD is listed in Table 106.1.

### Radiography

Radiography has an emergent role in IBD and, while not routinely used, familiarity with more reliable features of IBD remains important including "thumbprinting."[3] Of importance in UC and ileocolonic CD is toxic megacolon, with colonic dilatation seen on abdominal radiographs.[4] Dilatation of the transverse colon exceeding 56 mm in patients greater than 11 years (normal rarely >40 mm in younger patients) is a strong indicator of toxic megacolon, particularly if seen in conjunction with three of four criteria: fever, tachycardia, leukocytosis, or anemia (Fig. 106.1).[5]

### Ultrasound

As discussed in Chapter 104, abdominal and pelvic ultrasound (US) now plays an important role in pediatric IBD, for monitoring disease, diagnosis if magnetic resonance imaging (MRI) is not an option, and problem solving in acute situations by demonstrating abscesses, stenoses, fistulae or an acute flare, with advantages and limitations as previously considered.[6] US after ingestion of nonabsorbable oral contrast can assist if colonic strictures render ileocolonoscopy nondiagnostic.[4] Good specificity but lower sensitivity of conventional US is primarily due to differences in detection of colonic inflammation by location, limiting its usefulness as a screening tool. US accuracy is high in a majority of the large bowel but lower in the transverse colon and rectum.[4,7]

Mural and extramural features in colonic CD emulate small bowel findings (see Chapter 104). Crohn colitis can have skip lesions or be right side only (e-Fig. 106.2). In comparison, UC is characterized by continuous involvement of the colon from the rectum progressing retrograde with intermediate wall thickening, slightly hypoechoic and nonhomogenous mucosa, and submucosal edema (acute phase) with preserved mural stratification. Chronic UC can have submucosal fibrosis ± fat deposits, loss of haustrations, and stiffness. Even so, distinction from Crohn colitis is poor (Fig. 106.3).[8] Pancolitis can be associated with backwash ileitis (6%–20%).[9] Transmural involvement is rare in UC, as are extramural findings. Regional variations with macroscopic rectal sparing and cecal patches are not usually evident on cross-sectional imaging.

Perianal and perineal US have a small role in the acute setting to rapidly identify a perianal abscess that may require urgent drainage. A percutaneous approach can demonstrate fistulae, although with variable accuracy, and classification largely depends on use of endoanal probes that are seldom utilized in children and adolescents.[4]

### Fluoroscopy

Single or double contrast enemas are now rarely used in IBD imaging due to the ionizing radiation and inability to evaluate transmural and extramural features. Infants and young children may still benefit from this technique for diagnosis and documenting extent of very early onset IBD (e-Fig. 106.4). Water-soluble contrast agents are now often used in preference to barium. Mucosal ulceration, pseudopolyps, loss of haustrations, stenoses, and fistulae have all been documented in CD. Enteroenteric fistulae may be demonstrated to lesser extent with fluoroscopy than with other techniques.[10] UC typically has shallower ulcers, with less wall deformity and stricturing.

### Computed Tomography and Magnetic Resonance Imaging

#### Computed Tomography/Magnetic Resonance Enterography and Colonography

The colon is evaluated when included in computed tomographic enterography (CT) and magnetic resonance enterography (MRE) assessment of small bowel, without any special colonic preparation. CD features are similar to that seen in small bowel (see Chapter 104) with deep ulcers, pseudopolyps, mural thickening and hyperenhancement, engorged vasa recta, and on MRE, T2 hyperintensity and restricted diffusion. In UC, mural thickening can be subtler with preservation of the smooth outer contour of the bowel wall (Fig. 106.5). As with US, MRI can occasionally demonstrate mural fat in chronic UC, although infrequently seen in children (e-Fig. 106.6). In both, loss of colonic haustrations can be seen ("lead pipe" configuration).[11] In Crohn colitis in particular, extramural changes can include fibrofatty proliferation, mesenteric enhancement, or edema, abscesses, and fistulae.[4,12] Although strictures can be difficult to appreciate in collapsed large bowel, this was not an impediment to detection of colonic inflammation, with a recent small study comparing MRE with endoscopic biopsies showing a sensitivity of 90% and specificity of 60% for active inflammation (Fig. 106.7).[13] Unsuspected perianal disease is increasingly recognized on MRE, and this region warrants careful review (see later in this chapter).[14]

CT colonography (virtual colonoscopy) uses colonic air insufflation, and MR colonography uses rectal instillation of warm water or saline to distend the colon, although colonic IBD can be seen

## Abstract:

A diverse range of acquired colonic disorders resulting from inflammatory and infectious etiologies is discussed in this chapter. Their pathophysiology, clinical manifestations, imaging features and treatment options will be reviewed.

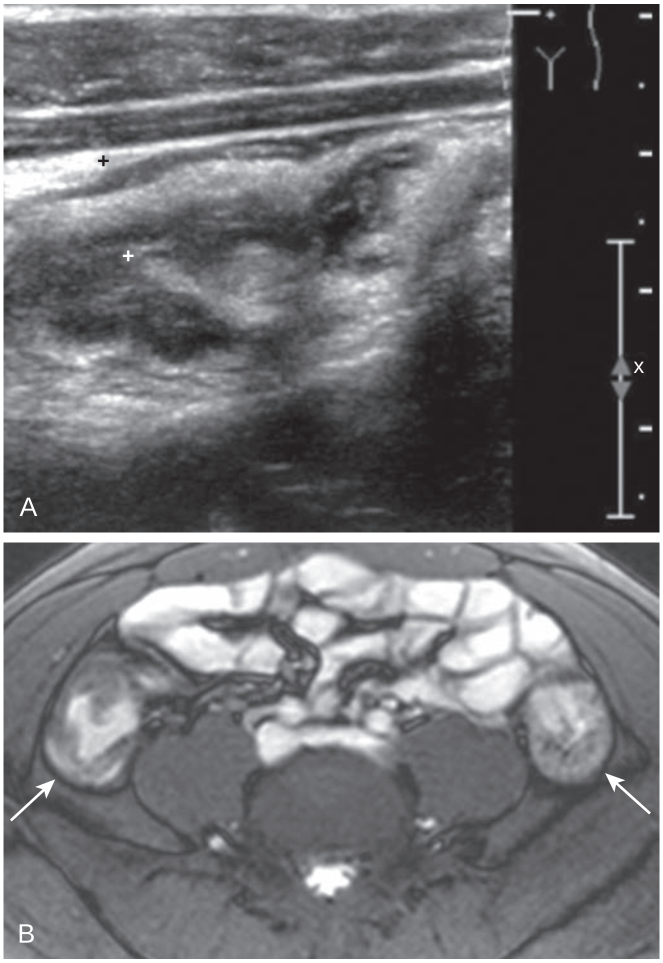
Inflammatory bowel disease (IBD) manifests in the large bowel as ulcerative or Crohn colitis, with or without perianal disease, and hemolytic uremic syndrome can result in hemorrhagic colitis. They may arise from immunologic defects and/or infections. Colitides with more defined etiologies include antibiotic-associated pseudomembranous colitis from *Clostridium difficile*, radiation and neutropenic colitis.

Where diagnostic imaging is indicated, abdominal radiographs or ultrasound are usually sufficient, largely replacing contrast enemas. Magnetic resonance imaging (MRI) and to lesser extent computed tomography (CT), are utilized selectively as in evaluation of IBD. Although imaging of infectious colitis is seldom required, in rare instances imaging can aid distinction from other diseases, such as the invasive fungal infection gastrointestinal basidiobolomycosis that can mimic lymphoma. CT and MRI are of limited value in diseases such as Graft-Versus-Host colitis as imaging findings are usually non-specific.

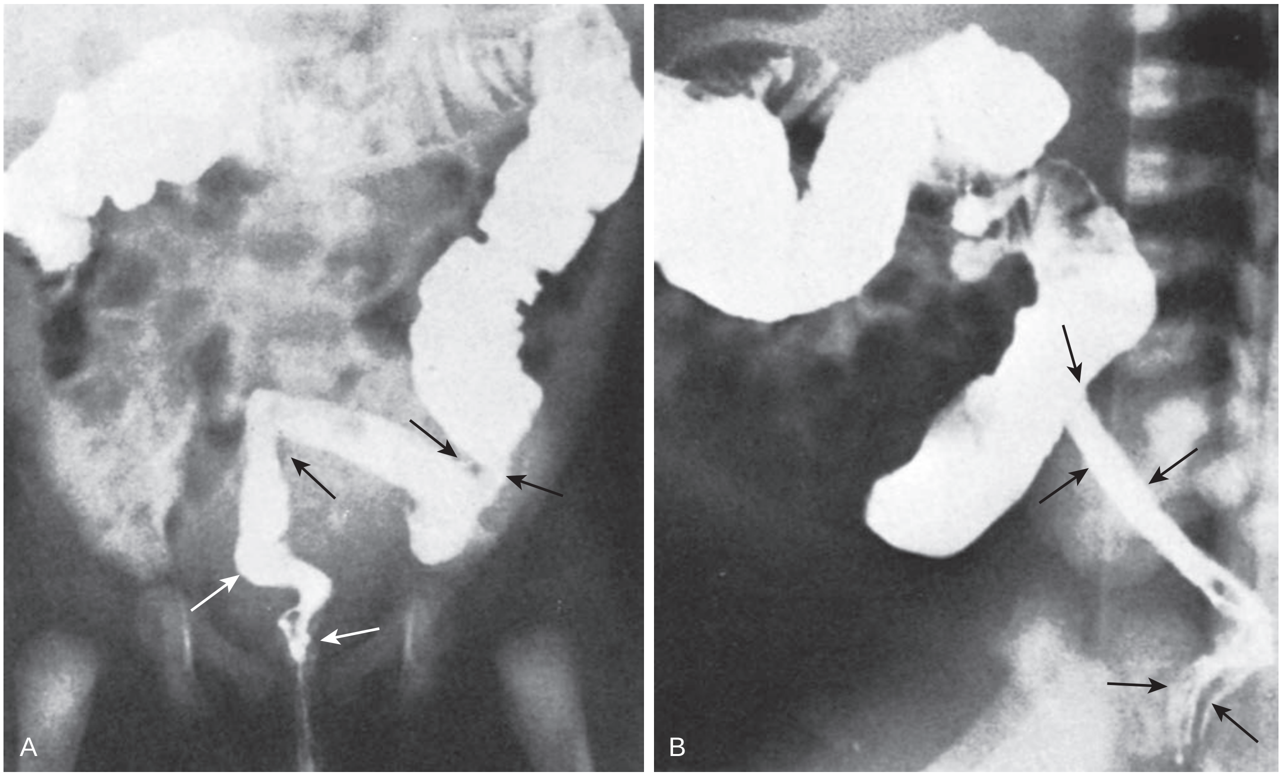
Appendicitis warrants special attention. A common condition in childhood and adolescence, inflammation of the appendix can be challenging to diagnose, symptoms non-specific in up to a third of cases, particularly in younger patients. Complications from delayed or missed diagnoses can be significant. Changing diagnostic pathways have greater reliance on imaging, ultrasound usually first line. In equivocal cases, CT and more recently MRI have a useful role. These modifications have contributed to improved patient outcomes with a decline in negative appendectomy rates.

## Keywords:

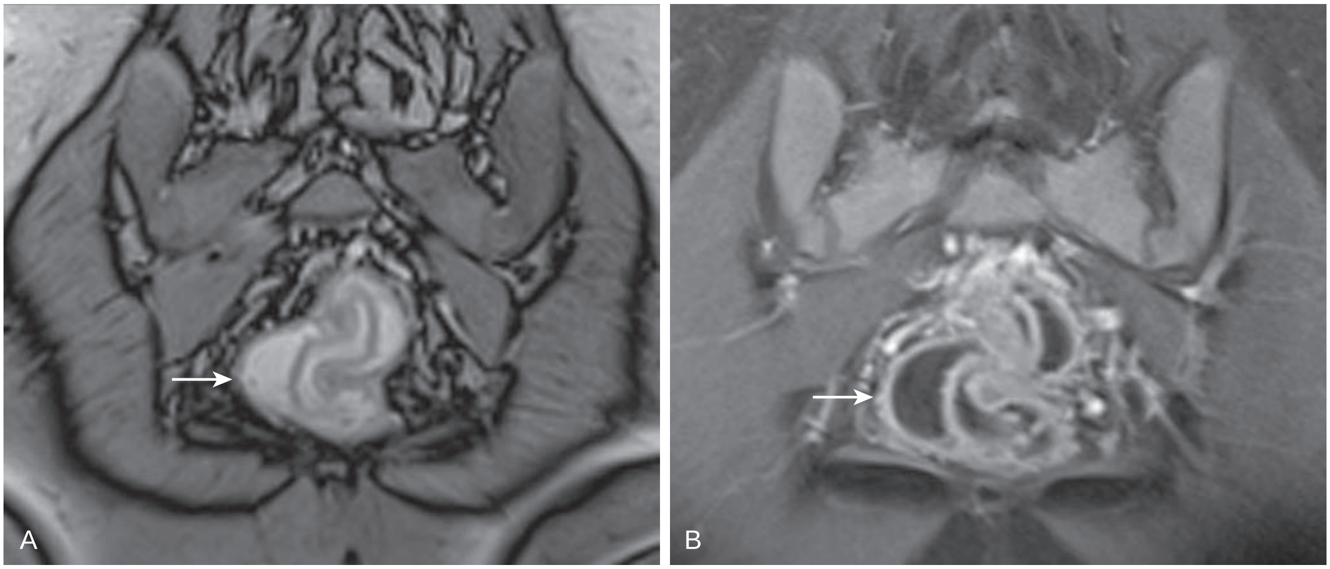
Ulcerative colitis
Crohn colitis
pseudomembranous colitis
infectious colitides
appendicitis



**e-Figure 106.2. Crohn disease flare in a 15-year-old boy.** Ultrasound (US) and corresponding magnetic resonance enterography (MRE) images show circumferential wall thickening of the cecum that is hyperechoic on US (A) and hyperintense on axial T2-weighted steady-state free precession fat-saturated MRE (B), with similar finding in the descending colon *(arrows)*.



**e-Figure 106.4. Infantile ulcerative colitis in a 3-week-old girl with rectal bleeding.** Frontal (A) and lateral (B) projections during barium enema show tubular narrowing of the rectum and sigmoid colon *(arrows)* with an abrupt transition zone. The findings were suggestive of aganglionosis, but biopsy revealed ulcerative colitis.



**e-Figure 106.6. Chronic ulcerative colitis on MR enterography.** Intramural fat in the rectosigmoid in a 16-year-old boy is demonstrated by increased signal on (A) coronal non–fat-suppressed T2-weighted steady-state free precession image and deceased signal on (B) coronal contrast-enhanced T1-weighted 3D gradient echo sequence *(arrows)*.

even without good distension (e-Fig. 106.8).[12,15] MR colonography, lacking ionizing radiation, may have value if ileocolonoscopy is incomplete due to strictures or patient contraindications. This provides mucosal, mural, as well extramural information, which in undifferentiated IBD can aid in distinguishing CD from UC.[4,12] In pediatric IBD, patient tolerance precludes MR colonoscopy from being employed routinely in conjunction with MRE, although it is done in some centers. There are variable rates of detection reported for CD on MR colonography (which performs better for UC), such that ileocolonoscopy remains the mainstay of evaluation in pediatric IBD.[4,15]

### Pelvic MRI

For perianal disease, occurring in up to 21% of pediatric CD patients, pelvic MRI is the imaging reference standard (Fig. 106.9).[12,16–18] Fistulae and abscesses are well depicted, and MRI is superior to US and examination under anesthesia, although accuracy is increased when these are combined.[4] Skin tags can also be seen. Described according to Parks' or St. James University Hospital classifications, one review has suggested the Parks' classification is more suited to children due to shorter anal canal length, typically performed without an endoanal coil.[19–22] Contrast-enhanced and diffusion-weighted imaging can help define disease activity as well as distinguishing fistulae from abscesses. Activity measures (e.g., Van Assche and predictors of treatment response) are increasingly used to guide therapy, with better responses seen with maximum fistula length less than 2.5 cm and abscess volume less than 1 mL.[23,24] Contraindications for MRI and risks relating to iodinated and gadolinium-based contrast agents will be discussed elsewhere. There is seldom a role for CT in perianal disease in children.

## Nuclear Medicine

A negative scintigraphy study in CD (e.g., radiolabeled leucocytes or positron emission tomography (PET)/CT or PET/MR) can exclude active disease with high accuracy.[4] While monitoring

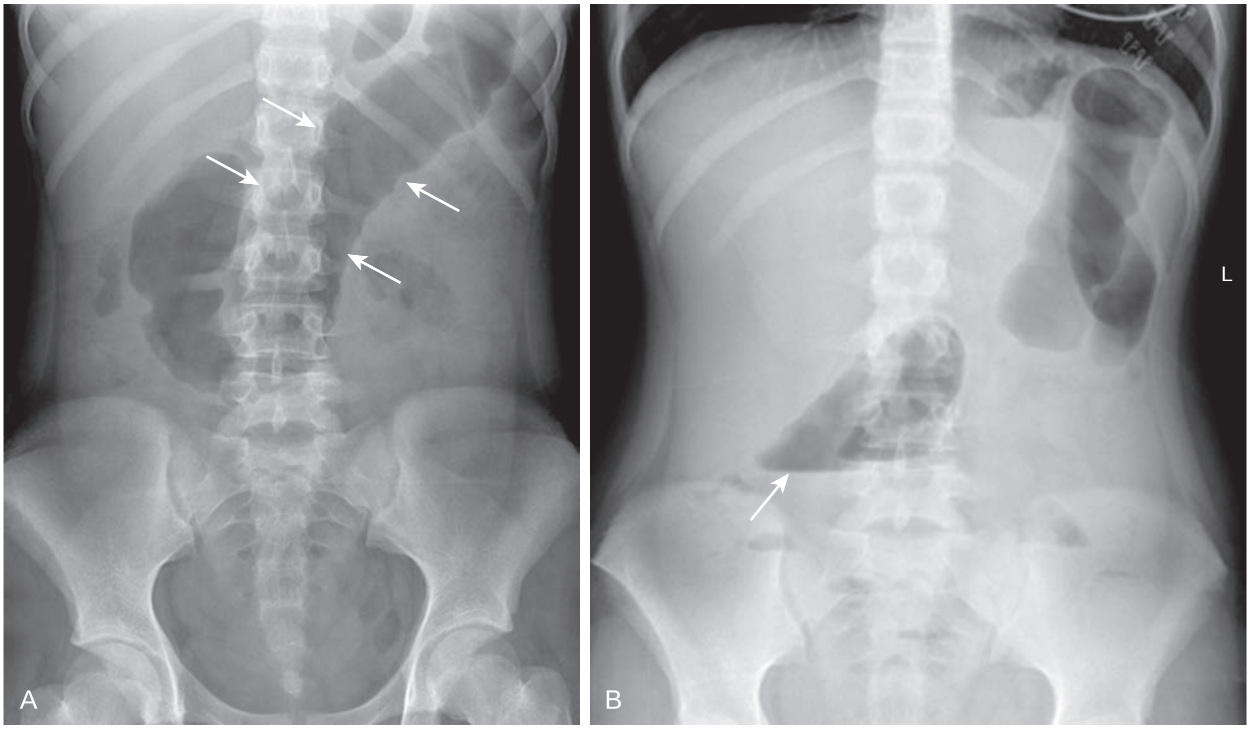

**Figure 106.1. Toxic megacolon in a 13-year-old girl with ulcerative colitis.** (A) Supine abdominal radiograph shows dilated transverse colon (5.9 cm) with loss of haustrations and mild wall thickening *(arrows)*. The remainder of the abdomen and pelvis is relatively gasless with a paucity of stool. (B) Upright radiograph shows multiple air-fluid levels *(arrow)*.

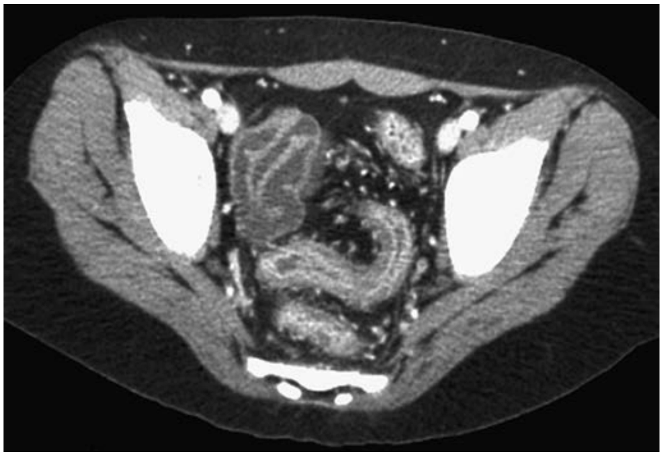

**e-Figure 106.8. Ulcerative colitis in a 12-year-old.** Contrast-enhanced CT image shows a smooth outer wall with marked mucosal enhancement of the rectosigmoid colon and engorgement of pelvic vessels. *(Courtesy Dr. Marta Hernanz-Schulman, Nashville, TN.)*

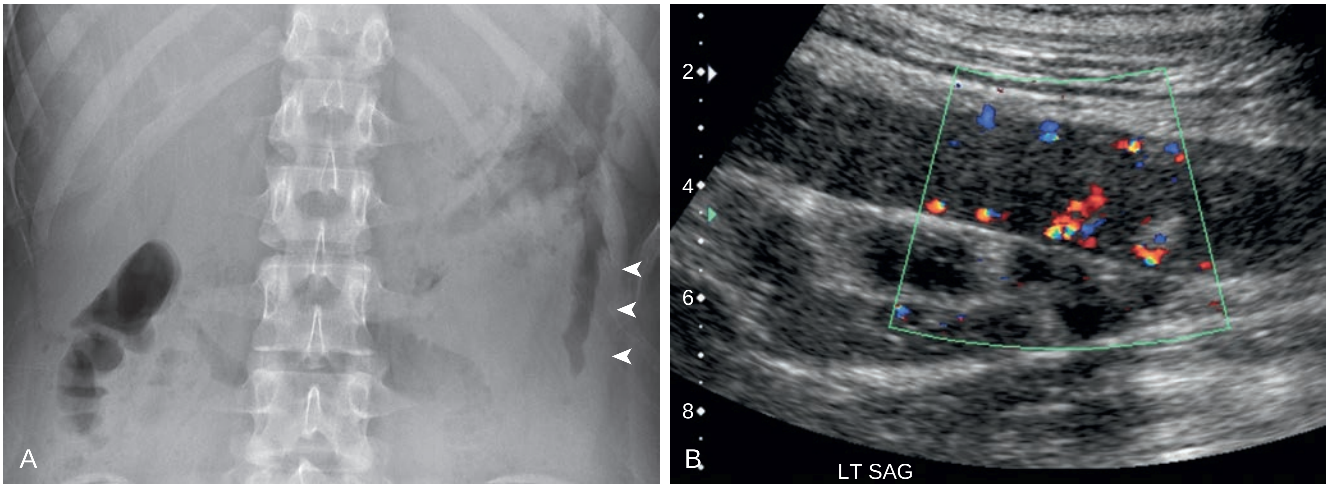

**Figure 106.3. Ulcerative colitis in a 15-year-old with acute-on-chronic changes.** (A) Abdominal radiograph shows diffuse thickening of featureless descending colon with "lead pipe" configuration and no stool contents *(arrowheads)*. (B) Color Doppler sonogram reveals diffuse mural thickening, hyperemia, and luminal narrowing. Note the absence of extracolonic soft tissue changes.

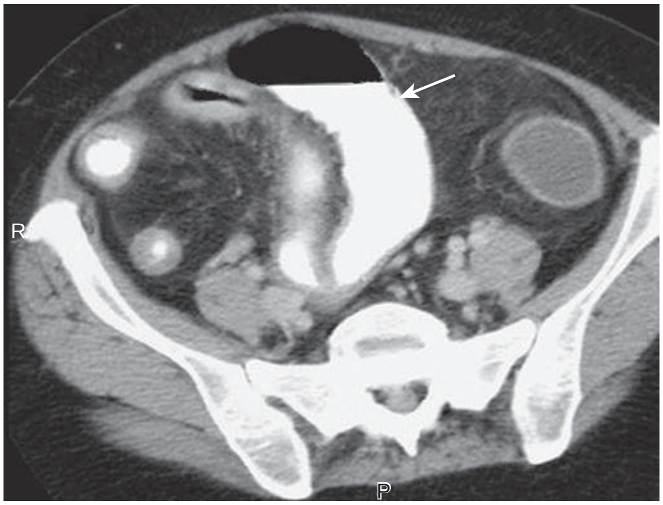

**Figure 106.5. Active Crohn disease in a 19-year-old.** Contrast-enhanced CT shows the distended ileum *(arrow)* proximal to the thick-walled ileal loops and mesenteric stranding and vascular engorgement, resulting from active inflammation. Mural thickening and vascular engorgement of colonic segments is apparent. Positive oral contrast in the lumen interferes with evaluation of mucosal enhancement.

treatment response and distinction of inflammatory and fibrotic strictures is promising, as with small bowel (see Chapter 104), there is limited application for pediatric IBD due to the ionizing radiation and poor evaluation of perianal disease.[4,25,26]

***Treatment.*** *Toxic megacolon* requires aggressive therapy combining medical and surgical approaches due to a high risk of perforation. Managing the underlying cause and supportive therapy with bowel rest, then enteral feeds, low-dose heparin for deep venous thrombosis prophylaxis, high-dose steroids, and antibiotics should not exceed 48 hours. Nasogastric suction is not beneficial. Subtotal colectomy and end ileostomy with a Hartmann's closure of the rectum, required in 47%, has a lower mortality rates than total colectomy, although emergent total colectomy is sometimes needed.[5,27]

Medical treatment and surgical intervention in Crohn colitis is discussed in Chapter 104.[28,29] In UC, corticosteroids and 5-aminosalicylates are initially used to achieve and maintain mucosal healing. Antitumor necrosis α (anti-TNFα) therapies such as infliximab are reserved for persistently active UC in up to 20% of steroid-dependent patients.[28] Colectomy rates vary geographically, approximating 15% at 5 years and 20% 10 years after presentation and, while curative, is not without morbidity.[30,31]

Perianal fistulae and abscesses involve both medical and surgical options such as antibiotics, topical or systemic biologic agents, fistulotomy, fecal diversion, and primary incision and drainage. The choice depends on severity, activity, and prognostic features of fistula length and abscess volume.[23] Anti-TNFα agents should be avoided with abscesses but in combination with seton drainage achieves a 90% response, although relapse rates are high.[32]

## PSEUDOMEMBRANOUS COLITIS

Pseudomembranous colitis refers to severe colonic disease that occurs in approximately 15% to 25% of patients with antibiotic-associated diarrhea.[33]

***Etiology.*** The toxins produced by the bacterium *Clostridium difficile* are the most important cause of antibiotic-associated pseudomembranous colitis, producing whitish, raised, plaquelike lesions restricted to the colon, as distinct from nonantibiotic-associated pseudomembranous colitis, which can also involve small bowel.[33–35] Other less common toxins include those produced by *C. perfringens* and *Staphylococcus aureus*. The diagnosis is a combined clinical and laboratory one (enzyme immunoassay detection of toxin A and B in stool and higher sensitivity polymerase chain reaction toxin gene detection). Infants exposed to *C. difficile* do not become unwell due to inability of the toxin to bind to immature colonic mucosa, thus pseudomembranous colitis is more common in adults than in children and rare in infants.[34] Recently, studies have shown an association of recurrent *C. difficile* colitis in older patients who had undergone remote appendectomy, suggesting a role of immune protection by the normal appendix.[36,37]

***Clinical Presentation.*** Pseudomembranous colitis is characterized by fever, bloody diarrhea, cramping, and colonic mucositis and can be life-threatening. The condition most commonly follows

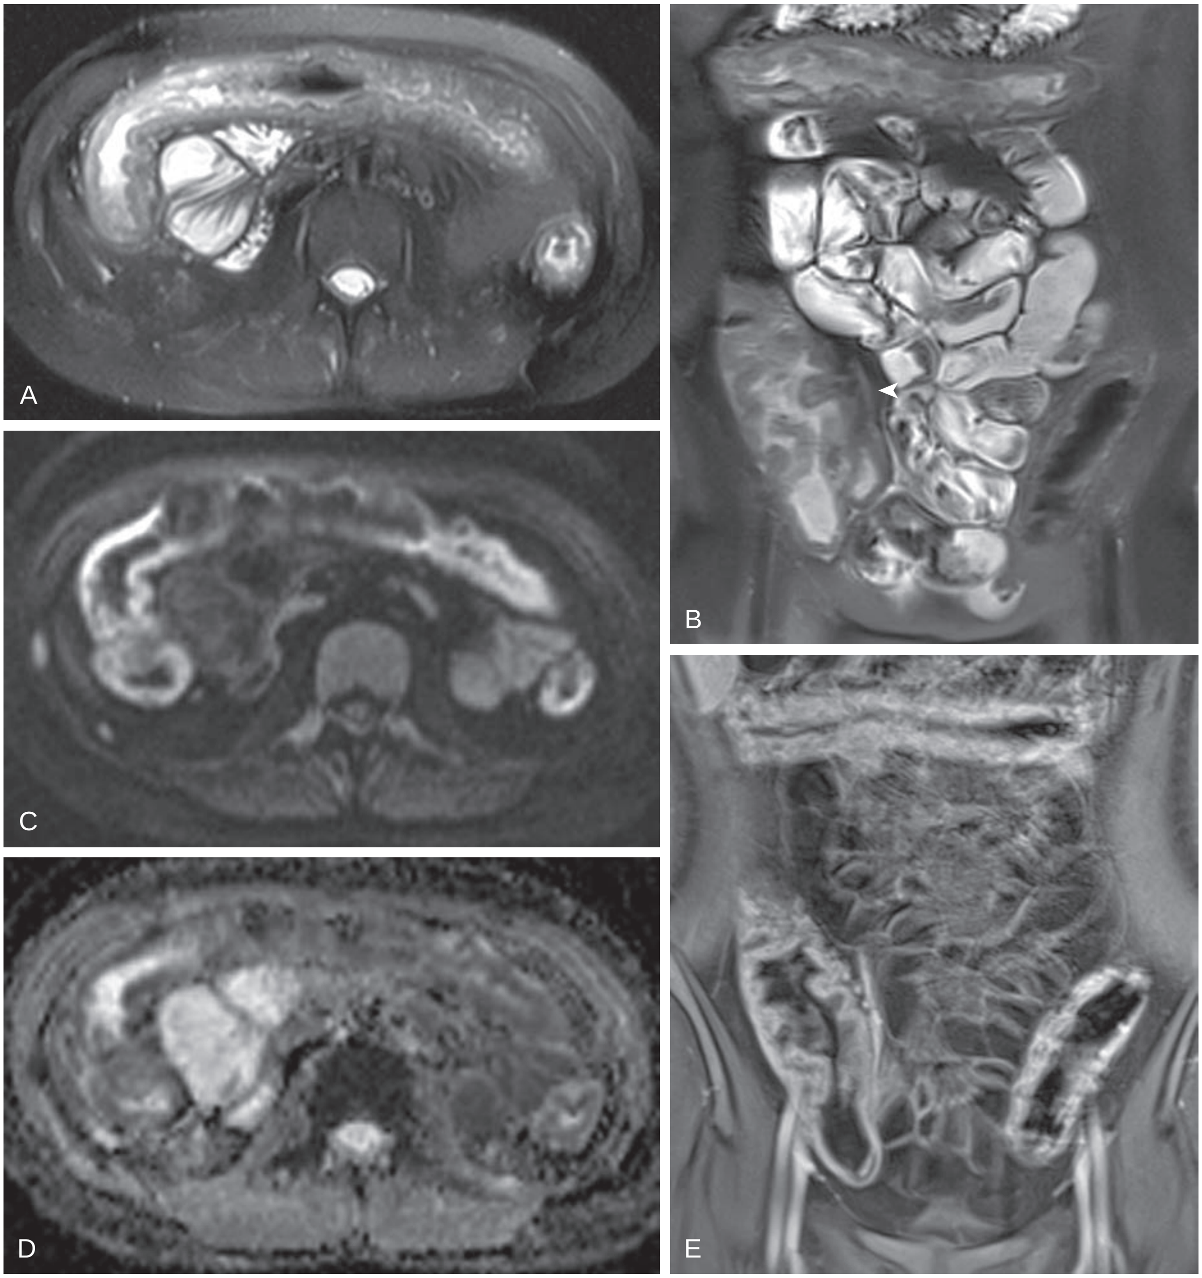

**Figure 106.7. Ulcerative colitis with pancolitis on MR enterography.** The same 16-year-old boy in e-Fig. 106.6 with precolectomy MR enterography. There is continuous transmural involvement of the colon with severe acute-on-chronic inflammation showing deep ulceration, increased mural signal on (A) axial and (B) coronal T2-weighted single-shot images; restricted diffusion on axial diffusion weighted imaging (DWI) with increased mucosal signal on b = 800 s/mm$^2$ (C) and corresponding decreased signal on apparent diffusion coefficient (ADC) map (D); and transmural hyperenhancement on (E) coronal contrast-enhanced fat-suppressed T1-weighted 3D gradient echo images. Note sparing of the terminal ileum, partially seen on (B) *(arrowhead)* and remainder of the small bowel, and smooth serosal surface of the colon with no significant pericolonic inflammation that help distinguish this from Crohn colitis.

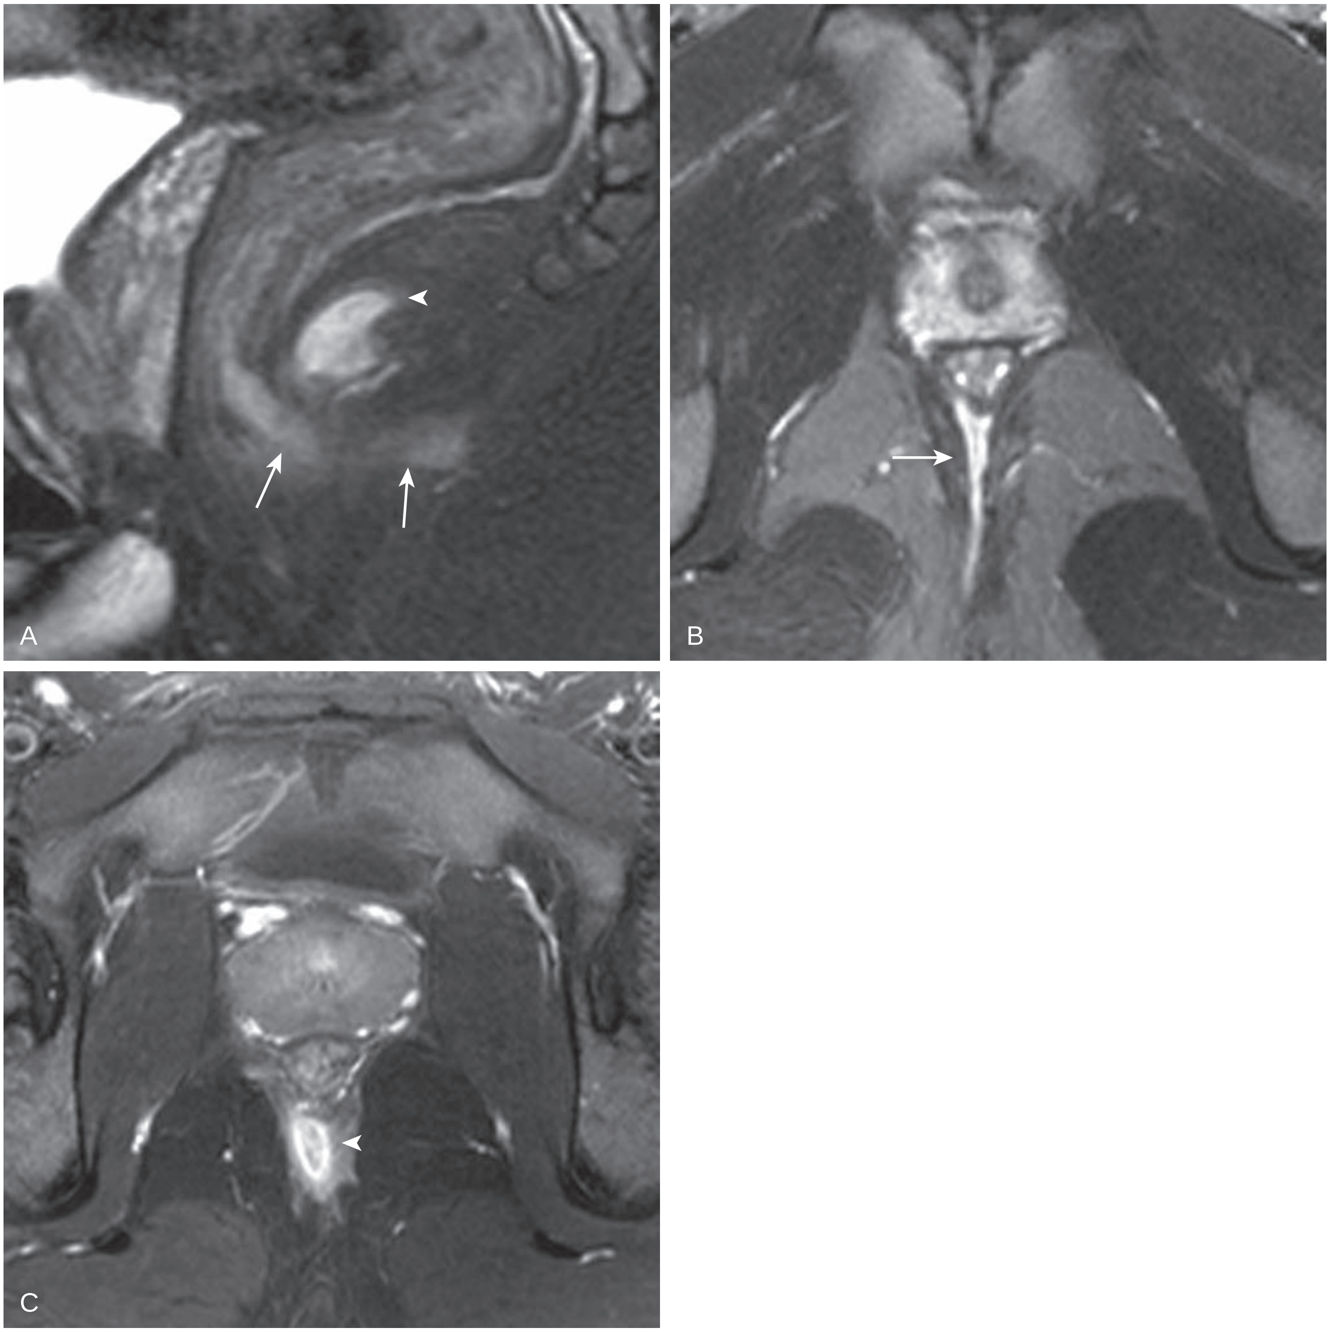

**Figure 106.9. Perianal Crohn disease in a 17-year-old male.** Pelvic MRI reveals a perianal abscess at 6 o'clock superiorly *(arrowheads* in A and C*)*, rim enhancing with fluid signal centrally, and trans-sphincteric fistula (TSF) *(arrows)* more inferiorly at 6 o'clock, with a high signal enhancing tract in (A) sagittal fat-suppressed T2-weighted and (B and C) axial fat-suppressed, contrast-enhanced, T1-weighted sequences.

broad-spectrum antibiotic therapy occurring in hospitalized patients who are often debilitated, immunocompromised, or recovering from surgery.[34,38] However, it may occur without preceding antibiotic therapy in patients in whom the gut flora has been altered, such as after weaning or surgery. The onset of diarrhea may occur within weeks after cessation of antibiotic therapy.

***Imaging.*** Imaging is less specific than clinical and laboratory findings.[39] On abdominal radiographs, findings of pseudomembranous colitis are similar to other colitides unless it is severe, with small bowel dilatation, "thumbprinting" in segments of variable length, haustral thickening and colon dilatation, and rarely gross cecal distension.[35,40] Enemas should be avoided. US, MR, or CT findings of pancolitis, with or without ascites, can be seen. Bowel wall thickening on US is predominantly hypoechoic, and on CT and MR, occasionally nodular haustral thickening can be seen (the "accordion" pattern).[39,40]

***Treatment.*** Preceding antibiotic therapy associated with the colitis should be stopped. The first line of antibiotic treatment is oral metronidazole and supportive measures including rehydration. Other oral or intravenous (IV) antibiotics may be needed initially and with recurrence; colectomy is now rarely indicated.

## HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is a thrombotic, nonimmune, microangiopathic condition characterized by renal failure, hemolytic anemia, and thrombocytopenia.[2,41] In children, it can be related to foods such as undercooked meat in 90% of cases, causing infection often with diarrhea. The syndrome has a peak incidence of approximately 6.1 per 100,000 in children aged less than 5 years.[41]

***Etiology.*** Most cases of HUS are caused by a Shiga-like toxin produced by *Escherichia coli* serotype 0157:H7 (STEC-HUS). This is found in raw or incompletely cooked beef and unpasteurized dairy products. Rarely HUS can arise from severe disseminated *Streptococcus pneumoniae* (pneumococcal-HUS). When these infections are excluded, HUS is designated atypical (aHUS), usually without diarrhea, and dysregulation of the complement system is recognized as the pathogenic effector mechanism.[2,41] Hemorrhagic colitis is common. Renal and central nervous system complications can markedly affect the course and prognosis of this disease; outcomes typically are more severe in aHUS.[41–43]

***Clinical Presentation.*** STEC-HUS is most common during the summer months in children younger than 5 years of age. It has a spectrum of clinical manifestations from asymptomatic carrier, to a short GI prodrome averaging 3 days from ingestion with nonbloody diarrhea, to clinical evidence of acute renal failure, fever, anemia, and thrombocytopenia.[2,42–44] A positive stool culture for the specific Shiga toxin–producing *E. coli* pathogen is definitive when positive. Pneumococcal-HUS may have respiratory and neurologic features in addition to the more severe HUS triad.[2] aHUS occurs as a single event, more frequently progressing to a chronic condition.[41]

***Imaging.*** In hemorrhagic colitis, US reveals concentric wall thickening, echogenic pericolonic fat, and narrowing of the bowel lumen, primarily affecting the cecum and ascending colon, although the small bowel may be affected.[45] These features are nonspecific and may be seen in other infiltrative and inflammatory colitides. Radiographs may show colon "thumbprinting."[46] This is better seen on CT and MRI (which are rarely indicated), with contiguous bowel wall thickening, free fluid, and fat stranding.[47] Radiographic IV contrast media should be avoided due to renal impairment. There is no role for fluoroscopy. Toxic megacolon and colonic perforation have been reported, and colonic strictures can occur as a late complication.[48]

***Treatment.*** Initial treatment for HUS is supportive and may include IV fluids, transfusion of blood products, and management of hypertension. Supportive renal dialysis, if needed, is usually for 10 days in 40% to 50% with STEC-HUS, with recovery of renal function in 55% to 70% of cases.[41] Patients with aHUS may need longer renal replacement support and have worse outcomes. Use of a monoclonal antibody eculizimab, blocking the C5 cascade, is showing promising results in limiting duration of HUS in the acute phase and improving outcomes after transplantation, reducing HUS recurrence.[2]

## RADIATION COLITIS

Secondary toxicity to the GI tract is a known complication of radiation therapy. The incidence of radiotherapy-related bowel toxicity is variable depending on the radiation port, radiation dose, dosing schedule, underlying bowel condition, and comorbidities. The presentation can be acute or chronic, and different mechanisms are responsible for each. The changes can occur months to years after exposure and may involve the small bowel, colon, or rectum.[49]

***Etiology.*** Radiation injury leads to activation of mucosal cytokines and increased levels of inflammatory mediators such as interleukin (IL)-2, IL-6, and IL-8.[50] The acute changes are attributed to inhibition of epithelial cell mitotic activity and thus denudation of the mucosal surface. The chronic changes are sequelae of progressive obliterative endarteritis and fibrosis that result in variable degrees of ischemia, necrosis, and eventually stricture and fistulae formations.[51] Radiation enteritis tends to develop in patients who have received in the order of 45 Gy but can occur with doses as low as 5 to 12 Gy.[49,52]

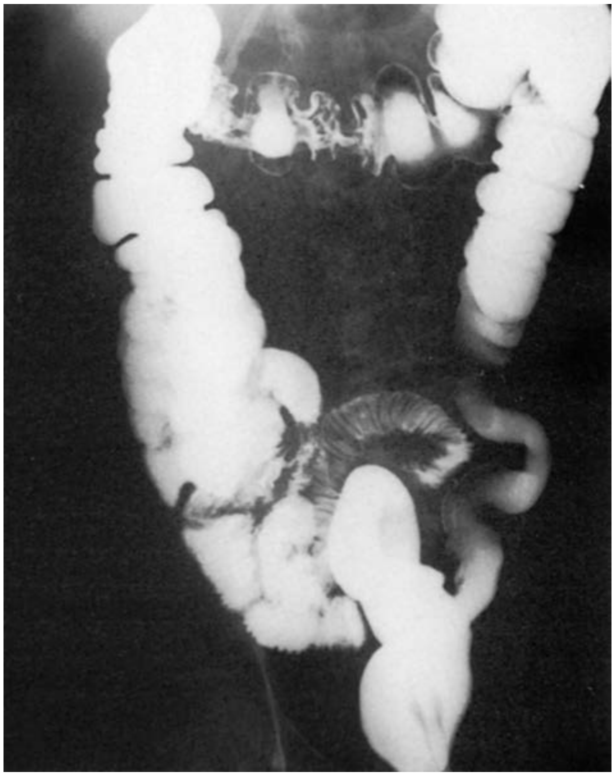
***Clinical Presentation.*** Diarrhea, cramping, and sometimes lower intestinal bleeding occur in the acute phase, which is usually self-limiting. Urgency and tenesmus can also be seen with radiation proctitis. Eventually, fibrosis may occur, which leads to stiffness and loss of mobility and distensibility of the affected portions of the colon. Additional complications include partial obstruction, chronic adhesions, and fragility of the bowel, which may culminate in perforation.[50] Perianal fistula, hematochezia, and incontinence have been reported in patients receiving pelvic radiation.[50,51]

***Imaging.*** Patients with radiation colitis do not usually undergo imaging examinations during the acute phase. Fluoroscopic imaging with contrast enema may delineate the chronic, fibrotic change to the affected colon (e-Fig. 106.10). The imaging findings range from normal (seen in 15%) to ulceration and contour abnormalities, intestinal fixation, decreased distensibility, and stenosis.[51] The "omega sign," caused by bilateral retraction at the base of a narrowed sigmoid loop, was seen in nearly 60% of patients with radiation colitis.[51] CT and MR show relatively nonspecific findings of bowel wall thickening with an occasional target sign in acute stages and stenosis later on. The main diagnostic clue is the distribution of these changes within the radiation port.[49]

***Treatment.*** Treatment is geared toward symptom relief and includes dietary changes in addition to medications for nausea and diarrhea. Initial medical treatment usually includes antiinflammatory medications such as oral- or enema-delivered steroid or 5-aminosalicylic acid preparations.[51] Treatment options also include sucralfate, short-chain fatty acids, misoprostol, hyperbaric oxygen, and antioxidant vitamins.[51] Management of patients with chronic disease can be challenging; as many as 30% of patients may require surgery for fistulae, perforation, or bowel obstruction that does not respond to nonsurgical management.[52]

## NEUTROPENIC COLITIS

Neutropenic colitis, also known as *typhlitis*, is a necrotizing colitis primarily seen in children with low neutrophil counts from hematopoietic malignancies, although it is also seen in children with solid tumors who undergo high-dosage chemotherapy.[53] There are no definitive diagnostic criteria, although diagnosis is typically made when clinical and imaging findings are suggestive.



**e-Figure 106.10. Radiation colitis in an 8-year-old boy who had received radiation therapy for pelvic tumor 3 years earlier.** Barium enema shows narrowing, rigidity, and loss of haustration in the distal descending and sigmoid portions of the colon.

***Etiology.*** Development of the condition is associated with chemotherapy-related low neutrophil counts (usually less than $1.5 \times 10^9$/L) at which point the host immune system is impaired. It usually occurs between weeks 1 and 2 postchemotherapy corresponding to the neutrophil count nadir.[54] Acute lymphocytic and myelogenous leukemia are the most common underlying malignancies in pediatric patients.

The disease most often affects the cecum, hence the term typhlitis. This preferential vulnerability of the cecum is thought to be attributed to its relative low vascularity and blood supply.[54] The appendix may be involved and may produce clinical findings that mimic acute appendicitis.[55] Edema and inflammation of the colon (mainly the ascending colon) and the terminal ileum may occur, although other bowel segments can be involved.[54,56] Pneumatosis, perforation, or abscess may supervene. Bowel wall thickening, transmural edema with mucosal ulceration, ecchymoses, fibrin exudates, and partial- to full-thickness hemorrhagic necrosis are often discovered only at autopsy.[54]

***Clinical Presentation.*** This condition occurs in less than 5% of children with neutropenia. Abdominal pain, diarrhea, fever, and distended abdomen are the common presenting symptoms.

***Imaging.*** Radiographs are typically nonspecific and may show a focal ileus in the right lower quadrant. Often, a sentinel loop of dilated terminal ileum may be seen.[57] Enema studies are contraindicated in the acute phase and while there is neutropenia. Because the clinical presentation may mimic acute appendicitis, cross-sectional imaging is a critical diagnostic differentiating tool. US shows a markedly thickened cecal wall that may be either hyperechoic or hypoechoic.[58] Intraluminal fluid and ascites may also be identified. CT shows marked thickening of the affected portions of the colon, which is usually more marked in the cecum, surrounding inflammatory change and free fluid (Fig. 106.11).[56] Extension of this process may involve the terminal ileum and the appendix.

***Treatment.*** Management most often is conservative and includes antibiotics, but rarely bowel resection is necessary. Recovery is more related to the presence and severity of comorbidities than to the neutropenic colitis.[59]

## GRAFT-VERSUS-HOST DISEASE COLITIS

Graft-versus-host disease (GVHD) colitis can be seen in the immunocompromised patient postallogenic bone marrow transplantation. It occurs when the donor lymphocytes in the graft mount an immune reaction against the host. GVHD usually affect the skin, liver, and GI tract (predominantly the ileum and colon).[60]

***Clinical Presentation.*** GVHD is classified as acute when it occurs during the first 100 days and chronic when it happens after 100 days, although there can be overlap.[61] Patients can present with maculopapular rash, increased conjugated bilirubin and alkaline phosphatase, watery or bloody diarrhea and abdominal pain, anemia or thrombocytopenia, and possible nephrotic syndrome.

***Imaging.*** CT imaging findings are not very specific and include wall thickening with a halo of decreased attenuation within the wall. With severe mucosal disease, there may be prolonged coating of both the small and large bowel with oral contrast material with incorporation of contrast into the bowel wall with healing.[60] The main diagnostic clue is the clinical history of bone marrow transplantation.

## INFECTIOUS COLITIS

The same agents that affect the small bowel, discussed in Chapter 104, usually cause the infectious colitides. Imaging is rarely needed, and when performed shows nonspecific colitis. However, there are potential emerging infections to consider.

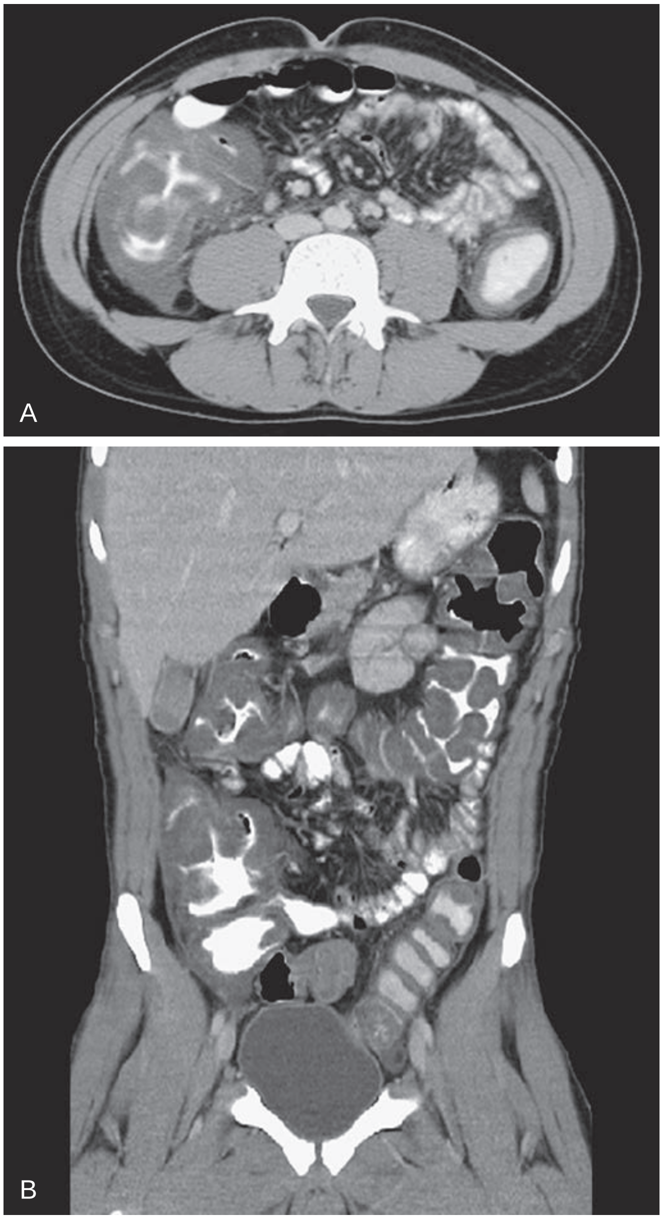


**Figure 106.11. Neutropenic colitis.** Contrast-enhanced CT in an 18-year-old man with acute myelogenous leukemia, fever, and neutropenia. (A) Axial image shows the marked thickening of the cecum and a small amount of free fluid. (B) Coronal reformat image shows pancolitis, affecting the right colon to a greater extent.

### Gastrointestinal Basidiobolomycosis

***Etiology.*** Previously known as a *chronic skin fungal infection*, gastrointestinal basidiobolomycosis infection (GIB) is a very rare invasive fungal infection caused by *Basiodobolus ranarum* with a predilection for large bowel. It is a mimicker of lymphoma and CD, the differential also including intestinal tuberculosis, sarcoidosis, schistosomiasis, and amebiasis. Left untreated, there is a high risk of perforation and a mortality rate of 18%.[62–64]

*B. ranarum* is found in soil and vegetation worldwide and is likely of low virulence given the small number of cases reported. However, GI infection is increasingly recognized in immunocompromised and, more recently, immune competent patients.

Males are affected more than females, with a slight increase in number of cases in the late first decade.[63]

***Clinical Presentation.*** Patients typically present with fever and vomiting, abdominal pain, constipation, weight loss, and a palpable abdominal mass.[63,64] Marked eosinophilia and raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also present.[65] Blood, urine, and fecal samples are usually negative for fungi.[63] Biopsy shows transmural granulomatous inflammation and a prominent eosinophilic component, and the diagnosis is confirmed by tissue biopsy with polymerase chain reaction (PCR), with fungal hyphae and zygospores on staining.[63]

***Imaging.*** US is the first imaging modality and may show a large soft tissue mass involving the cecum and extending beyond the wall, typically sparing the appendix, with multiple regional mesenteric lymph nodes. CT has a similar appearance with bowel wall thickening, large lobulated soft tissue mass(es) centered in the cecum and ascending colon, with luminal narrowing with or without obstruction (e-Fig. 106.12). Perforation or abscess can be seen.[63,64] One study showed the large bowel was involved in 82% and small bowel in 36%, with liver and gallbladder disease in 30%.[64]

***Treatment.*** Early recognition to avoid perforation is critical. Surgical resection of the infected tissue followed by a prolonged course of itraconazole is the preferred treatment, with good results.[62–64]

## FIBROSING COLONOPATHY

Fibrosing colonopathy was first described in 1994 in patients with cystic fibrosis (CF) who received lipase replacement therapy.[66]

***Etiology.*** The majority of CF patients depend on pancreatic-enzyme supplements to treat exocrine pancreatic insufficiency. With the introduction of oral, enteric-coated, high-dose pancreatic enzyme medication, clinicians increased the amount of enzyme supplements to many of these patients. Some who received particularly high doses later came to medical attention with what has been termed *fibrosing colonopathy*.[67] Children were at higher risk than adults, until strict dosage guidelines were implemented. This entity is now rare because of compliance with appropriate dosage recommendations.[68]

***Clinical Presentation.*** The clinical presentation includes abdominal pain, distension, nausea, vomiting, constipation, and occasionally colonic obstruction. Although nonspecific, these signs and symptoms do not respond to medical therapy.

***Imaging.*** The most common contrast enema findings are colonic strictures, loss of haustra, and colonic shortening.[69] The bowel wall may be thickened, and ascites may be evident on cross-sectional imaging.

***Treatment.*** Some of these patients require surgery to relieve the obstruction, and they may also require resection of the fibrotic segment of colon.[68]

## APPENDICITIS

The vermiform appendix is a thin, tubular, intestinal diverticulum attached to the base of the cecum that is often referred to as a *vestigial organ*. Although conventional wisdom asserts that the appendix has no function, there is increasing evidence suggesting that it plays a role in immune function and as a reservoir for normal gut flora.[36,37] Inflammation of the appendix remains the most common indication for surgery in both children and adults. There are approximately 70,000 to 90,000 pediatric cases annually in the United States with an estimated incidence of 75 to 233 per 100,000 children. The incidence increases with age and peaks in adolescence. The lifetime risk to develop appendicitis is 8.6% for males and 6.7% for females.[70] Although rare, appendicitis does occur in young children and infants. Boys are affected more frequently than girls by a ratio of 1.4 to 1.0. Classically, appendicitis has been considered a clinical diagnosis with reported negative appendectomy rates between 12% and 20%.[70,71] This rate is no longer considered acceptable given operative complication rates and improvements in imaging diagnoses.[72] Preoperative imaging results in noticeable decrease of the negative appendectomy rate without increasing the rate of perforations.[73] Negative appendectomy rates have declined to 5% in many centers with the increased use of preoperative US and CT.[74]

***Etiology.*** Appendicitis commonly occurs in the setting of luminal obstruction. Subsequent distension of the appendix and ischemic mucosal damage leads to bacterial overgrowth and invasion of the wall that, in turn, results in transmural inflammation and ultimately in perforation. Luminal obstruction may be secondary to the presence of fecaliths, hyperplasia of lymphoid follicles, and foreign bodies that include parasites and neuroendocrine (carcinoid) tumors.[75] The pathophysiology of appendicitis is believed to be a dynamic process that occurs over 24 to 36 hours. Although infrequent, subacute appendicitis and spontaneous resolution of acute appendicitis have been described. Spontaneous resolution of luminal obstruction is the proposed pathophysiology in these cases and has been mostly associated with CF and appendiceal lymphoid hyperplasia.[76,77]

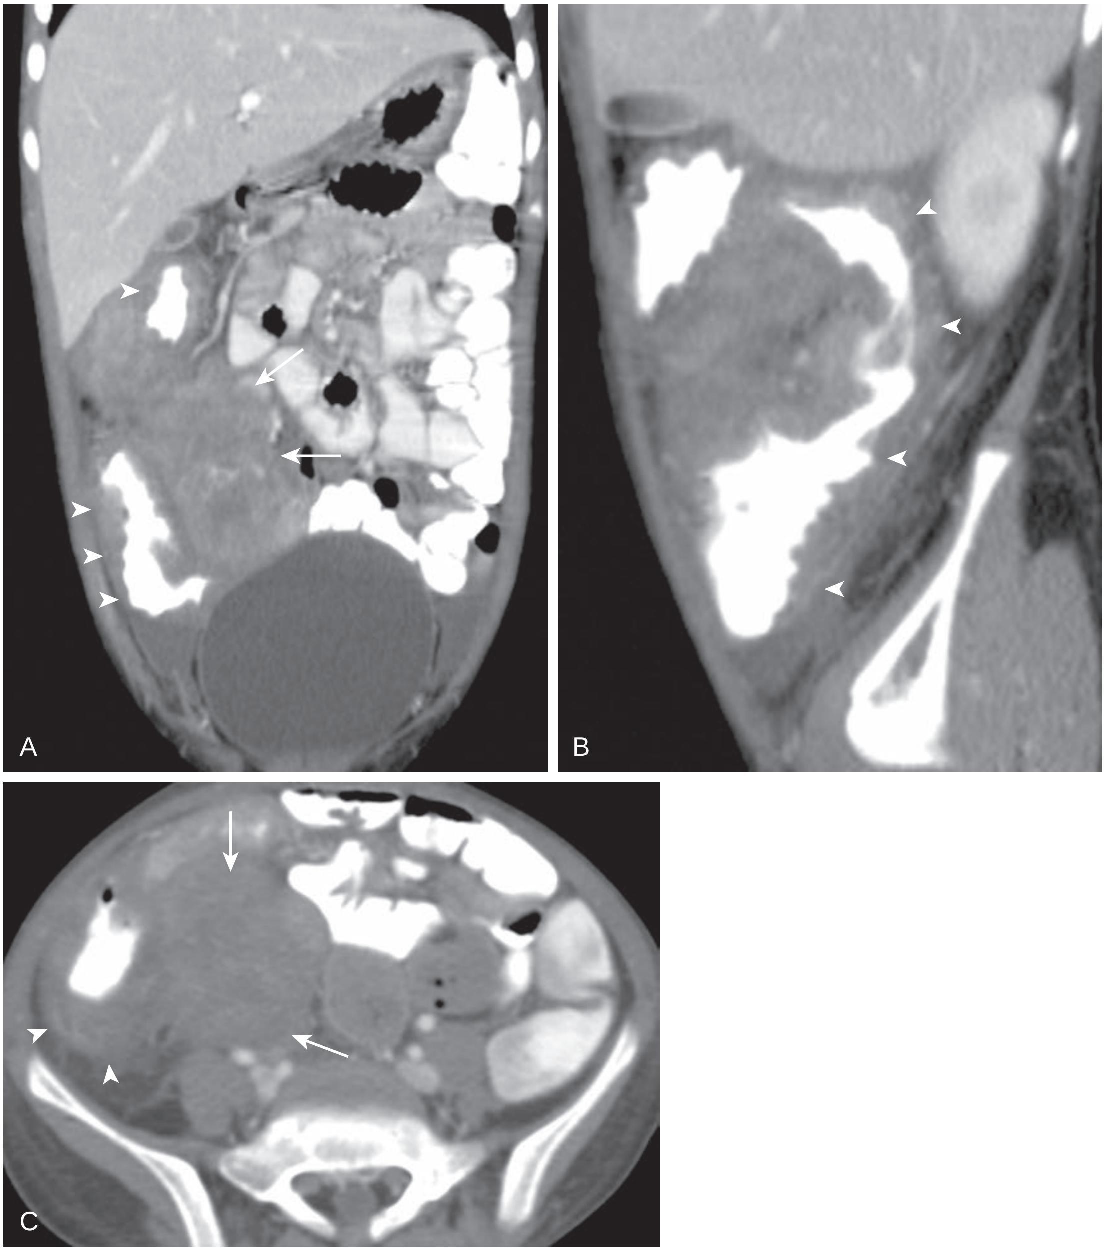
***Clinical Presentation.*** Appendicitis can be a challenging diagnosis in children; the clinical presentation is nonspecific in approximately one-third of patients.[78] The classic clinical presentation—early periumbilical pain, followed by migration of localized pain to the right lower quadrant, with associated fever and vomiting—occurs in less than 50% of pediatric patients.[79] More often, the constellation of findings is nonspecific. Younger children may be unable to communicate symptoms effectively, resulting in delayed diagnosis and higher perforation rates. Initial relief of pain and/or more generalized abdominal pain with fever occurs after perforation, which usually results in a local phlegmon or walled off abscess adjacent to the appendix. Perforation is usually contained by the omentum, but generalized peritonitis can also occur. Reported perforation rates in children range from 23% to 88%.[78]

***Imaging.*** Imaging plays a vital role in diagnosing suspected appendicitis. The effectiveness of imaging for suspected appendicitis in children has been debated in the medical literature, which has specifically looked at the impact of imaging on the negative appendectomy and perforation rates. Several studies suggest a stable perforation rate with preoperative imaging,[80–82] whereas others demonstrate a significant decrease in perforation rate, from 35% to 15.5%, with preoperative imaging.[83] A decrease in the negative appendectomy rate has been demonstrated in numerous studies.[83–85] CT generally outperforms US in depicting the inflamed appendix, but increased awareness and concerns about radiation dose and long-term adverse effects has restricted CT use in children with suspected appendicitis.[86,87] Most pediatric centers use US as a first imaging modality, reserving CT (and increasingly MRI) for unclear/equivocal or problematic cases.

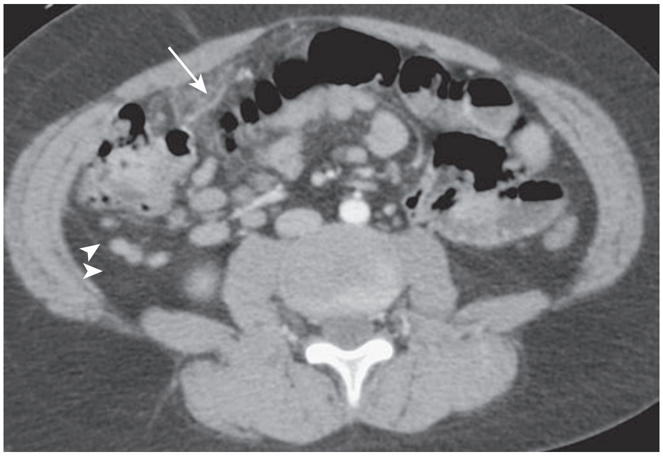
When the appendix is normal, alternative diagnoses, particularly in young children, must be considered. The differential diagnoses, in decreasing order of prevalence, are mesenteric adenitis, ovarian cyst, pyelonephritis, infectious or inflammatory colitis, omental infarction (e-Fig. 106.13), urinary system stones, and inflamed Meckel's diverticulum.[88,89] A summary of imaging findings is listed in Box 106.1.

### Radiographs

Before the advent of current cross-sectional imaging modalities, imaging of appendicitis relied on abdominal radiographic findings, which are often normal or nonspecific in approximately 77% of



**e-Figure 106.12. Gastrointestinal basidiobolomycosis (GIB).** Abdominal CT with oral and intravenous contrast in a 6-year-old boy who presented with fever, abdominal pain, and diarrhea for 2 weeks. (A) Coronal, (B) sagittal and (C) axial images demonstrate diffuse mural thickening of large bowel *(arrowheads)* secondary to this invasive fungal infection, preferentially involving cecum, ascending colon and hepatic flexure. Medially, in the right lower quadrant, there are large, rounded soft tissue density masses extending beyond bowel into the retroperitoneum *(arrows in A and C)* with intermingled nodal enlargement. The differential includes Burkitt lymphoma. *(Courtesy Dr. Abeer Almehdar, King Abdulaziz Medical City, Jeddah, Saudi Arabia.)*



**e-Figure 106.13. Omental infarction.** Contrast-enhanced CT through the lower abdomen in a young boy who underwent CT for clinically suspected appendicitis. Note typical location of edematous omentum anterior to the cecum with a prominent central vein *(arrow)*, a classic finding in omental torsion. Portions of the normal retrocecal appendix *(arrowheads)* are seen, as are several incidental mesenteric nodes medial to the cecum. The patient was managed expectantly, with resolution of the symptoms. *(Courtesy Dr. Marta Hernanz-Schulman, Nashville, TN.)*

children with appendicitis.[79] The presence of a radiographically visible appendicolith, considered to be the most specific radiographic sign of appendicitis, is only present in 5% to 15% of patients with appendicitis.[79,90] Appendicoliths are seen in 43% to 50% of cases on CT and are multiple in 30% (e-Fig. 106.14).[91,92] Additional nonspecific radiographic findings include a paucity of bowel gas or a soft tissue mass in the right lower quadrant, ileus that may be either focal or diffuse, and less often, small bowel obstruction.[93] Mild levoconvex curvature of the spine may be present as a result of splinting in response to abdominal pain.

## Ultrasound

US using a graded compression technique for evaluation of appendicitis was first described in 1986.[93] Numerous studies have addressed the efficacy of US and to evaluate additional sonographic findings.[94–98] The limitations of US include operator experience, larger patient body habitus, and limited field of view. Optimized technique for US evaluation of suspected appendicitis is essential. The examination is performed with a high-frequency linear transducer that ranges from 9 to 15 MHz, depending on the size of the patient. A linear transducer is necessary not just to obtain the appropriate resolution but also to effect adequate graded compression. Graded compression is essential, because it displaces overlying bowel gas and helps decrease the distance between the transducer and the appendix. Additionally, compression helps differentiate normal bowel from an inflamed appendix. The compression is "graded" in that it is exerted slowly, without sudden release, to optimize patient tolerance and prevent rebound tenderness. Transverse and longitudinal scans are performed over the point of maximal tenderness. A recommended approach is to start by locating the cecum, ileocecal valve, and the terminal ileum, then to gently angle the probe caudally. The appendix is most commonly seen in the midpelvic region over the right common iliac vessels. If the appendix is not identified at this point, additional sonographic interrogation is necessary given the variability in location of the appendiceal tip. The appendix can be found in the retrocecal region, deep pelvic region, and abdomen above the iliac crests.[99] Visualization of the tip of the appendix, the base, and the full length of the blind-ending tubular structure should be clearly described in the report.

US demonstration of the normal appendix is useful in excluding the diagnosis of appendicitis, characterized as a compressible, blind-ending tubular structure originating from the base of the cecum without peristalsis; diameter less than 6 mm; absence of wall thickening (<3 mm); and presence of a central echogenic line that represents acoustic reflection from the collapsed luminal interface (Fig. 106.15).[98,100,101] The terminal ileum can mimic the appendix but is distinguished by its hypoechoic folds and peristalsis.

The US signs of an inflamed appendix include a noncompressible, blind-ending tubular structure with a transverse diameter measuring greater than 6 mm. Additional features include appendiceal wall thickness greater than 3 mm, wall hyperemia on color Doppler, periappendiceal hypoechoic halo that reflects appendiceal wall edema, periappendiceal hyperechogenicity that reflects periappendiceal edema, and the presence of an appendicolith, variably accompanied by bright periportal echoes in the liver (Fig. 106.16).[97,102]

These secondary sonographic findings vary depending on the progression of the inflammatory process. In a multivariate analysis by Trout et al.,[103] the inflammation of the periappendiceal fat (Fig. 106.17) was the only finding statistically significant in predicting acute appendicitis (odds ratio (OR) = 68.93, $P < 0.0001$), other criteria, though not independently predictive of appendicitis, remain important markers pointing toward the diagnosis of appendicitis. Kessler et al.[104] found that the most accurate appendiceal finding for appendicitis was a diameter of 6 mm or larger, with a sensitivity, specificity, negative predictive value and positive predictive value of 98%. These and other studies support that a constellation of findings is the most accurate in making the diagnosis of appendicitis.

Early uncomplicated appendicitis will demonstrate a target-like appearance with hypoechogenicity centrally as a result of luminal distension with pus or fluid, increased echogenicity of the inflamed submucosa, hypoechoic edematous serosa, and increased periappendiceal echogenicity (see Fig. 106.17). As the inflammatory process advances and suppurative appendicitis ensues, the periappendiceal tissues demonstrate a heterogeneous pattern of increased

### BOX 106.1 Imaging Features in Acute Appendicitis

**PLAIN RADIOGRAPHS**

- Ileus, often localized to right lower quadrant
- Antalgic scoliosis from splinting
- Appendicolith
- Small bowel obstruction, most commonly in younger children
- Abscess with mass effect and/or atypical air collection

**ULTRASOUND**

- Appendiceal diameter >6 mm
- Noncompressible appendix
- Increased flow in wall with color Doppler
- Appendicolith with acoustic shadowing
- Periappendiceal fluid or abscess
- Periappendiceal echogenic fat
- Perforation that may decompress the appendix
- Abscess

**COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE**

- Dilated appendix >7 mm
- Wall enhancement and thickening with surrounding fat stranding
- Appendicolith or luminal pus
- Abscess or phlegmon

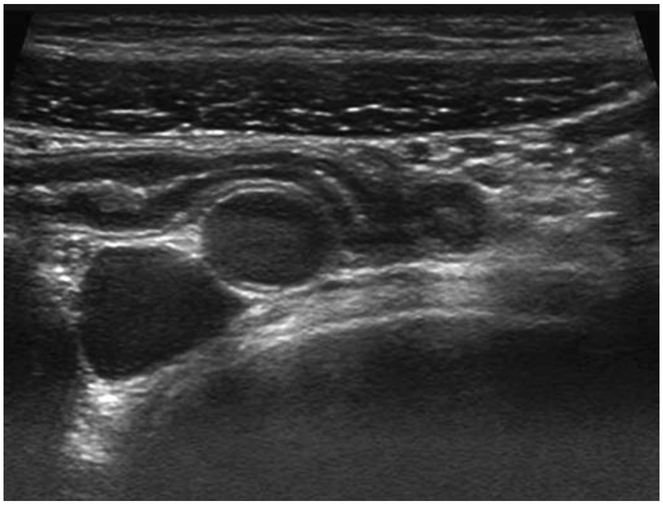


**Figure 106.15. Normal appendix.** Ultrasound image of the normal appendix shows typical location of a nondilated, blind-ending tubular structure posterior to the terminal ileum and anterior to the iliac vessels with a central echogenic line within the nondistended appendix.

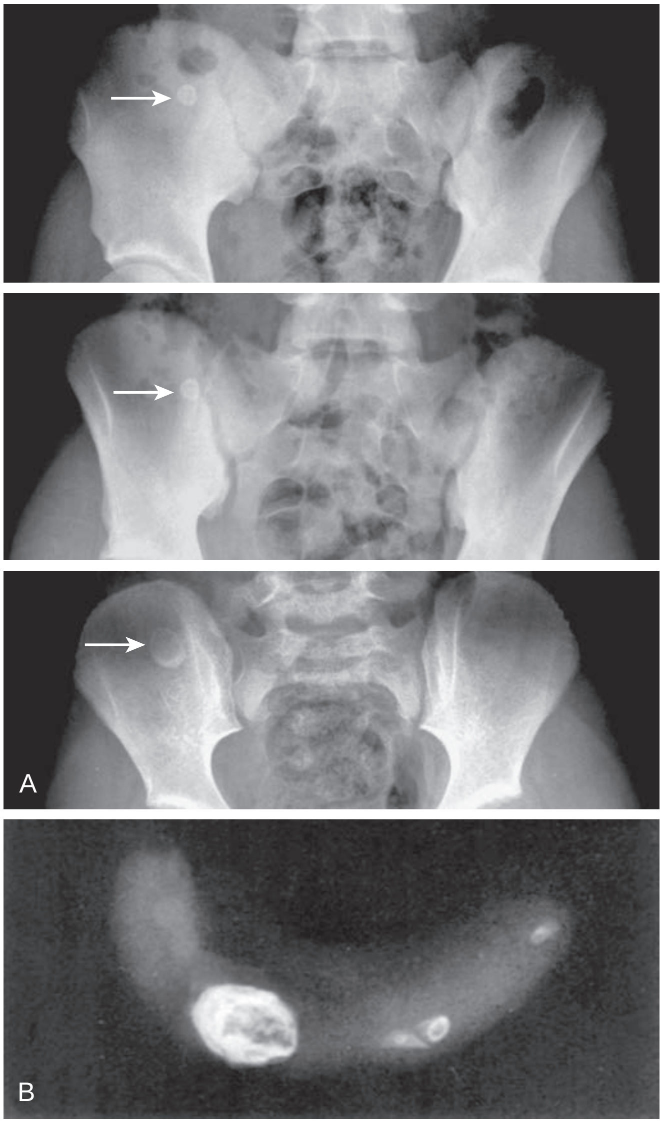

**e-Figure 106.14. Acute appendicitis.** (A) Radiographs showing appendicoliths *(arrow)* in three different patients. (B) Resected appendiceal specimen in another patient shows a large appendicolith obstructing the appendiceal lumen.

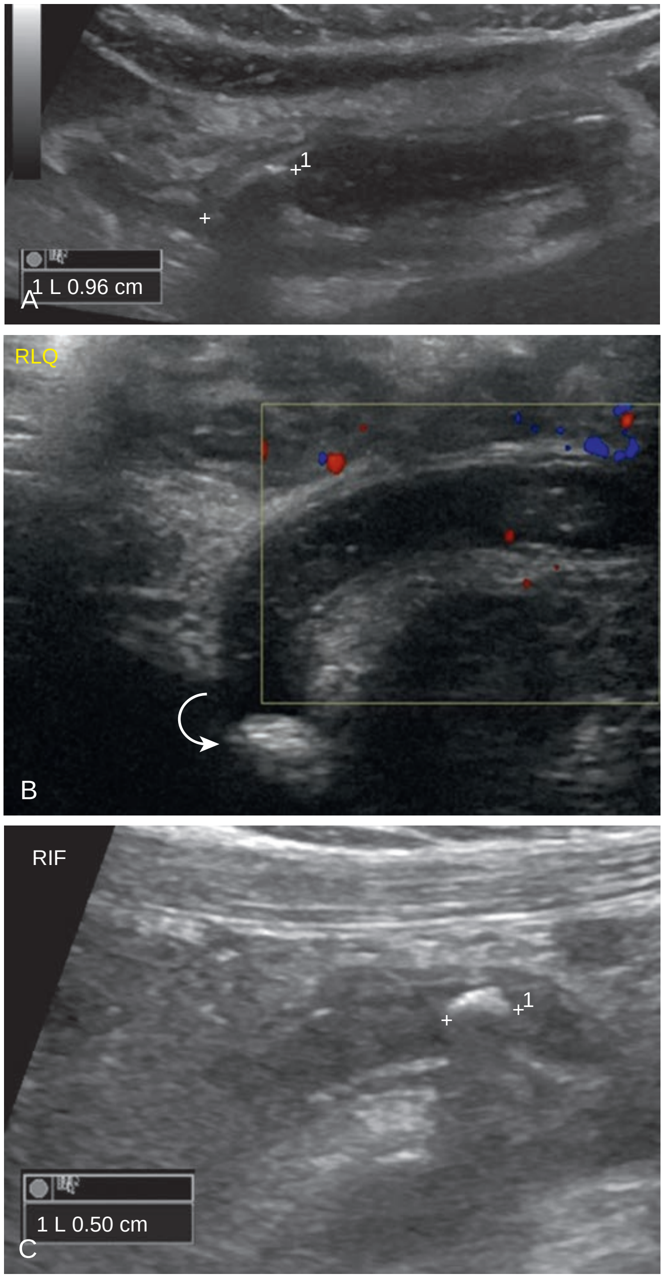

**Figure 106.16. Appendicoliths.** (A) Gray-scale and (B) color Doppler sonograms in two patients with appendicoliths at the base of dilated fluid-filled inflamed appendices (indicated by *calipers* in A, *curved arrow* in B). (C) Companion sonogram of an appendicolith (indicated by *calipers*) with no other sonographic signs of acute inflammation.

echogenicity with hyperemia on color Doppler (Fig. 106.18). Increasing appendiceal dilatation, interruption or loss of the echogenic submucosal layer, and absence of vascularity with color Doppler are signs of supervening gangrenous change and portends pending microperforations (Fig. 106.19). Although the abnormal appendix may not be visualized with perforated appendicitis, sonographic findings suggestive of perforation include phlegmon with poorly defined bowel loops in the right lower quadrant demonstrating increased echogenicity, a mass of mixed echogenicity, focal bowel wall thickening, intraperitoneal fluid, loculated fluid collections, or frank abscess. On occasion, the perforated appendix may appear decompressed with a diameter less than 6 mm.

Absence of visualization of an abnormal appendix in the setting of acute appendicitis may be due to a retrocecal location, obscuration by superimposed bowel gas, or limited US penetration. Additionally, appendiceal inflammatory changes may be confined to the tip of the appendix which is commonly referred to as *tip appendicitis*.[105] If the entire appendix has not been visualized on US, and clinical symptoms suggest appendicitis or other intraperitoneal pathology, further imaging may be warranted, particularly if there are secondary signs of right lower quadrant inflammation.

## Computed Tomography

CT is highly sensitive and specific for the diagnosis or exclusion of appendicitis in children. It is often utilized in the setting of a negative or equivocal US or perforated appendicitis. Scanning parameters should be adjusted appropriately for the size of the child to optimize dose. CT protocols vary with respect to the administration of oral, IV, and rectal contrast in addition to targeted imaging versus imaging the entire abdomen and pelvis.[74] A systematic review concluded that IV contrast alone performs as well as or better than CT with IV and positive enteral contrast for the diagnosis or exclusion of appendicitis.[106]

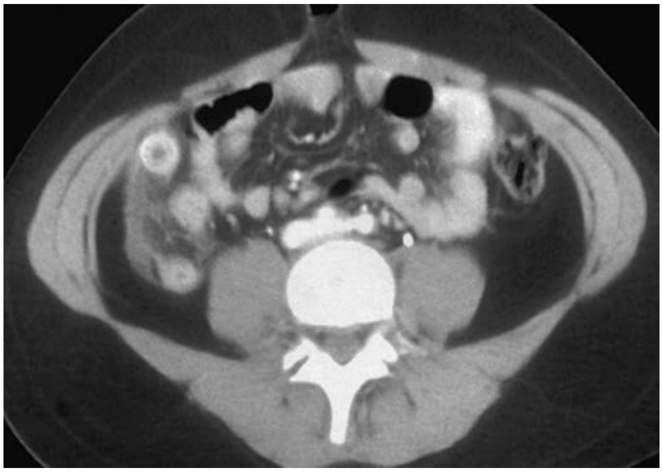
Although the average diameter of the normal appendix typically approximates 6 mm, actual size may vary on CT, from 2 to 11 mm, because the examination is not done with compression, and the appendiceal lumen may distend with gas or feces. The absence of associated CT signs of appendicitis is helpful to confirm a normal appendix. In a recent study, there were significant differences in intra- and interreviewer appendiceal diameter measurements, indicating that measurement alone is not a definitive appendicitis indicator and should not be interpreted in isolation of the other pertinent signs.[107]

As is the case with US, the appearance of the abnormal appendix varies with the histopathologic stage and severity of the disease process. The inflamed appendix on CT is a dilated, thick-walled tubular structure with centrally decreased attenuation that demonstrates wall contrast enhancement (e-Fig. 106.20 and Fig. 106.21). An obstructing appendicolith may be present in up to 50% of cases (Fig. 106.22).[91,92] Adjacent inflammation produces periappendiceal stranding and fluid. Additional nonspecific findings include intraperitoneal free fluid, cecal wall thickening and thickening of adjacent terminal ileum and sigmoid colon, small bowel obstruction, and mesenteric lymphadenopathy.[108]

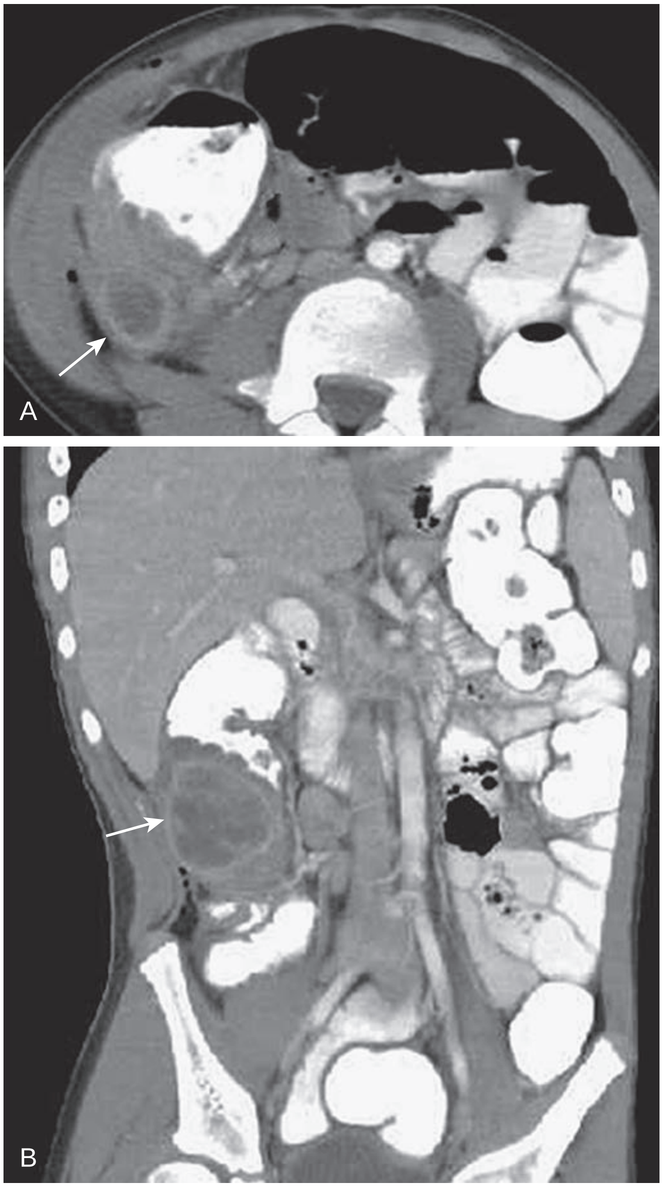
With perforation, the appendix may decompress or may even fail to be visualized. Perforation may result in diffuse intraperitoneal inflammation or, more commonly, in localized phlegmon and abscess formation (e-Fig. 106.23). Diffuse peritonitis is more common in infants younger than age 2 than in older children. Hepatic abscesses and mesenteric or portal pyelophlebitis can also occur. CT is extremely helpful in identifying and characterizing smaller abscesses and extruded fecaliths that may act as a potential source of recurrent infection.

## Computed Tomography and Ultrasound

CT and US are reported to have a nearly equivalent specificity, 95% and 94%, respectively.[109] Although CT has a greater sensitivity than US (94% and 88%, respectively, bearing in mind that US is much more variable and operator dependent),[109] concerns regarding the potential risks of ionizing radiation exposure associated with CT have prompted increasing use of US in the imaging evaluation of suspected appendicitis.[110,111] US is considered the most appropriate initial imaging modality to evaluate children with suspected appendicitis by the American College of Radiology appropriateness criteria. Various imaging algorithms have been described in the literature that includes the staged utilization of initial evaluation



**e-Figure 106.20. Acute appendicitis.** Contrast-enhanced CT image shows a dilated, enhancing appendix with marked periappendiceal inflammation.



**e-Figure 106.23. Perforated appendix.** (A) Contrast-enhanced CT image with enteric contrast shows a well-defined retrocecal abscess *(arrow)* with adjacent cecal wall thickening and mesenteric adenopathy medial to the cecum. (B) Coronal CT reformat shows the full craniocaudal extent of the abscess *(arrow)*.

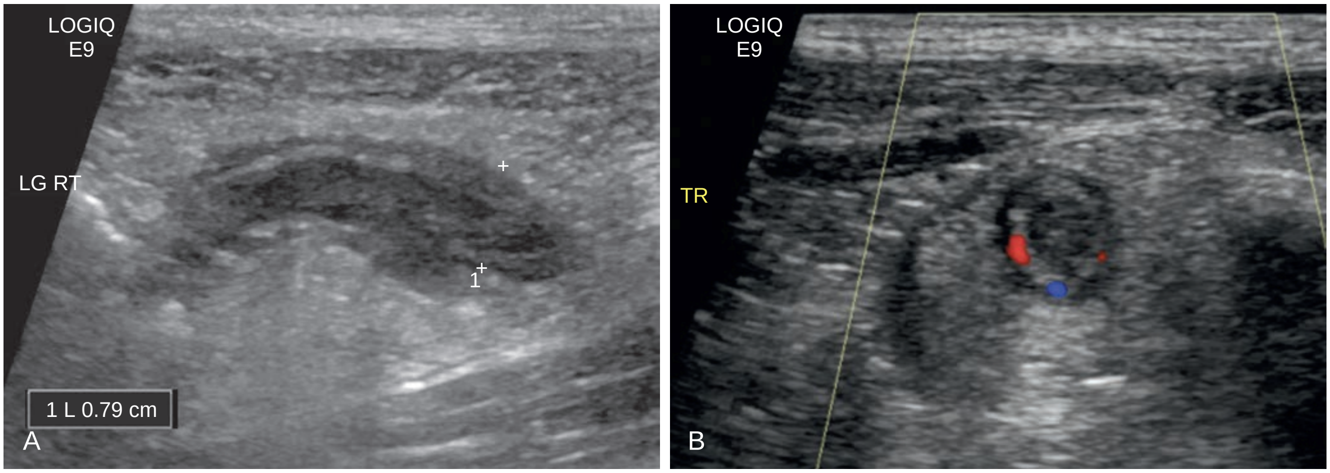


**Figure 106.17. Acute appendicitis.** (A) Longitudinal and (B) transverse color Doppler sonograms from a 13-year-old boy with acute right lower quadrant pain demonstrate a distended hypoechoic lumen, thick-walled, hyperemic appendix *(target sign)*. Circumferential zone of increased echogenic tissue around appendix in keeping with regional inflammation, possibly walled off by omentum.

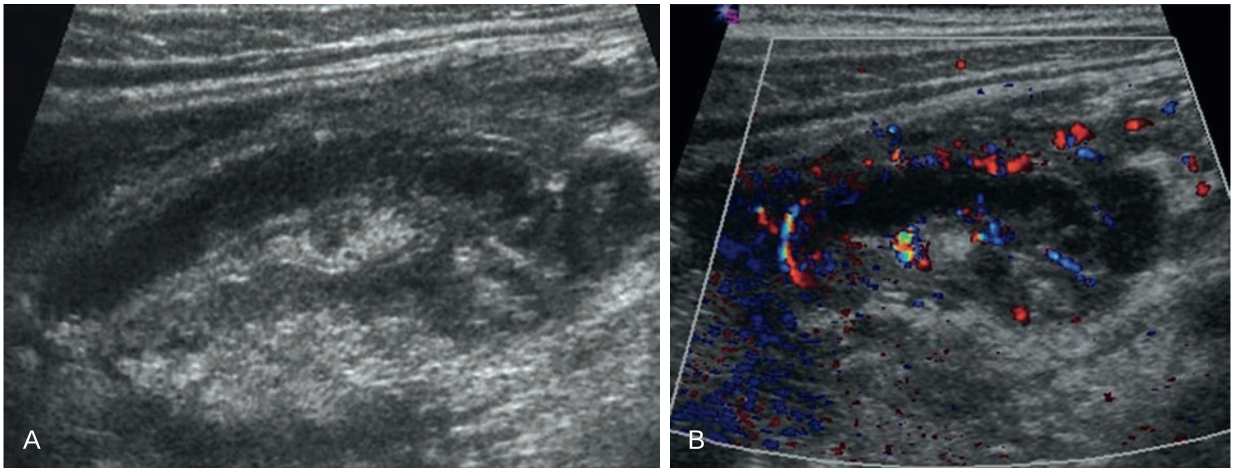

**Figure 106.18. Advanced acute appendicitis.** (A) Sonogram shows an abnormal appendix with increased mixed echogenicity of the adjacent tissues and a small amount of periappendiceal fluid. (B) Color Doppler sonogram demonstrates hyperemia in the wall of the appendix and in the adjacent soft tissues.

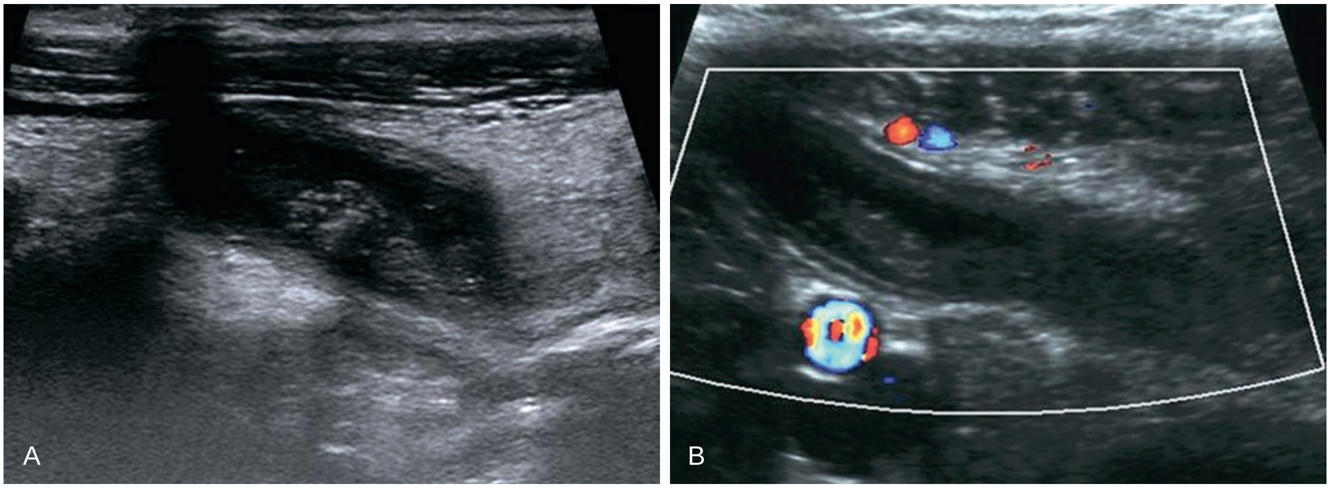

**Figure 106.19. Gangrenous appendicitis.** Longitudinal gray-scale (A) and color Doppler (B) sonograms show a dilated appendix with loss of the echogenic submucosal layer and absence of vascularity with color Doppler evaluation. There is increased echogenicity of the periappendiceal fat.

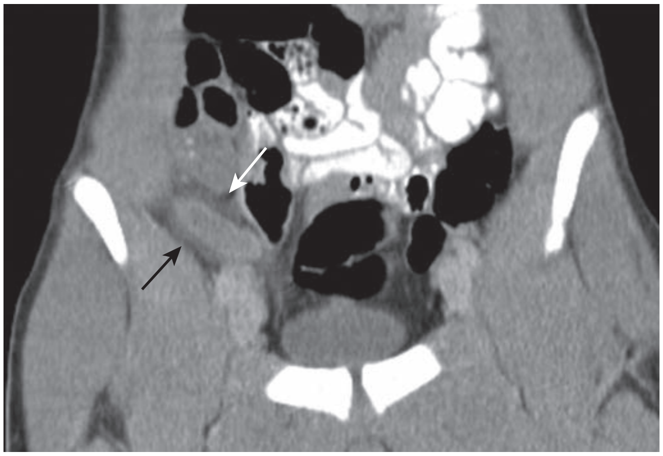

**Figure 106.21. Acute appendicitis.** Coronal reformatted contrast-enhanced CT image of the pelvis demonstrates a dilated appendix with wall enhancement and periappendiceal inflammation *(arrows)*.

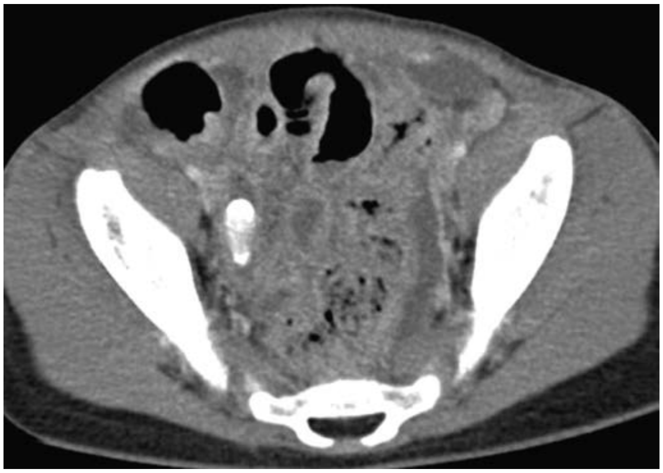

**Figure 106.22. Perforated appendicitis.** Axial contrast-enhanced CT image shows an appendicolith in the right lower quadrant in the remnant of the appendix. Extensive peritoneal inflammation is present with several abscesses.

**TABLE 106.2** Diagnostic Performance (%) of MRI Versus US and CT in Children With Suspected Appendicitis

| | MRI^ | US^ | MRI ** | CT** |
|---|---|---|---|---|
| Sensitivity | 93.3 | 90.0 | 94.4 | 100 |
| Specificity | 98 | 86.3 | 100 | 97.9 |
| PPV | 96.5 | 79.4 | 100 | 97.8 |

with US followed by CT for equivocal or nondiagnostic US studies.[74,112,113] The reported ratio of US to CT in one of the largest prospective studies that follow this algorithm was about 6:1 overall and 24:1 in children.[113]

## Magnetic Resonance Imaging

MRI has been reported to yield excellent results in the evaluation of suspected appendicitis with high sensitivity and specificity (Table 106.2).[114,115] Imaging protocols vary between institutions, but typically use unenhanced sequences with average examination times of 14 to 25 minutes.[116,117] The abnormal appendix demonstrates thickening of the appendiceal wall with high-signal intensity on T2-weighted images, a dilated lumen with high T2-signal intensity contents with restricted diffusion (indicating pus), and increased signal intensity of the periappendiceal tissues (Fig. 106.24).[118]

Although MRI has the appealing advantage of no ionizing radiation, current limitations precluding routine use of MRI for suspected appendicitis include a relatively long examination time and limited availability compared with CT. Sedation may be needed for very young children, although faster sequences and imaging protocols have been described and performed without sedation in children as young as 3 years.[114,118]

Fig. 106.25 is a suggested imaging algorithm for suspected appendicitis in children and adolescents. This proposal draws

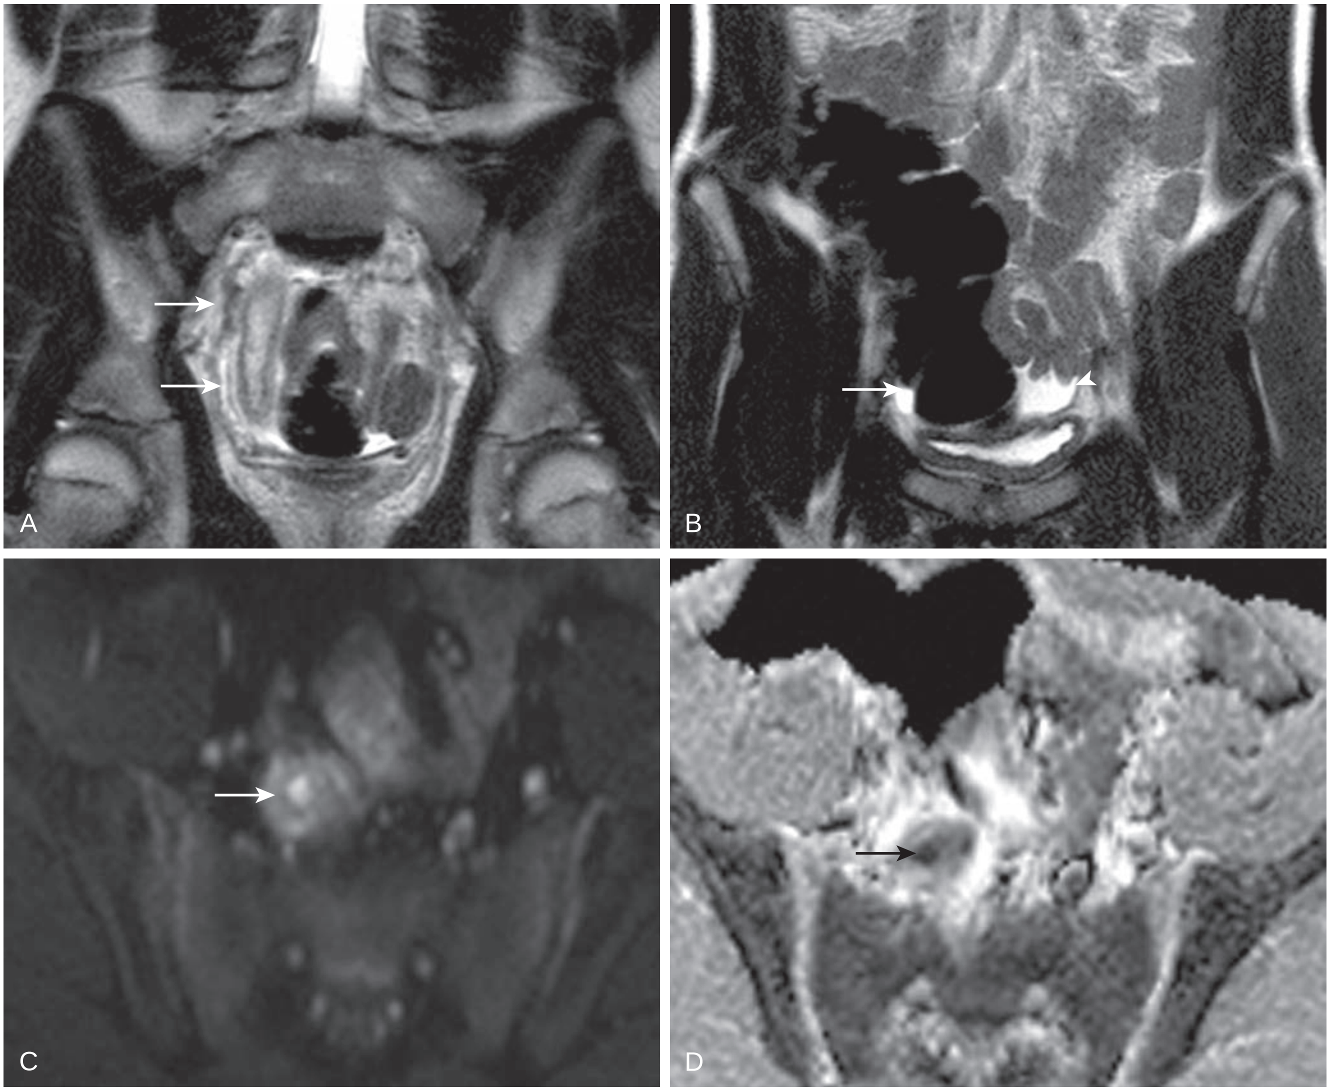

**Figure 106.24. Magnetic resonance imaging (MRI) of acute appendicitis.** A 13-year-old boy with vomiting and right lower quadrant (RLQ) pain. Ultrasound done initially was not diagnostic due to gassy RLQ. Coronal single-shot T2-weighted sequence with (A) distended blind-ending tubular appendix in RLQ *(arrows)* with wall and periappendiceal edema, and immediately anterior to this is (B) a gas-filled low lying cecum *(arrow)* and pelvic free fluid *(arrowhead)*. on available literature and the experience of various pediatric institutions.

***Treatment.*** Although appendectomy is the mainstay in the treatment of acute appendicitis, the literature is variable on the management of appendicitis and depends on the institution and the individual surgeon with respect to surgical procedure, timing of the surgical procedure, antibiotic therapy, and the clinical presentation of the patient.[119–121] Laparoscopic appendectomy has become a preferred surgical approach.[122,123] Several studies suggest that emergent appendectomy may not be necessary, and that IV antibiotics with appendectomies delayed for 12 to 24 hours after presentation do not significantly increase the rate of perforations, operative time, or length of hospital stay.[124,125] Timely imaging, however, remains essential for proper diagnosis and treatment planning. Patients with perforated appendicitis generally undergo antibiotic therapy followed by interval appendectomy several weeks later. If an abscess is present, the child will typically undergo image-guided drainage.[126]

## MISCELLANEOUS DISORDERS

### Colonic Volvulus

Colonic volvulus refers to a twisting or torsion of a portion of the colon, such as the cecum or the sigmoid. It is less common in children than in adults. When it occurs in children, the cecum is the most common area to twist; in adults, the sigmoid colon is the most common location.

***Etiology.*** A mobile cecum is a normal variant, seen in as many as 15% of individuals. Cecal volvulus is very rare in the pediatric population and results from dilatation of a mobile cecum, typically in patients with relative immobility, such as that resulting from neurologic impairment; cecal volvulus leads to obstruction and bowel distension.[127–129]

Iatrogenic causes of cecal volvulus include the presence of a ventriculoperitoneal shunt and the Malone antegrade continence enema (MACE) procedure.[130] This procedure provides a

catheterizable stoma for colonic enema in patients with chronic constipation, and it may provide a focal point for the bowel to twist around.

Sigmoid volvulus[131,132] and volvulus of the transverse colon can also rarely occur in children.[129,133] Predisposing factors are abnormal mesenteric attachments or neurologic impairment, and these lead to hypomobility and severe obstipation.[128]

***Clinical Presentation.*** Colonic volvulus presents with signs of obstruction—nausea, vomiting, abdominal pain, and distension—although the findings may be relatively nonspecific and confused with other causes of obstruction or even gastroenteritis.[128]

***Imaging.*** Radiographs demonstrate bowel obstruction with marked dilatation of the colonic segment, which may be present in the right lower quadrant or over the midabdomen, if the volvulus involves the right colon (Fig. 106.26). The typical appearance on contrast enema of the site of volvulus obstruction is the "bird beak" sign. On CT, enlargement of the twisted portion of the colon is apparent, as is a "whirl sign" at the site of the twist.[129] The markedly enlarged colonic segment may have an enhancing thickened wall (e-Fig. 106.27). If the bowel becomes ischemic, the wall may not enhance, and pneumatosis may be present.[129]

***Treatment.*** Most children undergo surgical exploration and reduction of the volvulus as an emergency procedure, with resection of necrotic bowel when necessary. There are reports of enema reduction of both cecal and more distal volvulus in children, although now using water-soluble contrast agents rather than barium.[134]

## Pneumatosis Coli

***Overview.*** Pneumatosis intestinalis and pneumatosis coli, are terms that refer to the radiographic, US, or CT finding of air in the wall of the intestine or colon respectively, and it may be due to both benign and serious clinical conditions.

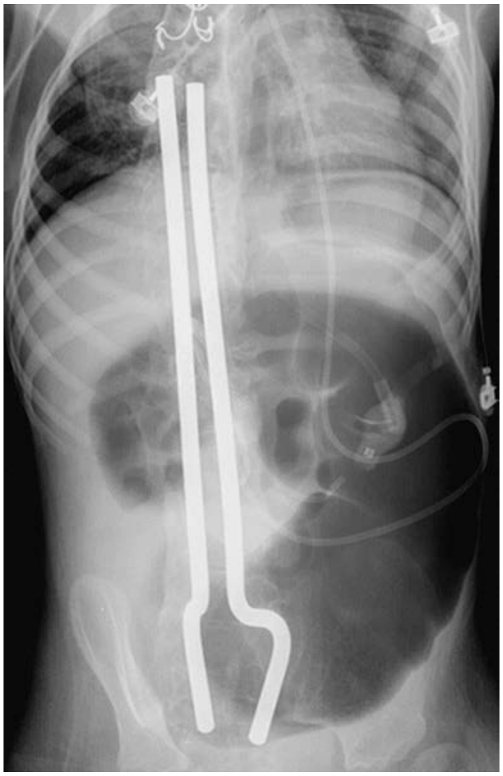

**Figure 106.26. Acute cecal volvulus around ventriculoperitoneal shunt tubing.** Frontal abdominal radiograph of a teenage boy with developmental delay and chronic constipation, who presented with acute onset of vomiting and abdominal pain. The radiograph shows marked distension of a colonic loop in the left abdomen, which was found at surgery to represent an acutely twisted right colon.

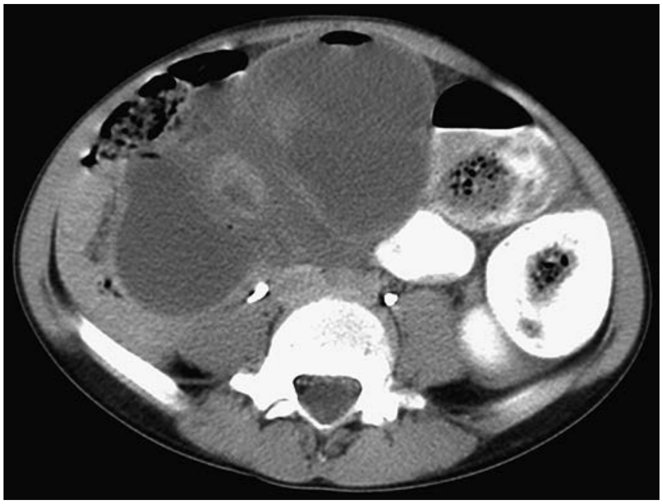

**e-Figure 106.27. Acute cecal volvulus around a Malone antegrade continence enema (MACE) procedure.** This 12-year-old boy came to medical attention with acute abdominal pain and vomiting without fever. He underwent rectal and intravenous contrast-enhanced CT, which showed a markedly dilated cecum. At surgery, the cecum had twisted around the MACE and was resected.

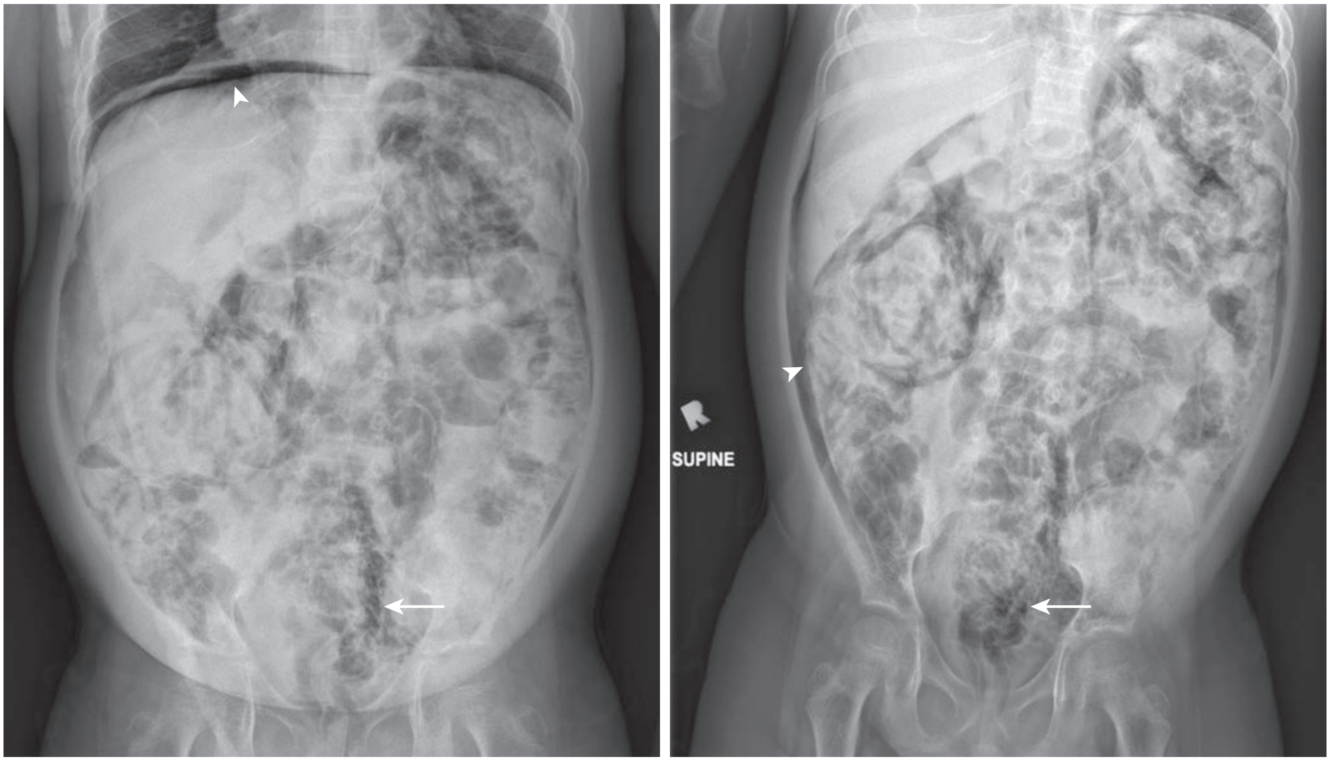

**Figure 106.28. Pneumatosis.** Erect (left) and supine (right) abdominal radiographs showing extensive pneumatosis intestinalis and pneumatosis coli *(arrows)* with pneumoperitoneum *(arrowheads)* in an adolescent on long-term steroid therapy for chronic bowel graft-versus-host disease.

***Etiology.*** Pneumatosis is well known to occur in patients with underlying ischemic bowel disease, such as necrotizing enterocolitis (NEC), and in some cases of bowel obstruction. However, it is also described in a wide variety of more benign or chronic conditions, such as CD, UC, AIDS, in transplant patients, and with viral infections, particularly cytomegalovirus.[135–140] Children are more likely to have pneumatosis than are adults, and depending on the etiology, the condition may generate few symptoms or may be asymptomatic. In most, the mechanism is not evident, however bacterial overgrowth and mechanical factors have been postulated.[135,139] It is also described as an epiphenomenon probably caused by gas dissection in CF,[138,141] and in some cases it is related to steroid therapy.

***Imaging.*** When NEC is a clinical concern, abdominal radiography is used for the detection of associated findings that include pneumatosis, ileus, perforation, or portal venous air (see Chapter 105). When perforation is a concern, cross-table lateral projections in unstable neonates and upright views in otherwise well patients are performed (Fig. 106.28). In some, pneumatosis may be an unexpected finding on radiographs. For the many associated benign conditions, and in those children who are asymptomatic, there is no evidence that serial radiographs are useful.

There is considerable variability in interpretation of the objective radiographic signs in detecting NEC.[142,143] Sonography may detect pneumatosis of the small or large bowel and may predict outcome in patients with NEC.[144,145] Standardization in approach and complementary use of US can assist in accurate detection.

***Treatment.*** Treatment is directed to the underlying condition.

## KEY POINTS

- Transmural disease is characteristic of Crohn disease but not of ulcerative colitis.
- Magnetic resonance enterography is increasingly used for evaluation and monitoring of disease activity in inflammatory bowel disease.
- The toxins produced by the bacterium *C. difficile* are the most important cause of antibiotic-associated pseudomembranous colitis.
- Most cases of HUS are caused by a Shiga-like toxin–producing *E. coli*, serotype 0157:H7, found in raw or incompletely cooked meats and in unpasteurized dairy products.
- Radiation colitis can occur months to years after exposure. Endarteritis with end-vessel and microvascular circulation compromise is the hallmark of supervening chronic ischemia.
- Neutropenic colitis (typhlitis) is a necrotizing colitis primarily seen in children with hematopoietic malignancies.
- Sonography is the initial cross-sectional imaging test recommended for appendicitis evaluation, followed by CT or alternately MRI if available, as necessary.
- CT imaging should be justified and optimized for the clinical indication and size of the child (see www.imagegently.org).
- Segmental colonic volvulus occurs in the setting of inanition associated with marked obstipation and distension and deficient supporting ligaments.
- Pneumatosis intestinalis occurs in a variety of benign and serious conditions in children.

# 107 Intussusception

Kimberly E. Applegate and Marta Hernanz-Schulman

## OVERVIEW

Intussusception is an acquired invagination of the bowel into itself (Fig. 107.1). The more proximal bowel that invaginates into more distal bowel is termed the *intussusceptum*, whereas the recipient bowel that contains the intussusceptum is termed the *intussuscipiens*. Invagination of the bowel, if sustained, leads to edema, and ischemic changes eventually supervene. Intussusception is thus an urgent condition, and delay in diagnosis results in increased risk for bowel necrosis and perforation.

Intussusception can occur in any part of the bowel at any age. In infants and young children, idiopathic ileocolic intussusception is by far the most common, comprising approximately 95% of all cases, and is the most common cause of small bowel obstruction in patients aged 3 months to 5 years.[1] The documented incidence of intussusception varies with geographic location, averaging approximately 74 cases in infants younger than 1 year of age per 100,000 infant-years worldwide, ranging in the United States between 33 and 52 per 100,00 infant-years with a male:female ratio of approximately 2 : 1.[2,3]

## ETIOLOGY

### Idiopathic

Approximately 90% to 95% of cases of intussusception in children are ileocolic and idiopathic.[4,5] The majority occur in the first year of life, with a peak age of 5 to 9 months. Circumferential lymphoid hypertrophy about the terminal ileum is thought to play an etiologic role in the onset of idiopathic intussusception.[4,6,7] Antecedent infection with adenovirus has been implicated in cases of idiopathic intussusception,[8] likely as a cofactor in the development of lymphoid hyperplasia. Other infectious agents, particularly enterovirus, also have been implicated.[9–11] Although typically associated with seasonal peaks in the May, June, and July,[4] recent reports have identified no specific seasonality, suggesting no, or more than one, antecedent gastrointestinal pathogen.[12]

### Rotavirus Vaccine

Shortly after the first rotavirus vaccine was introduced in the United States in 1998 for routine vaccination of infants at ages 2, 4, and 6 months, several reports to the Centers for Disease Control and Prevention (CDC) suggested an association between the vaccine and intussusception, prompting vaccine removal from the market. A subsequent case-controlled study of this tetravalent vaccine found “a strong, temporal, and specific” relationship, sufficient to provide “evidence of a causal association” between the vaccine and intussusception.[13] Since then, a monovalent and a pentavalent vaccine have been developed, and both have undergone extensive evaluation worldwide.[14] They have been found to have a lower but not nonexistent risk of intussusception, particularly within a week of receiving the first dose. However, institution of these vaccines has significantly lowered the mortality and morbidity associated with rotavirus disease, for a positive risk-benefit ratio.[3,15–19]

### Lead Points

There may be a definable, pathologic, lead point, such as a focal mass, or a more diffuse bowel wall abnormality accompanying the intussusception, particularly when intussusception occurs outside of the typical idiopathic age range, or when nontransient intussusception is confined to the small bowel or to the colon. Lead points may be found in approximately 5% of children presenting with intussusception in the first year of life but are present in 60% of intussusceptions in 5- to 14-year-old patients and are also more frequently found in infants less than 3 months of age; 44% of lead points present by 5 years of age. Although the absolute number of lead points is approximately equal in infants and in older children,[20] the percentage of lead points in children outside the typical age bracket for idiopathic intussusception is much higher because the denominator is so much smaller. The most common focal lead points in infants are Meckel diverticulum and duplication cyst, whereas in older children polyps and lymphoma are more common. Parasitic infestations can act as or produce lead points for intussusception in the large or small bowel, particularly ascariasis, although others such as schistosomiasis have also been reported.[21–24] Diffuse bowel thickening, such as is seen with Henoch-Schönlein purpura, typically leads to small bowel intussusception. Polyps can act as lead points in the small bowel or in the colon and can present with colocolic intussusceptions. Although patients with detected lead points will eventually have surgery, nonoperative reduction may be attempted in ileocolic intussusceptions to allow for nonurgent surgery.

Lead points are more likely in patients with recurrent intussusception but only represent approximately 14% to 19% of recurrent intussusception cases[4,20]; the majority of patients with recurrent intussusceptions do not have lead points.

Intussusception can also occur around gastrostomy and gastrojejunostomy tubes (see Chapter 103).

## CLINICAL PRESENTATION

Idiopathic intussusception occurs most commonly in infants aged between 3 months and 3 years, with a peak age of 5 to 9 months; large series report 57% to 85% of cases presenting before the age of 1 year (an average of 67% occur by age 1 year).[7,25]

The classic clinical presentation of the child with intussusception is the triad of colicky abdominal pain, vomiting, and bloody stools.[7] Individually, each of these symptoms is present in a large number of patients, although all three are found less frequently. Colicky abdominal pain is found in 58% to 100% of cases, vomiting in up to 85% of cases, and bloody stools in up to 75% of cases, but the triad is seen in 25% to 65% of patients, depending on the series and age group.[5,26–28] In patients presenting in the first year of life, irritability, bile-stained vomit, and lethargy are more likely to be present.[5] In other patients, clinical signs and symptoms of intussusception may be nonspecific and overlap with those of more common conditions, such as gastroenteritis, and some authors have found no reliable clinical prediction models that identify all children with intussusception.[27,29,30] One retrospective analysis of patients found that only 50% of children were correctly diagnosed clinically at initial presentation.[31] Vomiting or diarrhea may lead to dehydration, which exaggerates lethargy. Venous hypertension leads to hematochezia, with a typical mixture of stool, blood, and blood clots that has been described as “currant jelly stools,” a clinical finding highly suggestive of intussusception.

## DIAGNOSIS AND IMAGING

Box 107.1 summarizes the evidence regarding imaging management of intussusception.

## Abstract:

To describe the various types of bowel intussusception that occur in pediatric patients. Ileocolic intussusception with and without lead points is discussed. Additional discussion includes ileoileal intussusceptions, and key points in differentiation from ileocolic intussusception, as well as differentiation between transient clinically insignificant small bowel intussusceptions, as well as those which are significant and may produce ischemic bowel. The various methods of nonsurgical reduction are described and discussed, including complications and success rate.

## Keywords:

Intussusception
ileoileal
ilelileocolic
ileocolic
colocolic
lead points
plain film diagnosis
ultrasound diagnosis
nonsurgical reduction
air enema
liquid enema
complications
recurrence

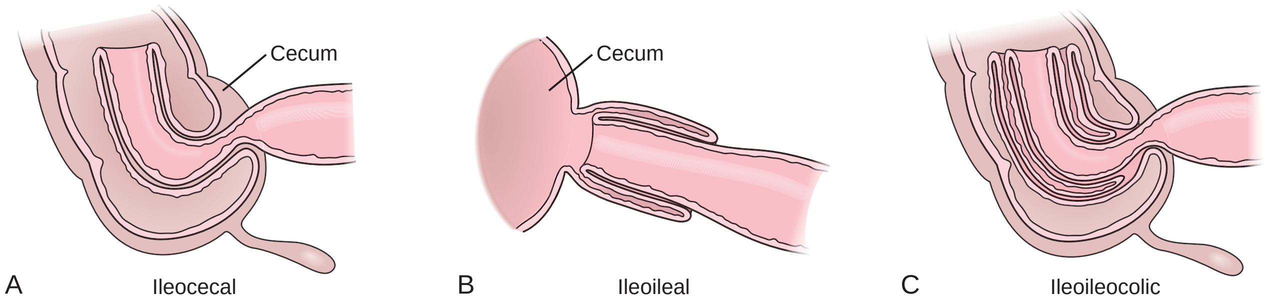

**Figure 107.1. Types of pediatric intussusception, in longitudinal section.** (A) Ileocecal. (B) Ileoileal. (C) Ileoileocolic.

**BOX 107.1** Diagnosis and Management of Intussusception

Plain radiographs are useful for:
- Differential diagnosis; screen for other conditions
- Detect bowel obstruction
- Free air

Ultrasound is highly sensitive and specific in detecting intussusception
- Ultrasound can also detect lead points
- Findings suggesting decreased chance of nonoperative reduction
  - Trapped fluid at the leading edge of the intussusceptum
  - Absence of flow on Doppler evaluation

Enema is indicated for reduction in the absence of:
- Free air
- Peritoneal signs

## Abdominal Radiographs

Overall, abdominal radiographs are considered to have a low sensitivity and specificity for intussusception; sensitivities of 45% to 62% and specificities of up to 87% have been reported,[32,33] with reports of higher sensitivity although with lower specificity when employing a three-view examination.[34] Abdominal radiographs typically include a frontal view and a horizontal ray view; left side down decubitus is most helpful, because in addition to assessing air-fluid levels and free air, gas is gravitationally directed into the ascending colon, which can help in diagnosis or exclusion of intussusception. In one series, the addition of the decubitus radiograph improved diagnostic performance, with 67% of studies considered determinate for diagnosis, and a sensitivity and specificity of 74% and 58%, respectively.[35] The visualization of the intussusceptum as an intracolonic mass outlined by gas, termed the *crescent sign*, is nearly pathognomonic of intussusception but is seen in only approximately one-third of cases (Fig. 107.2).[35] The absence of stool and bowel gas in the ascending colon is one of the more suggestive radiographic signs of intussusception, while the clear presence of stool or an air-fluid level within the cecum is the most specific sign to exclude it. However, small bowel or sigmoid gas located in the right abdomen on radiographs may mimic ascending colon or cecal gas, and fluid filling the right colon in a patient with gastroenteritis may also show a similar appearance.

In this era of widely available ultrasound, perhaps the more important role of abdominal radiographs is to screen for other conditions, ranging from constipation to free air to foreign body, and to assess for the presence of bowel obstruction, which helps guide the ultrasound and is also an important prognostic factor for reduction.

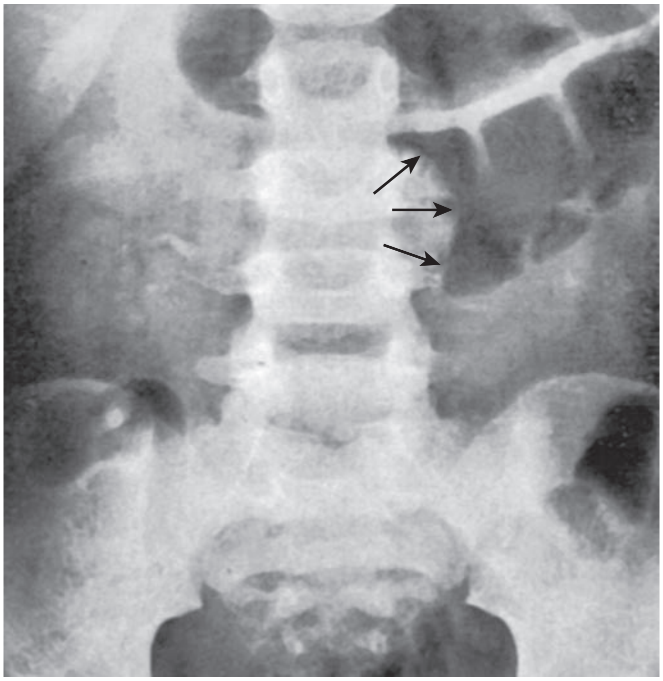

**Figure 107.2. Ileocolic intussusception in a 4-year-old child.** The leading edge of the intussusception *(arrows)* is outlined by gas within the transverse colon. No gas or other colonic contents can be seen in the cecum or in the ascending colon, which are occupied by the intussusceptum.

## Ultrasonography

Ultrasound is highly sensitive in the detection of intussusception, with sensitivity and specificity at or close to 100%, even when performed by relatively inexperienced operators.[36,37] Ultrasound is the primary imaging modality used by more than 90% of European pediatric radiologists[38] and is highly accurate when used as the primary imaging modality for the diagnosis and exclusion of this condition.[33] Initial evaluation by ultrasound circumvents the more invasive enema in patients who do not have intussusception and allows diagnosis of other conditions in which performance of an enema would be noncontributory or contraindicated mesenteric adenitis or colitis.[27,39,40] Ultrasound evaluation has been found to be part of the most cost-effective strategy in the diagnosis and treatment of children with intussusception.[41]

Intussusception is diagnosed by identifying the bowel-within-bowel appearance of the intussusceptum within the intussuscipiens, which are clearly visible with high-resolution equipment. Initial reports described pseudokidney, donut, and target signs, resulting from the central hyperechoic mesentery resembling a renal hilus, and the surrounding loops of bowel resembling the kidney when imaged longitudinally, and a donut or target on transverse images.[42] Today, much greater detail allows the bowel-within-bowel appearance to be easily demonstrated; the leading edge shows the inversion of the inner and outer sleeves of the intussusceptum, with or without trapped fluid or lead point. Typically, flow can be identified with color Doppler (Fig. 107.3).

Ileocolic intussusception is most often encountered in the right upper quadrant, but all four quadrants are evaluated and documented; review of abdominal radiographs that can localize bowel gas and determine the presence of dilated small bowel loops can be helpful in performing and interpreting the ultrasound. Overview with a curved transducer may be done, but the diagnostic examination is typically performed with a linear transducer focused to encompass the entire abdominal thickness. Once the intussusception is encountered, it should be followed to its leading edge to determine the presence of anechoic trapped fluid and/or a potential lead point.

Ultrasound findings have prognostic correlations with the nonoperative reducibility of an intussusception. Anechoic fluid trapped between the intussusceptum and the intussuscipiens (Fig. 107.4) has been associated with lack of reducibility.[39] Lack of color Doppler signal in the wall of the intussuscepted bowel suggests bowel ischemia.[39,43] Because ischemia and perforation can be focal, identification of flow does not exclude underlying ischemic changes or potential for perforation. There are conflicting reports as to whether free peritoneal fluid is associated with fewer successful reductions,[44,45] but it is present in approximately one-half of patients.[42] Although these findings are associated with fewer successful reductions, none represents a contraindication to enema reduction. The only absolute contraindications to enema reduction are signs of peritonitis and free intraperitoneal air.

The detection of lead points by imaging is best accomplished by ultrasound at presentation by paying careful attention to the leading edge of the intussusception (Fig. 107.5). In a recent review, focal lead points were detected in 74% of infants at presentation.[20] Before the incorporation of ultrasound into the routine diagnosis

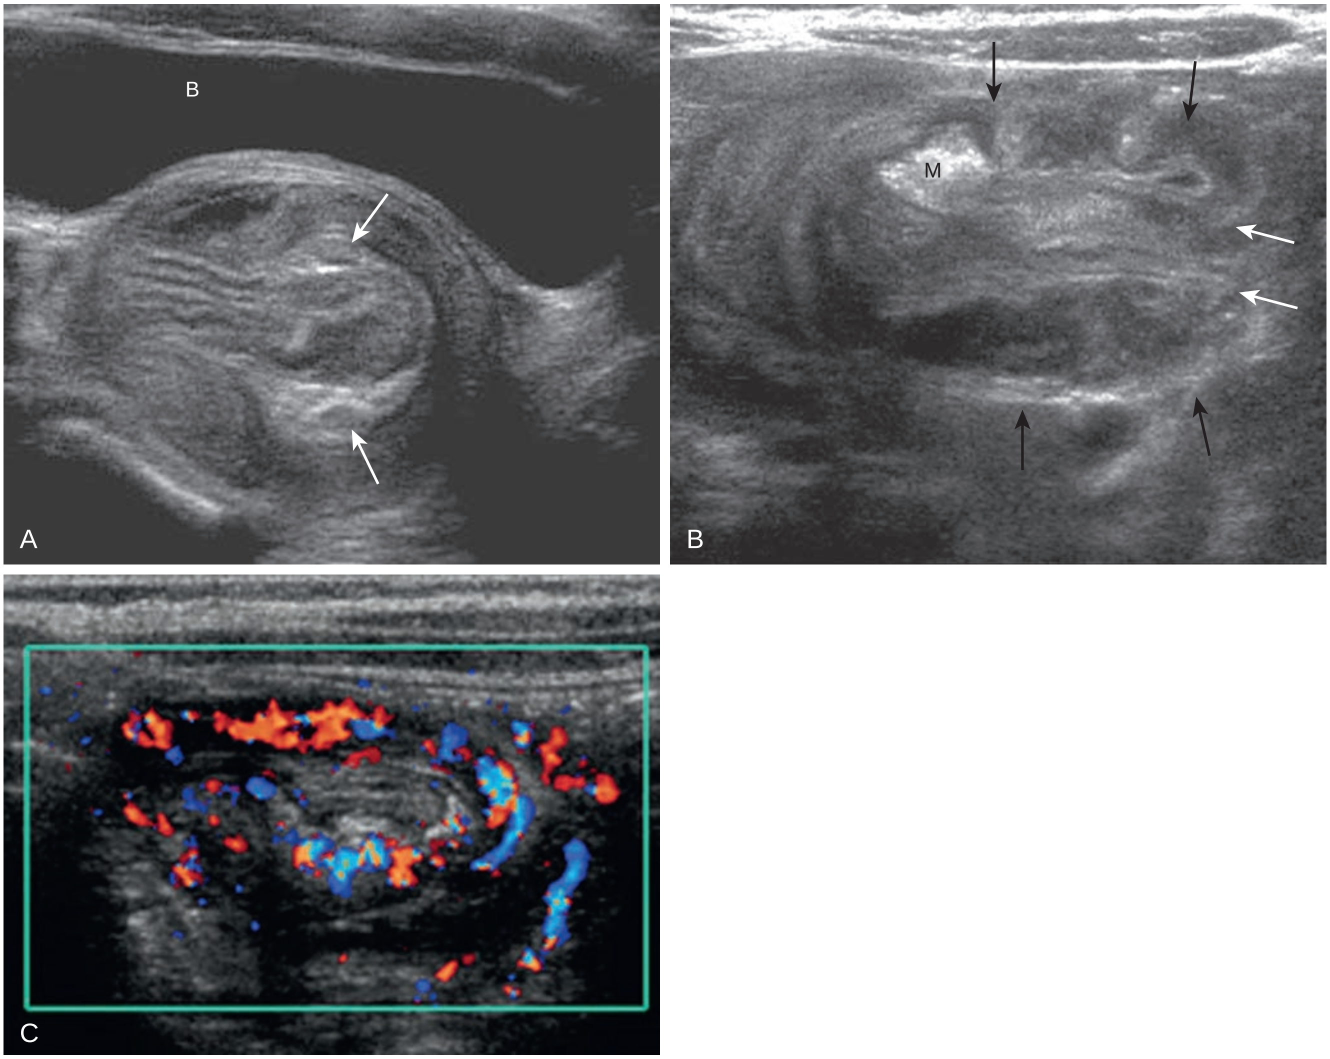

**Figure 107.3. Intussusception.** (A) Transverse sonogram in a 5-year-old boy through the intussusceptum complex shows mesentery and lymph nodes *(arrows)* in the space between the inner and outer sleeves of the intussusceptum. The intussusception was in the rectum. *B*, Bladder. (B) Longitudinal sonogram in a 3-month-old child shows mesentery *(M)* between the inner and outer sleeves of the intussusceptum *(white arrows)*, which represent the entering limb and the everted, returning limb. *Black arrows* outline the outer edge of the intussuscipiens. Note that there is no evidence of a lead point. (C) Transverse color Doppler sonogram of an intussusception demonstrating typical concentric rings of flow.

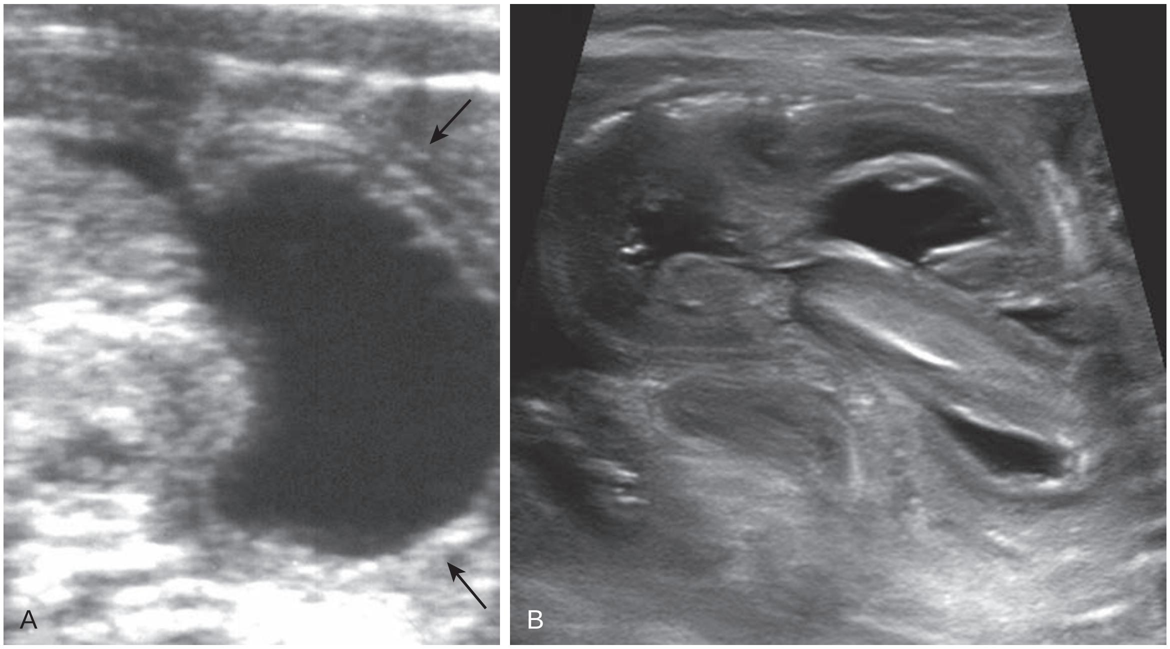

**Figure 107.4. Intussusception.** (A) Sonogram shows fluid at the leading edge of the intussusceptum complex, outlining the eversion of the inner and outer sleeves of the intussusceptum. *Arrows* point to the outer edge of the intussuscipiens. (B) Longitudinal sonogram of intussusception in a 3-month-old boy with high-grade small bowel obstruction. Note the large amount of fluid trapped within the intussusceptum complex. The intussusception was only partially reducible, and a partial colectomy was necessary for nonviable bowel.

of intussusception, approximately 40% of lead points were identified by liquid enema, while detection by air enema is approximately 11%.[20] Patients in whom a lead point has not been identified but is suspected may need further evaluation, with consideration of follow-up ultrasound, computed tomography, contrast studies, or endoscopy based on the etiology of concern.[20]

## Small Bowel and Colocolic Intussusceptions

Small bowel intussusceptions are more often encountered in the mid, lower, or left side of the abdomen. There are two types of small bowel intussusceptions: transient, asymptomatic intussusceptions and significant intussusceptions, often associated with lead point, which may have undergone ischemia and require bowel resection.

Transient, typically asymptomatic small bowel intussusceptions are characterized by a smaller diameter and a length less than 3.5 cm, often visible peristalsis (e-Fig. 107.6, Video 107.1). They are often compressible, there is no evidence of abnormal flow on color Doppler interrogation, and there is no central mesenteric echogenicity and lymph nodes so characteristic of the ileocolic intussusceptions.[46–48]

Nontransient, symptomatic small bowel and colocolic intussusceptions are typically large and may be associated with ascites and small bowel obstruction (Fig. 107.7).[49] Lead points are often evident, identified by computed tomography or ultrasound (Fig. 107.5 and e-Fig. 107.8). Significant small bowel intussusceptions typically require surgery; enema is not considered appropriate or effective in reduction, because of the presence of the ileocecal valve, and the possibility of ischemic changes.[50–53]

## Nonoperative Treatment

### Techniques and Reduction Rates

Enema reduction should be undertaken in children with intussusception after surgical consultation. The only absolute contraindications to enema reduction are signs of peritonitis on clinical examination or free air on imaging (Box 107.2). The most important factor that predicts an unsuccessful enema reduction is longer duration of symptoms: 48–72 hours is considered a significant delay.[7,25] Other factors associated with lower rates of successful reduction include age less than 3 months, dehydration, small bowel obstruction, and intussusception encountered in the rectum (25% reduction rate).[7,25,32,54]

**BOX 107.2** Image-Guided Reduction of Intussusception

**ABSOLUTE CONTRAINDICATIONS**

- Peritonitis
- Free intraperitoneal air

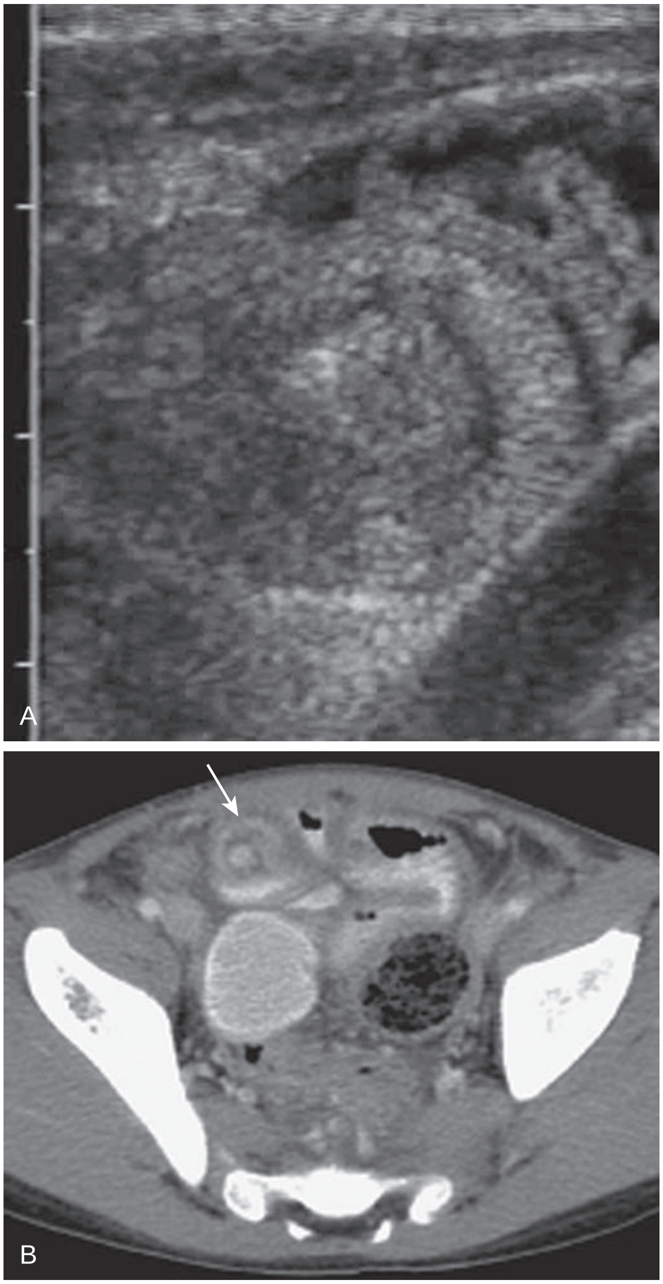
**PNEUMATIC REDUCTION TECHNIQUE**

- Patient should be well hydrated
- Use available measurement devices to control pressure; may use a pop-off valve
- May begin at 80 mm Hg; do not exceed 120 mm Hg mean pressure
- Compare small bowel gas pre- and postreduction into cecum (Most helpful in patients with small bowel obstruction)

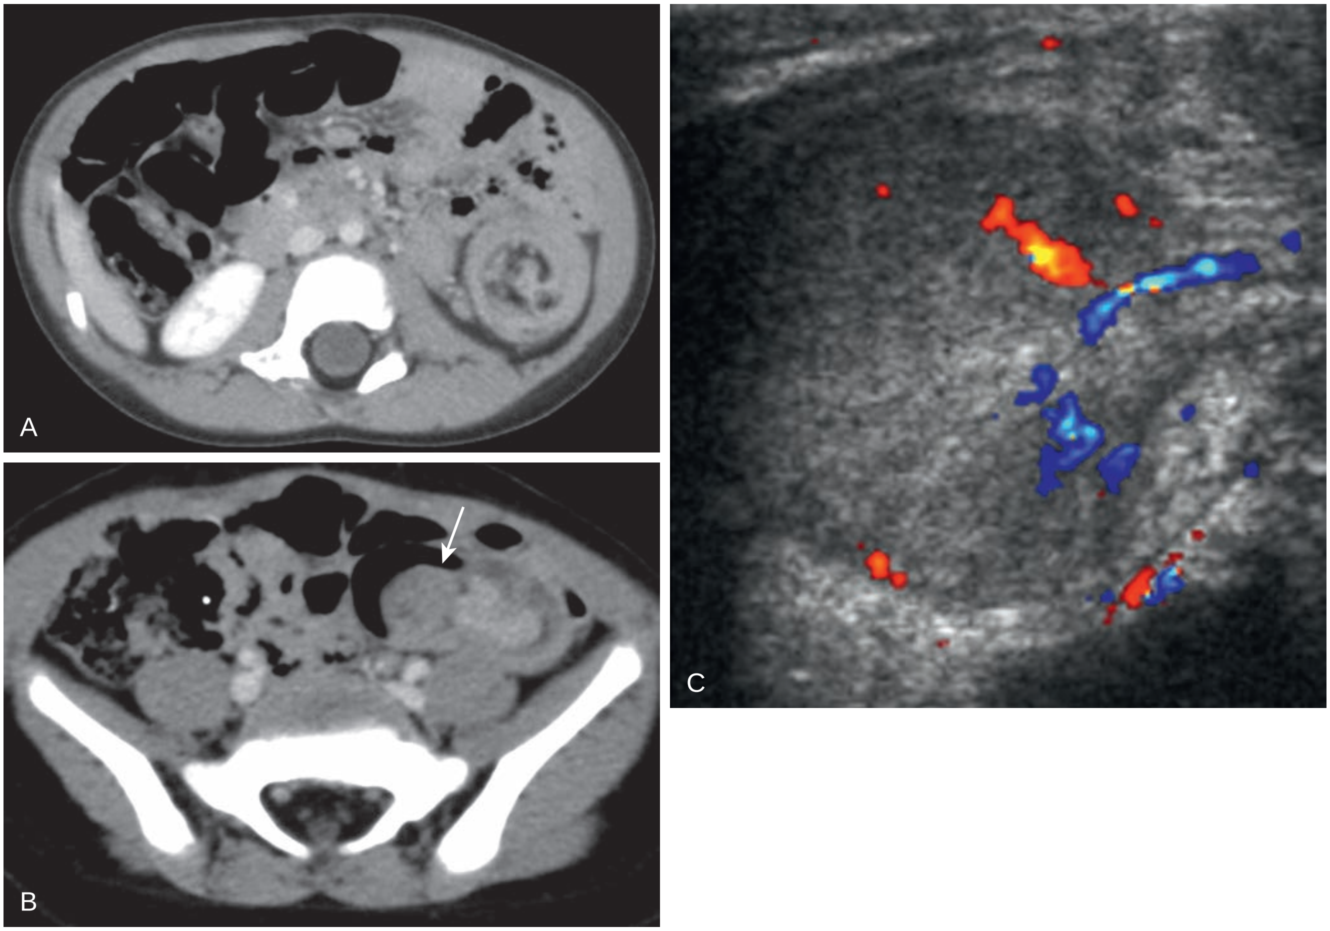
**HYDROSTATIC REDUCTION TECHNIQUE**

- Patient should be well hydrated
- Maintain pressure head no greater than 1 meter $H_2O$
- Make three attempts of 3 minutes each
- Be sure buttocks are well sealed
- Reduction is incomplete until distal small bowel loops are easily filled

Air and liquid contrast enemas are used for intussusception reduction. The air enema is considered by most to be superior to positive-contrast liquid enema for several reasons. If perforation occurs, there is considerably less spillage of fecal material in the peritoneal cavity with air than with liquid agents, and the contrast material in the peritoneum may cause additional complications



**e-Figure 107.6. Transient asymptomatic intussusception of the small bowel (also see Video 107.1).** (A) Transverse sonogram of an ileoileal intussusception incidentally identified in an infant with gastroenteritis; on longitudinal image, it measured less than 3 cm and could not be identified on rescanning of the area. (B) Contrast-enhanced CT of young child undergoing routine follow-up imaging of a testicular tumor. There is an asymptomatic, short-segment small bowel intussusception *(arrow)* that resolved spontaneously.



**e-Figure 107.8. Colocolic intussusception secondary to a polyp.** (A) Contrast-enhanced CT shows the intussusception in the descending colon. (B) The *arrow* points to the polyp. (C) Color Doppler image shows flow within the polyp.

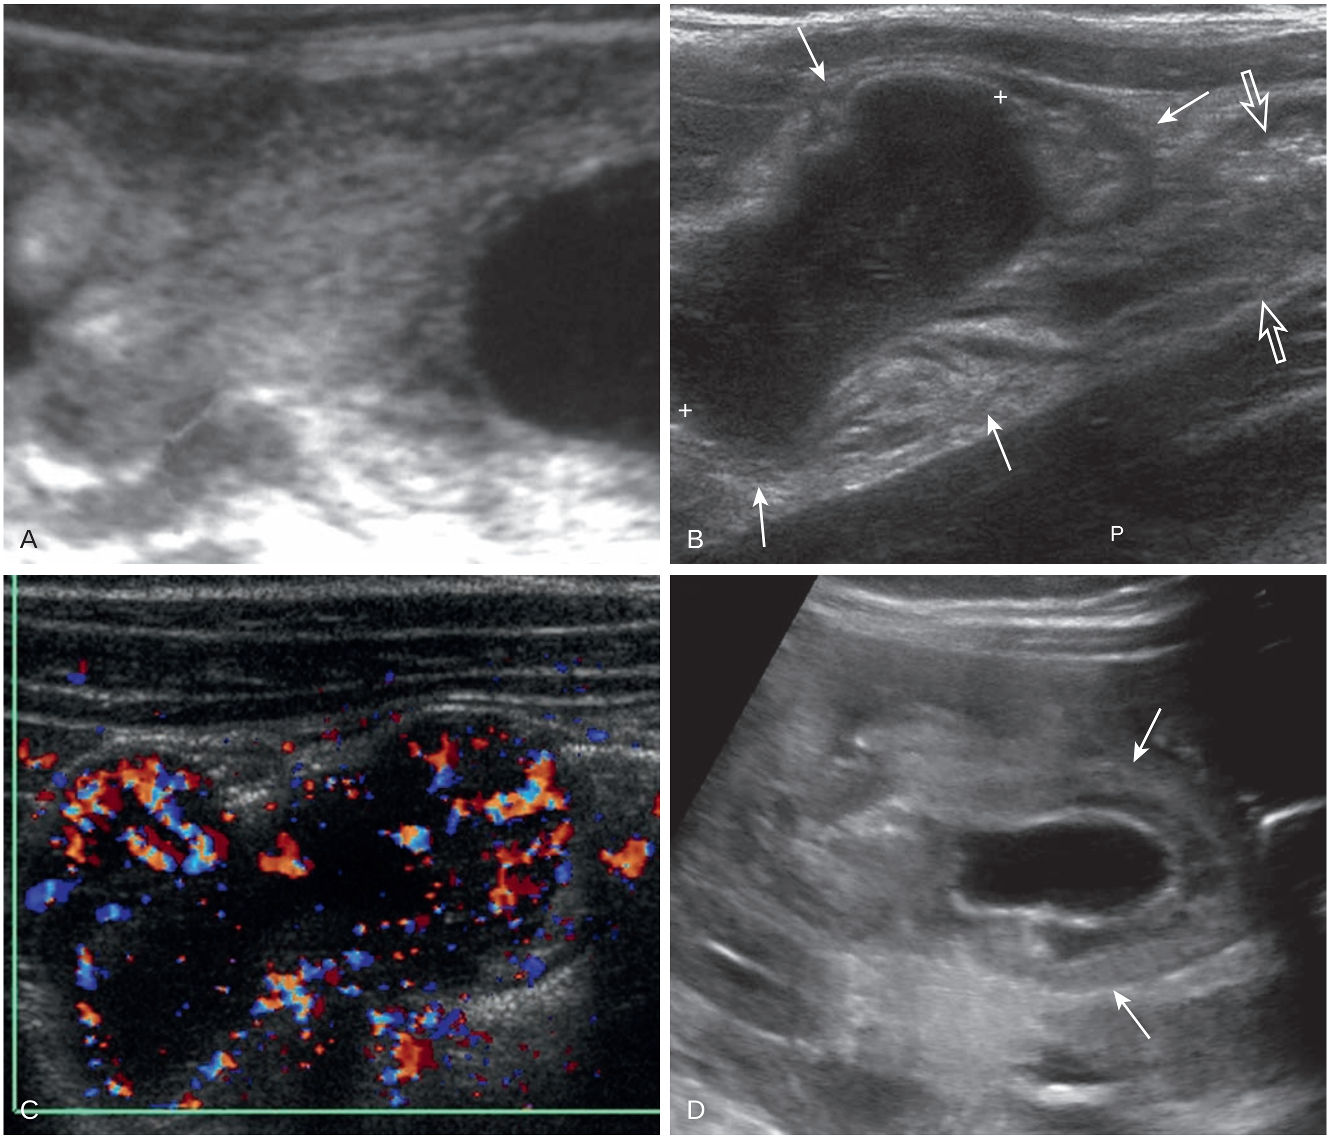


**Figure 107.5. Lead points.** (A) A 3-month-old infant with intussusception secondary to an ileal duplication cyst acting as a lead point. Note the difference in appearance from that of trapped fluid in a child without a lead point (Fig. 107.4A). (B and C) An 8-year-old boy presenting with severe, intermittent abdominal pain. Examination of the right lower quadrant shows an anechoic, solid mass with abundant flow on color Doppler interrogation (C), intussuscepted into the cecum *(arrows)*. Open arrows indicate the terminal ileum. *P*, Psoas muscle. Pathologic diagnosis was Burkitt lymphoma. (D) A 2-month-old infant with intussusception. A thick-walled hollow viscus *(white arrows)* was the leading edge, which was proved at surgery and pathology to represent a Meckel diverticulum. Air reduction was only partly successful; at surgery, a small segment of ischemic bowel was resected.

after perforation. There is no liquid or stool spillage on the patient or on the field of view, and the air-filled sigmoid and distal colon do not block the field of view as happens with radiodense contrast material. The rates of recurrence of intussusception after air or after liquid enema reductions do not differ (both are approximately 10%). Importantly, the radiation exposure is 2.3-fold lower when air is used.[28,55–60]

More than 70 published studies of enema reduction report an average reduction rate of 76% (Table 107.1).[25,61] More recent reports suggest a higher success rate for air enema over liquid (80% vs. 70%).[62] A recent meta-analysis that included 16,187 children undergoing air enema reduction and 13,081 children undergoing liquid enema reduction reported a success rate of 82.7% for air and 69.6% for liquid; perforation rates were 0.39% and 0.43%, respectively.[63]

Relative disadvantage of the air enema is a lower rate of detection of lead points, although these are best detected at preceding sonography.[20] Positive-contrast liquid enema also tends to outline the small bowel loops to determine reduction more easily, and ileoileal components may be more conspicuously identified. In 2004, 65% of pediatric radiologists in the United States reported using air enema, 33% liquid enema, and 3% liquid enema with sonographic guidance[64]; the proportion currently using air enemas is likely much higher.

All children should have surgical consultation before enema: (1) to assess for peritoneal signs precluding enema, (2) to alert the surgeons about a potential surgical candidate, (3) for urgent surgery in case of perforation, and (4) for management after reduction. Before enema reduction, dehydration should be treated with intravenous fluid resuscitation. Children with evidence of

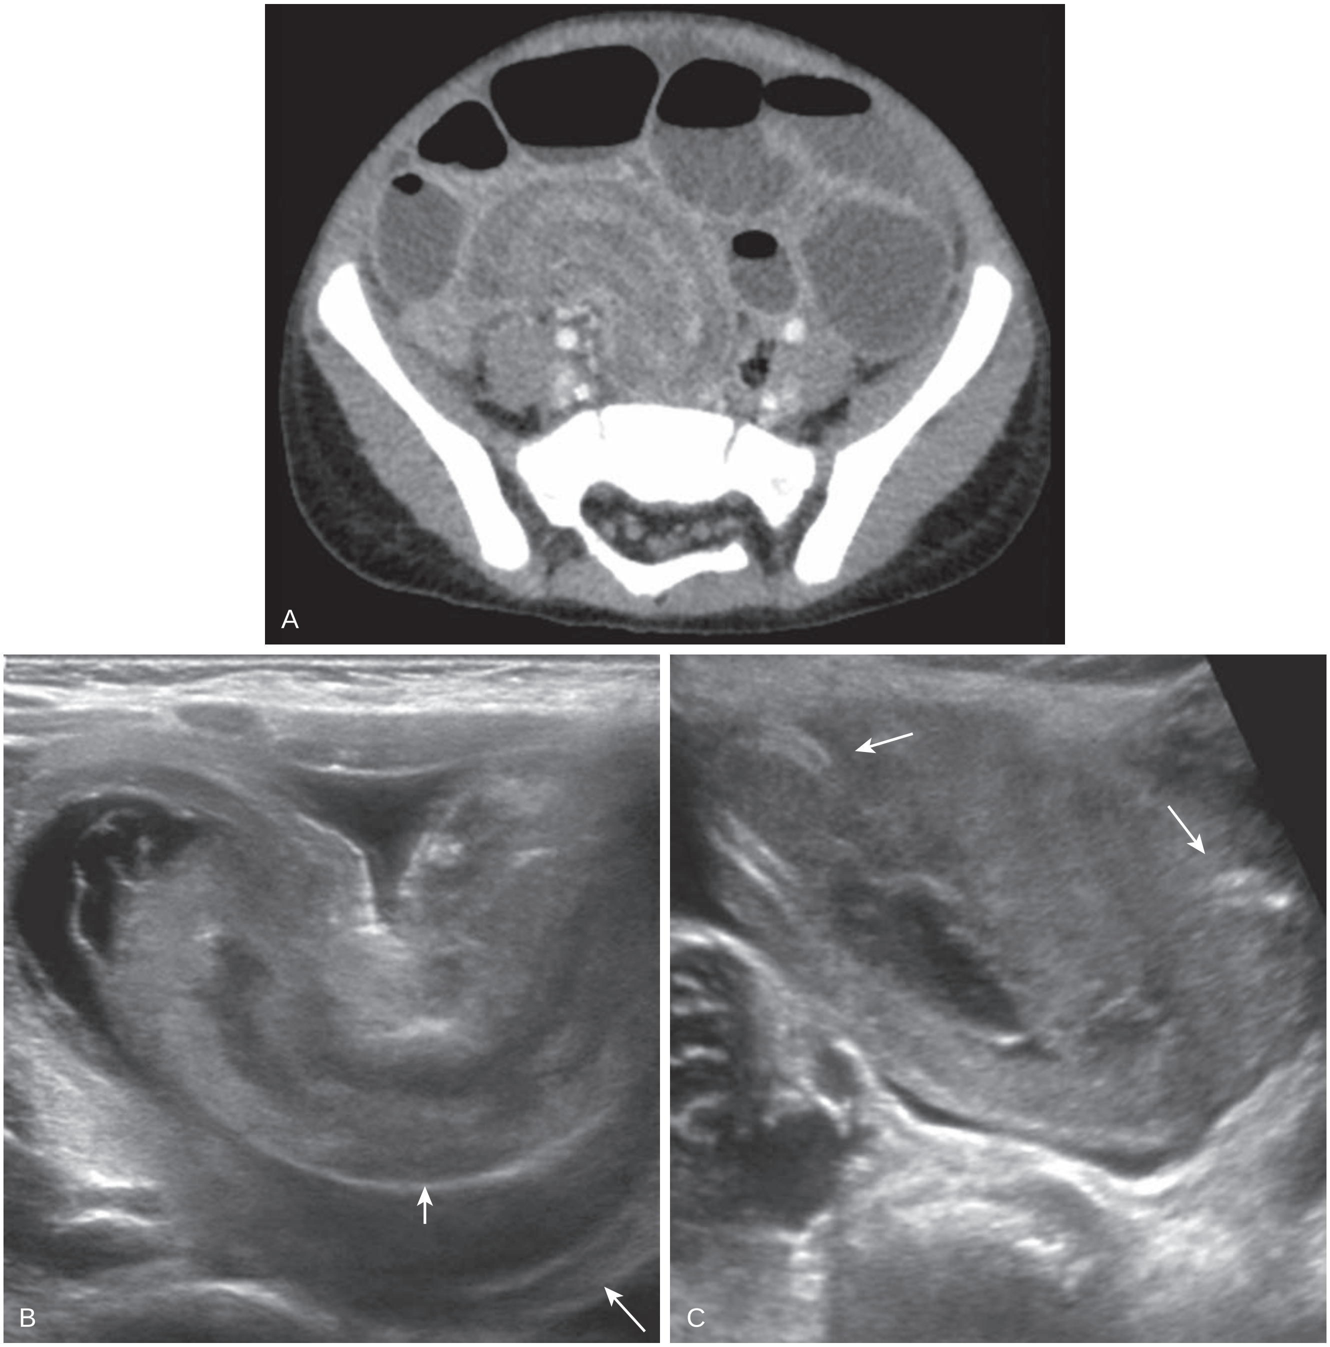

**Figure 107.7. Symptomatic small bowel intussusceptions.** (A) Contrast-enhanced CT shows a small bowel intussusception in a 3-year-old child presenting with bowel obstruction. No discrete lead point is identified. At surgery ischemic bowel segment had to be resected, and the child proved to have Henoch-Schönlein purpura. (B and C) Small bowel intussusception in a 5-year-old boy presenting with high-grade small bowel obstruction. The intussusception located in the mid abdomen shows an unusual linear echo *(short arrow)* between the inner sleeve of the intussusception and the trapped fluid; the *long arrow* points to the outer edge of the large intussusception complex. (C) Sonogram shows two portions of an Ascaris worm embedded within the intussusception *(arrows)*. The live worm was found at surgery, where ischemic bowel had to be resected.

peritonitis, shock, sepsis, or free air on abdominal radiographs are not candidates for enema.

## Air Enema Technique

In the air enema technique, the enema tip should be placed in the child's rectum and securely taped in place. The tape can be shaped into a funnel along the tube, to help form a seal. The buttocks are taped tightly together, and an assistant should also aid by holding the buttocks closed, whether the child is in a supine or a prone position. This technique is important because air leaking around the tube diminishes the pressure head. Air is rapidly insufflated into the colon under fluoroscopic observation, up to a constant, mean pressure of 120 mm Hg, thus maximizing reduction and

minimizing the risk for perforation. One device to perform the air enema has been described by Shiels et al.[65] A less laborious modification that uses the hospital air supply system has been recently described.[66]

Once the intussusception is encountered, its reduction is followed fluoroscopically until it is complete (Fig. 107.9). The use of pulsed fluoroscopy at a low setting, if available, is very important for reducing the radiation dosage, particularly when the reduction is lengthy. Fluoro "last image hold" images can document the progress of the reduction without additional exposures (Video 107.2). Air should flow freely from the cecum into the distal small bowel loops to signify complete reduction. Obtaining an image when the intussusceptum has reached the cecum is usually very helpful in documenting complete reduction, particularly in patients who already have abundant small bowel gas secondary to a bowel obstruction, by comparing the number of filled loops.

The examination is tailored to the patient and performed in collaboration with the surgeon. In general, we continue with the enema so long as there is progress and the procedure is tolerated, and stop when there is no movement of the intussusceptum. The attempts are tempered by information regarding the likelihood of reducibility gathered earlier from history, clinical examination, and prior imaging, again in consultation with the surgeons.

The radiologist should be vigilant for the appearance of free intraperitoneal air, which can be inconspicuous at first. In case of perforation, it is very important to open the buttocks and the rectal tube to allow colonic air to escape outside the patient; in addition, it is essential to have a large-gauge needle available to decompress the peritoneal cavity, as colonic perforation can result in tension pneumoperitoneum that impedes adequate breathing and may cause impaired venous return.

## Liquid Enema Technique

A general guideline to the liquid enema technique, often taught to radiology residents, is the "rule of threes": three attempts of 3 minutes' duration, with the liquid enema bag at 3 feet above the fluoroscopy table. Although there is little empirical evidence to support this rule, particularly regarding the height of the enema bag,[25,67] it serves well as a general guideline, although it has been

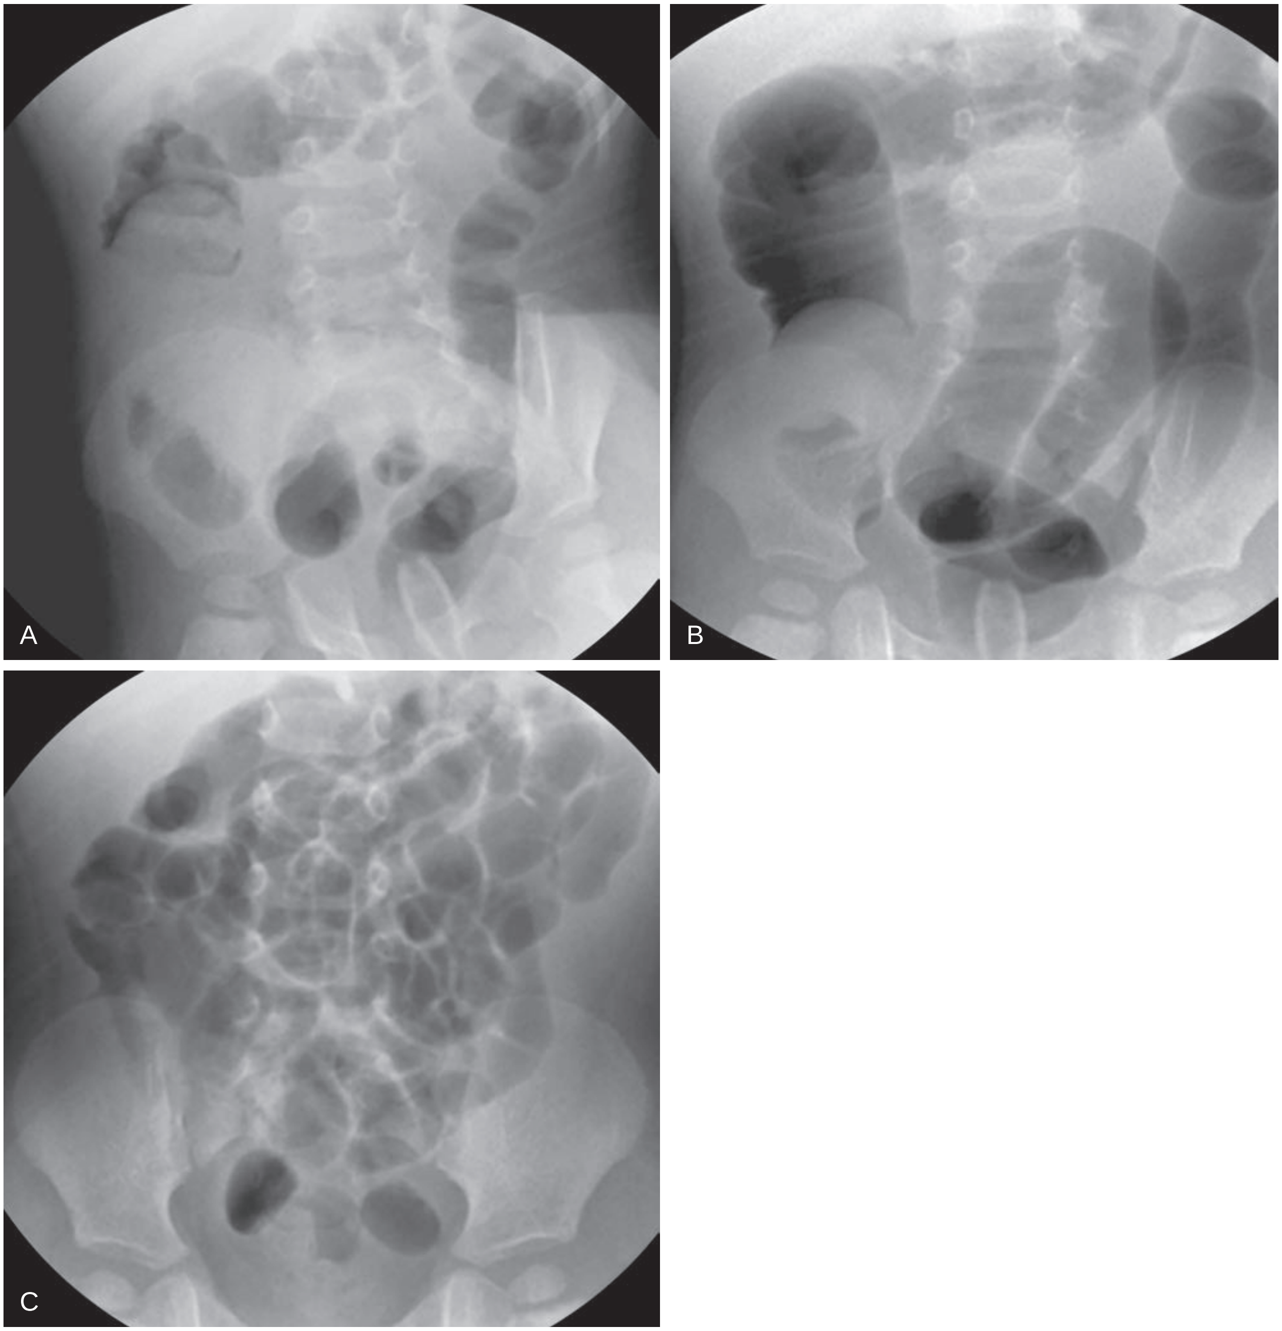

**Figure 107.9. Pneumatic reduction of intussusception (see Video 107.2).** (A) Initial fluoroscopic image shows the tube tip in the rectum, and the leading edge of the intussusception at the hepatic flexure. (B) With continued insufflation and further distension of the colon, the leading edge has moved into the right lower quadrant. (C) After successful reduction, there is gas filling multiple loops of small bowel.

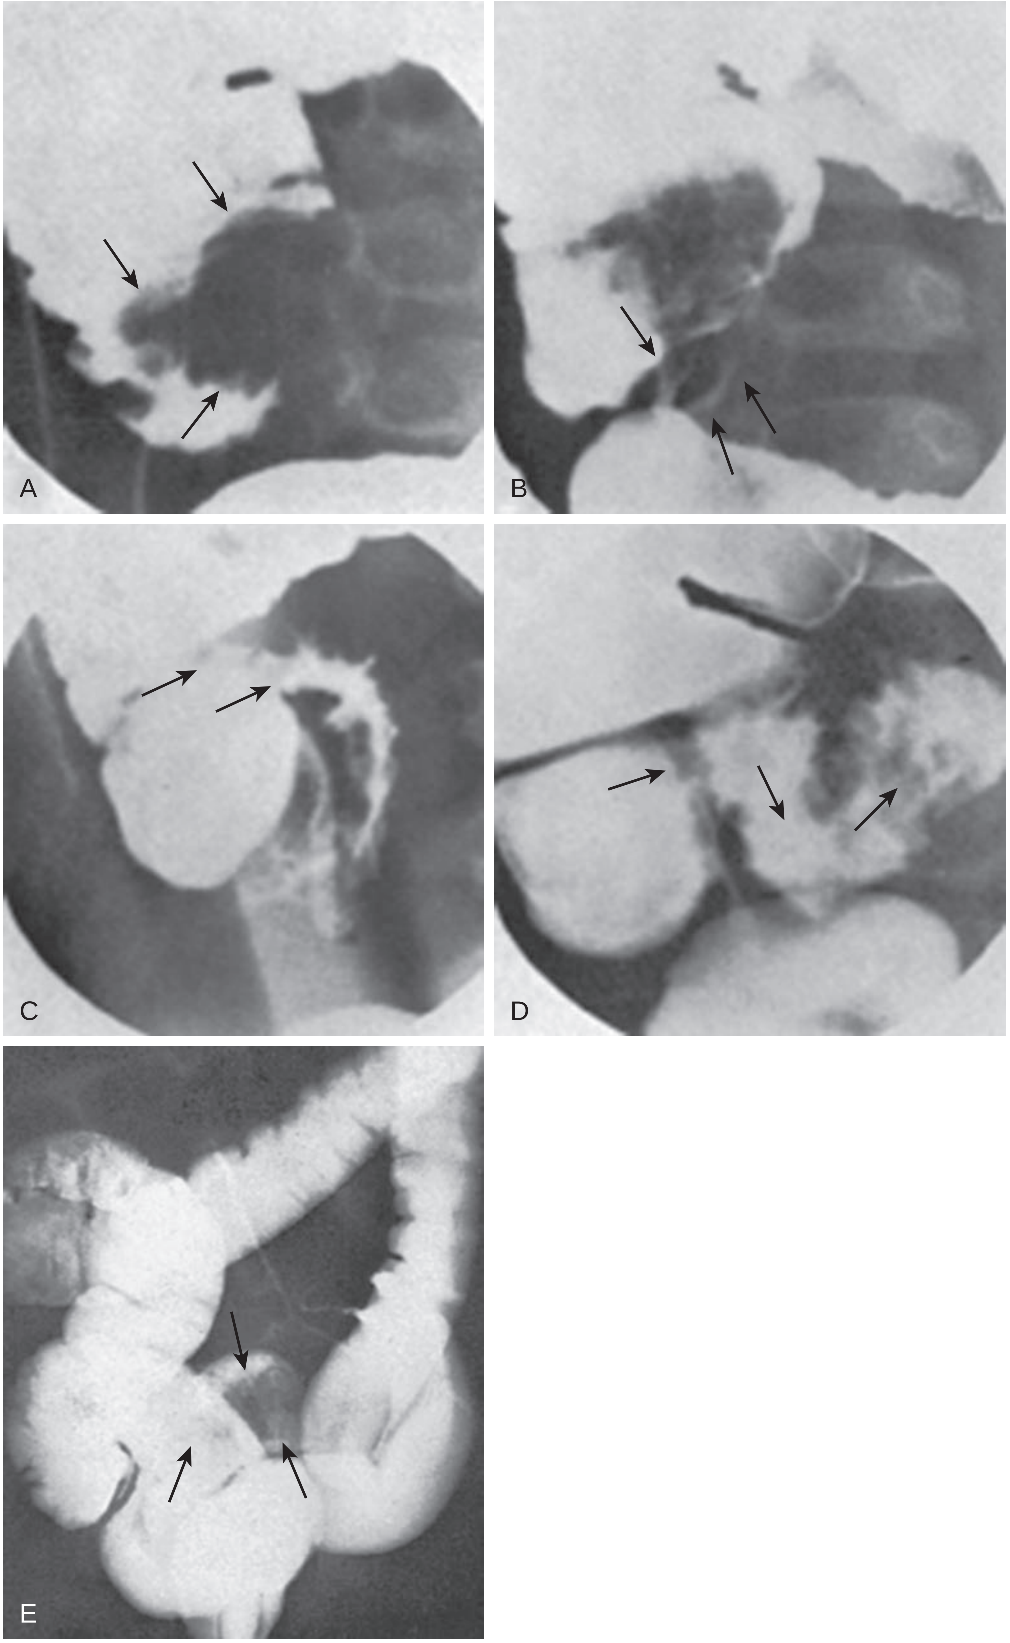
documented that columns of various liquid media differ in the height at which a pressure of 120 mm Hg is generated.[68] As with the air enema, the buttocks are tightly taped and held together to prevent escape of the liquid and loss of the pressure head (e-Fig. 107.10).

## Radiation Dosage

The radiation dosage a child receives depends on a number of factors, particularly the capabilities of the fluoroscopy equipment, the use of pulsed fluoroscopy, the use of fluorosaves versus exposures for documentation, the ease of reduction (that affects the fluoroscopy time), and the contrast medium used. Experienced pediatric radiologists using air enema averaged 95 seconds of fluoroscopy time to reduce an intussusception.[56] Air enema radiation dosages have been estimated to be one-third to one-half less than the dosage for liquid enema[69] and more recently were documented to be 2.3 times lower with air reduction due to interaction of the contrast medium with the automatic exposure control system.[60]

## Complications and Perforation

The most concerning potential complication of enema reduction is the perforation of weakened, ischemic bowel, or the uncovering



**e-Figure 107.10. Hydrostatic reduction of intussusception.** Serial radiographic changes at the ileocecal valve during hydrostatic reduction of intussusception in an 18-month-old infant. (A) The intussusception has already moved proximally from the transverse colon into the cecum, where it causes a filling defect *(arrows)*. (B) The appendix is beginning to fill *(arrows)*, and the cecal filling defect is smaller. (C) The terminal ileum is beginning to fill *(arrows)*, and the cecal filling defect has disappeared. (D) The terminal ileum is normally distended *(arrows)*, with visible mucosal relief. (E) In another child, residual ileoileal intussusception *(arrows)* in the terminal ileum after hydrostatic reduction of the colic component of an ileoileocolic intussusception. The leading edge was initially encountered at splenic flexure.

of a preexistent perforation during reduction. The risk for perforation depends on the patient population, but multiple series describe it as less than 1%.[70] A recent meta-analysis reported perforation rates of 0.39% for air and 0.43% for liquid enema.[63] The published difference in perforation rate between air and liquid enema is either nonexistent or not statistically significant (see Table 107.1). Although determination of clinical predictors of perforation is complicated by a lack of randomized prospective studies, a key factor is symptom length greater than 48 hours. Several reports in both porcine models and children suggest that there may be preexisting focal perforation in the necrotic intussuscipiens, or less commonly the intussusceptum, that are inapparent before reduction but are uncovered during the reduction process. The most common site of perforation is at or just proximal to the intussusception in the transverse colon.[25,28,71–74]

Barium should not be used for intussusception reduction because of the risks for barium peritonitis, infection, and adhesions if perforation occurs. Although among positive contrast media iodinated contrast is now preferred and is considered a safer agent than barium, it nevertheless may produce fluid and electrolyte shifts if perforation occurs.[28,59,69,74]

One complication unique to air enema is the tension pneumoperitoneum. In an early report, two deaths occurred from this complication, leading the proponents of air enema to advise having an 18-gauge needle readily available in the fluoroscopy room for emergent decompression. As previously discussed, it is important upon noting a perforation to immediately open the valve of the enema tube and also open the buttocks so that the colonic air may escape to the outside. Although it is theoretically possible, there have been no reports of air embolism.

## Alternative Enema Approaches

A number of different approaches have been described to try to improve intussusception reduction via enema. These include sedation, anesthesia, use of glucagon, manual palpation, and delayed repeat enema. Except for the delayed repeat enema, none of these approaches has been proven to increase the rate of successful reduction.

## Fluoroscopy Versus Sonography

In North America, fluoroscopy is most often used during enema reduction. Initial reports from Asia on the use of sonography with fluid show rates of successful reduction as high or higher than with fluoroscopic techniques.[75] More recent reports show sustained successful performance of this procedure, with reduction rates reported at approximately 83%.[76,77] Recognition of perforation with spillage of fluid into the peritoneal cavity might be difficult, particularly in those patients who already present with ascites, and with less experienced operators.[78] Fecal contamination upon perforation is likely to resemble that seen with liquid positive contrast media in fluoroscopy-guided reduction.

## Delayed Repeat Enema

In children in whom the initial enema reduction attempt is only partially successful, a delayed repeat enema may avoid the need for surgical reduction. The use of this additional delayed attempt, between 30 minutes and several hours after the initial procedure, has shown promise in increasing the success of nonoperative reductions by allowing some of the edema to subside after the initial, partial reduction. Published reports have achieved further reduction in 50% to 82% of cases that do not reduce at the initial enema.[79–83] The largest series to date reports fewer bowel resections after delayed enema than after immediate surgery after a single enema procedure, 26.4% versus 11.8%[84]; however, this is most likely due to the fact that the patients who went directly to surgery are those at greater risk of ischemia, either through risk factors as enumerated earlier, or by lack of progress on the initial reduction attempt. Further research to understand optimal timing and technique for delayed repeat enemas is needed. The child must remain clinically stable and be appropriately monitored during this time interval. Delayed enema should not be attempted if the initial enema does not move the intussusception at all.

## Management of Recurrent Cases

Intussusception recurrence rates average up to 10% (range, 5%–15%), regardless of whether the technique involved air or liquid enema. The recurrence rates are less than or equal to 5% when surgical reduction is performed, presumably because of the development of adhesions.[85] Approximately 50% of children who develop recurrent intussusception present within 48 hours, but recurrences have been reported up to 18 months later. Although the only known risk factors for recurrent intussusceptions are lead points, a pathologic lead point is only present in approximately 15% to 19% of children with recurrent intussusceptions, more likely when there is more than one recurrence.[4,20] On the hypothesis that hypertrophied Peyer patches are implicated in both initial and recurrent cases of intussusception, a randomized double-blind trial showed no recurrences among children receiving dexamethasone compared with 5% in the placebo group, but the actual utility of this treatment remains unclear.[86]

## Surgical Management and Financial Costs

Approximately 20% to 40% of children who undergo surgical reduction of their intussusception will require bowel resection.[87] The long-term risk for small bowel obstruction from adhesions is approximately 3% to 5% for children older than 1 month.[88] The costs of surgical care are considerably higher than those of nonsurgical reduction. Earlier reports indicate a four- to fivefold increase in the cost of surgical management.[89,90] A more recent report that included the performance of repeat delayed enemas shows a mean hospital cost of $9205 for the group receiving delayed enema and $14,422 for those receiving immediate surgery after first enema. For those patients who are successfully managed as outpatients and discharged from the emergency department, there are additional cost savings and reduced length of stay.[91]

### KEY POINTS

- Intussusception is the most common cause of small bowel obstruction in children aged 3 months to 5 years.
- Ninety to ninety-five percent of intussusceptions in children are ileocolic and idiopathic. Lead point mass lesions are found in approximately 5% in the first year of life.
- The most common lead points are Meckel diverticulum, duplication cyst, polyp, and lymphoma, the latter typically in the older children.
- The classic clinical symptom triad is vomiting, abdominal pain, and bloody stools; each of these is found in 58% to 100% of cases, but the full triad is documented in approximately 25% to 65%.
- Ultrasound is the primary imaging modality for diagnosing intussusception.
- Air enema overall has a reported higher success rate than liquid enema.
- Perforation rate is less than 1% for both air and liquid enema reduction.
- The most consistent factor that predicts unsuccessful enema reduction is duration of the symptoms.
- Recurrence rates range between 5% and 15%, regardless of reduction method, typically within the first 48 hours.

# 108 Tumors and Tumor-like Conditions

M. Beth McCarville*

Tumors and tumor-like conditions affecting the colon in children can be divided into several categories. For the purpose of this chapter, we will discuss benign lymphoid hyperplasia, vascular lesions of the colon, and neoplasms. Several neoplasms arise in patients with genetic disorders, and in those cases,[1] we provide a brief description of the disorder. Although these colonic lesions, particularly neoplasms, tend to be rare in children, it is incumbent on the radiologist to be familiar with them to provide a thoughtful, thorough consultation regarding imaging findings.

## NONNEOPLASTIC LESIONS

### Benign Lymphoid Hyperplasia

***Overview.*** Benign lymphoid hyperplasia is a benign condition of the bowel most frequently found in the distal ileum and the colon. These lesions represent patches of lymphoid tissue and can be seen in both adults and children. The precise prevalence in children is unknown, but the entity has been found in up to 30% of symptomatic patients undergoing colonoscopy.[1]

***Etiology, Pathophysiology, and Clinical Presentation.*** The observation of benign lymphoid hyperplasia in families suggests that genetic or environmental factors could be pertinent.[2] A high prevalence of lymphoid hyperplasia in adults has also been found, possibly related to an enhanced immune response.[3] In children, a number of theories have been proposed, including a local response to infection, immunodeficiency states, and local hypersensitivity reaction. Controversy also exists regarding the association of benign lymphoid hyperplasia with autism spectrum disorder.[4]

Benign lymphoid hyperplasia is usually discovered incidentally either on imaging or at endoscopy. As such, it is almost certainly underrecognized, and its true prevalence is unknown. Visual inspection at colonoscopy will demonstrate multiple raised, closely spaced areas along the bowel wall.

***Imaging.*** The appearance on imaging studies is that of innumerable small filling defects, mostly uniform in size, at times centrally umbilicated, and most commonly seen on double-contrast imaging of the colon (Fig. 108.1). The lesions typically range in size from 2 to 3 mm and are often too small to be detected on a single-contrast examination. One of the earliest imaging descriptions stressed the need to distinguish lymphoid hyperplasia from true polyps,[5] citing instances in which colectomies were performed because the benign nature of these lesions was not recognized. The characteristic pattern of innumerable small, uniform lesions also should be distinguished from benign lymphoid polyps, which are more common in adults and can become large and pedunculated.[6]

***Treatment.*** Lymphoid hyperplasia itself requires no specific treatment. If it is associated with another condition, then that condition would be treated accordingly.

### Vascular Lesions

***Overview.*** A number of vascular lesions and vascular tumors can arise within the colon. Although rare in children, they usually have specific clinical and imaging findings that can allow for a specific diagnosis. Some vascular lesions will be found incidentally while others present as lower gastrointestinal (GI) tract bleeding.

***Etiology, Pathophysiology, and Clinical Presentation.*** Vascular lesions of the colon represent a wide array of conditions. Colonic varices (particularly in the rectal region) appear as mural lesions and typically are associated with portal hypertension, providing a collateral pathway between the portomesenteric and the systemic venous systems. This collateral pathway has been reported to occur in nearly one-third of children with portal hypertension, in whom rectal bleeding is seen in 7%.[7]

Other colonic vascular lesions that cause lower GI bleeding include venous malformations, arteriovenous malformations, angiodysplasia, telangiectasias, and hemangiomas.[8] Most vascular malformations of the pediatric GI tract are vascular malformations of the cavernous type. These can be components of syndromes of anomalous vascular development such as Klippel–Trenaunay syndrome and blue rubber bleb nevus syndrome.

Because vascular lesions of the colon tend to come to light when they are symptomatic, the true incidence is unknown, but they are believed to be rare in children. The presentation can be that of lower GI bleeding or iron deficiency anemia. It should be noted that hemangiomas, though discussed here, fall under the category of vascular tumors of the GI tract and are associated with cutaneous hemangiomas in up to 50% of cases.

***Imaging.*** The lesions are difficult to resolve with most imaging modalities, but imaging with CT in the early arterial phase after contrast injection can demonstrate these lesions. Involved bowel will show intense enhancement (Fig. 108.2), and occasionally abnormal supplying arteries or draining veins are visible. In a minority of cases with bleeding, active extravasation can be seen.[9]

***Treatment.*** Much like vascular lesions elsewhere in the GI tract and indeed elsewhere in the body, the treatment depends on the specific lesion, its location, the degree and extent of involvement, and the clinical status of the patient. These lesions can be treated medically or surgically, embolized angiographically, or sclerosed endoscopically.

## NEOPLASTIC LESIONS

Neoplasms of the colon are rare in children. Most are benign juvenile polyps. Polyps associated with the hereditary polyposis syndromes are quite rare, and there is often a known family history. Primary malignancies arising from the colon and metastatic disease to the colon are rarer still. These three groups will constitute the remainder of this chapter.

Double-contrast barium enema has been essentially replaced by ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) for evaluation of colonic masses. These modalities are used in conjunction with endoscopy, snare resection, and/or surgical intervention for diagnosis and staging.

### Juvenile Polyps

***Overview.*** Juvenile or hamartomatous polyps are the most common intestinal tumors in childhood, with a prevalence of 1% to 3%. They may be single or multiple, and most are found in the sigmoid colon and rectum, but they can arise anywhere along the GI tract.

---

*The author acknowledges the contributions to this chapter of Jeffrey Traubici and Alan Daneman from the previous edition.

***Etiology, Pathophysiology, and Clinical Presentation.*** Histologically these lesions appear as mucus-filled glands, and they might be related to blocked, hyperplastic mucus glands. A dense infiltrate of inflammatory cells suggests an inflammatory inciting event, and thus the synonymous term "inflammatory polyp." However, the underlying etiology of these isolated polyps remains to be determined.

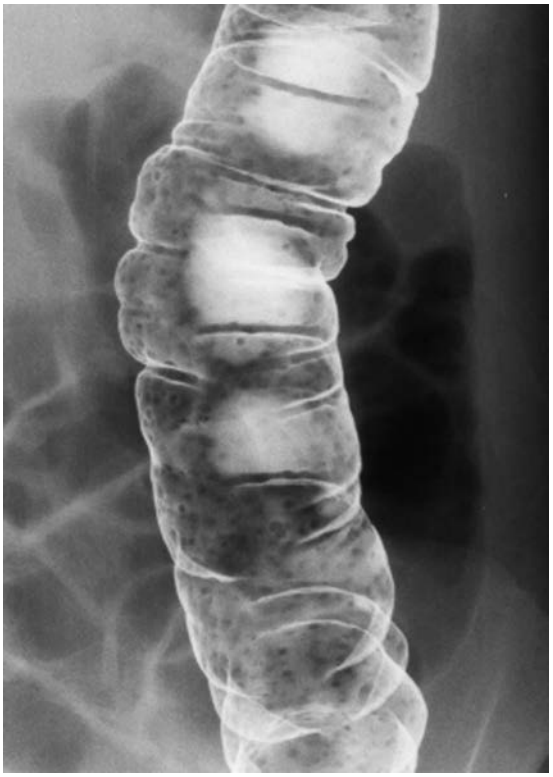

**Figure 108.1. Benign lymphoid hyperplasia.** An 11-year-old girl had a double-contrast barium enema as part of the workup for rectal bleeding. A spot image of the descending colon demonstrates numerous filling defects that are uniform in size. The findings are consistent with benign lymphoid hyperplasia. Similar findings were seen throughout the colon.

Most patients present in the first decade, typically between 2 and 5 years of age. The most common presenting symptom is painless, bright-red rectal bleeding. Pain is associated with the rare complication of colocolic intussusception. Some children present with iron deficiency anemia and others with a prolapsing mass, which can be mistaken for rectal prolapse.[12]

***Imaging.*** In the past, investigation for colonic neoplasms such as the juvenile polyp in a child with rectal bleeding often included a double-contrast enema. On such an examination, the lesions are typically smooth, can be sessile or pedunculated, and measure 3 cm or less. Currently the diagnosis is frequently made endoscopically or on cross-sectional imaging, with the lesions appearing as nonspecific intraluminal masses (Fig. 108.3).

***Treatment.*** Because these solitary lesions carry no increased risk of malignancy, the treatment is polypectomy alone. Most commonly, a polypectomy is performed with snare resection during a colonoscopy. Anemia is treated with iron supplementation or transfusion if necessary. With resection of the polyp, the blood loss should cease. If multiple polyps are present or a family history of juvenile polyps is uncovered, then the patient should be evaluated for the juvenile polyposis syndrome (JPS), discussed later.

## POLYPOSIS SYNDROMES

Although the inherited polyposis syndromes are rare, they have the potential to cause serious morbidity and mortality within affected families. A proper understanding of the various conditions is important for the primary clinician and consultant. Genetic screening and initiation of a surveillance plan is mandatory. Surveillance should include the GI tract as well as extraintestinal sites of potential disease.[13]

### Syndromes Associated With Juvenile or Hamartomatous Polyps

#### Juvenile Polyposis Syndrome

***Overview.*** First described in the literature in 1964,[14] JPS is an autosomal-dominant condition characterized by a multiplicity of

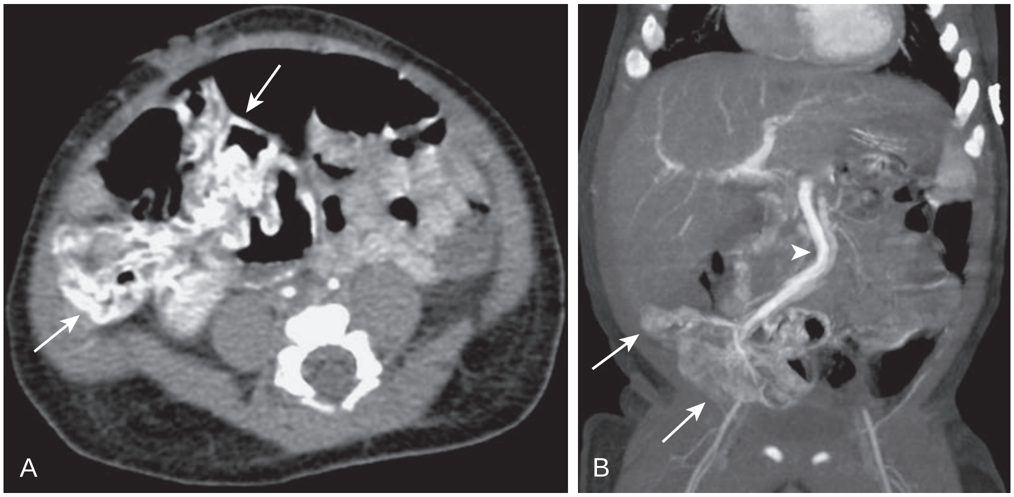

**Figure 108.2. Colonic infantile hemangioma.** An infant presented at 4 weeks of age with gastrointestinal bleeding requiring multiple transfusions. An enhanced computed tomography scan of the abdomen and pelvis was done in the arterial phase. Axial (A) and coronal reconstruction (B) demonstrates intense enhancement of the wall of the distal ileum and cecum *(arrows)*. Venous drainage is through a markedly dilated mesenteric vein (*arrowhead* in B). The affected segment was resected, and pathology confirmed that it was an infantile hemangioma.

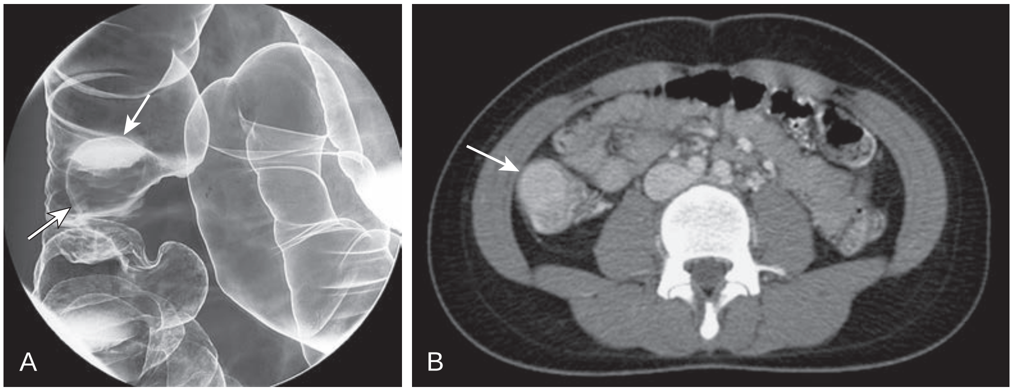

**Figure 108.3. Juvenile polyp.** A 15-year-old girl presented with a 2-month history of abdominal pain. (A) A double-contrast enema demonstrates a sessile mass consistent with a polyp arising from the wall of the ascending colon *(arrows)*. (B) A computed tomography scan in the same patient demonstrated an enhancing mass *(arrow)* within the lumen of the ascending colon.

GI hamartomatous polyps. It is the most common of the hamartomatous syndromes.

***Etiology, Pathophysiology, and Clinical Presentation.*** In approximately 75% of cases, a family history of the disease will be present. Mutations have been identified in the *SMAD4* gene on chromosome 18 and the *BMPR1A* gene on chromosome 10.[15]

From a clinical standpoint, the disease should be considered in any patient with five or more juvenile polyps in the colon, extracolonic juvenile polyps, or with any number of polyps when associated with a positive family history.[16] The clinical presentation can be more variable than in the patient with nonsyndromic juvenile polyps. In addition to rectal bleeding, anemia, and intussusception, patients with JPS in whom there is involvement of a large segment of the GI tract can present with failure to thrive, malabsorption, or hypoalbuminemia. Associated congenital anomalies include hydrocephalus and hypertelorism. Small series have described JPS in association with other conditions, including hereditary hemorrhagic telangiectasia.[17]

***Imaging.*** The imaging appearance of polyps in JPS differs in the number of polyps identified, but otherwise it is similar to that of isolated lesions.

***Treatment.*** Patients with JPS have an increased risk of colonic malignancy reported to be as high as 50%.[18] Screening of these children can be done with a combination of endoscopy, various imaging modalities, and capsule endoscopy. Polyps typically are removed via snare polypectomy.

## Cowden Syndrome

***Overview.*** Cowden syndrome is a rare autosomal-dominant syndrome with an estimated prevalence of 1 : 200,000 individuals.[19] Features include hamartomatous polyps of the GI tract; hamartomatous lesions of the skin; hamartomas of other solid organs; and neoplasms of the breast, thyroid, and endometrium.[19] GI tract polyps arising in these patients include inflammatory, hyperplastic, lipomatous, and even adenomatous lesions.

***Etiology, Pathophysiology, and Clinical Presentation.*** Cowden syndrome is one of several disorders that fall under the category of the protein tyrosine phosphatase and tensin (PTEN) hamartoma tumor syndromes. Mutations in the tumor suppressor gene *PTEN* are present in up to 80% of patients with Cowden syndrome.[19,20]

The presentation of patients with Cowden syndrome can be similar to the other conditions in which colonic polyps occur. Patients with Cowden syndrome also have an increased risk of neoplasms of the thyroid, endometrium, and breast. The lifetime risk of breast cancer in women with Cowden syndrome is between 25% and 50%. In these women, the onset of breast cancer is earlier than in sporadic cases. At present, the risk of GI malignancy in these patients is unknown.[19]

***Imaging.*** The imaging appearance of polyps in Cowden syndrome is similar to that of polyps described earlier in the chapter.

***Treatment.*** Polyps in patients with Cowden syndrome are treated with snare polypectomy; screening can include endoscopy, fluoroscopic and cross-sectional imaging modalities, and capsule endoscopy. Anemia is treated with iron supplementation and transfusion if necessary. Appropriate screening for the associated neoplasms also must be initiated. This screening consists of early breast self-examination and perhaps early initiation of mammography. Thyroid and uterine surveillance with screening ultrasound also is recommended.

## Peutz–Jeghers Syndrome

***Overview.*** Peutz–Jeghers syndrome is an autosomal-dominant syndrome with an incidence of approximately 1 : 120,000 people.[21] It was described separately, in 1921 and 1949, by the authors after whom the syndrome was named. In this condition, hamartomatous polyps develop in the GI tract, in association with skin and mucosal hyperpigmented lesions.

***Etiology, Pathophysiology, and Clinical Presentation.*** In familial Peutz–Jeghers syndrome, evidence indicates that the syndrome relates to mutations in the *STK11* (serine threonine kinase) gene. In up to 50% of cases, no family history of the disease is present, which suggests a fairly high rate of new mutation.[22]

The condition is characterized by pigmented lesions of the lips and buccal mucosa and hamartomatous polyps of the GI tract. The polyps can occur anywhere in the GI tract, but are most commonly found in the small bowel, particularly the jejunum. Polyps in the large and small bowel tend to be pedunculated, while those in the stomach tend to be sessile (Fig. 108.4A). Polyps also can arise in the gallbladder, bronchi, urinary bladder, and ureter.

The most common GI-related clinical presentation is abdominal pain as a result of intussusception, with a polyp as a pathologic lead point. Patients also can present with clinical findings related to GI hemorrhage.

***Imaging.*** The appearance of the polyps in Peutz–Jeghers syndrome does not differ significantly from that seen in other hamartomatous polyposes. It is not unusual for patients to present with intussusception and the typical associated imaging findings (see Chapter 107), with the polyp acting as a pathologic lead point (Fig. 108.4B and C).

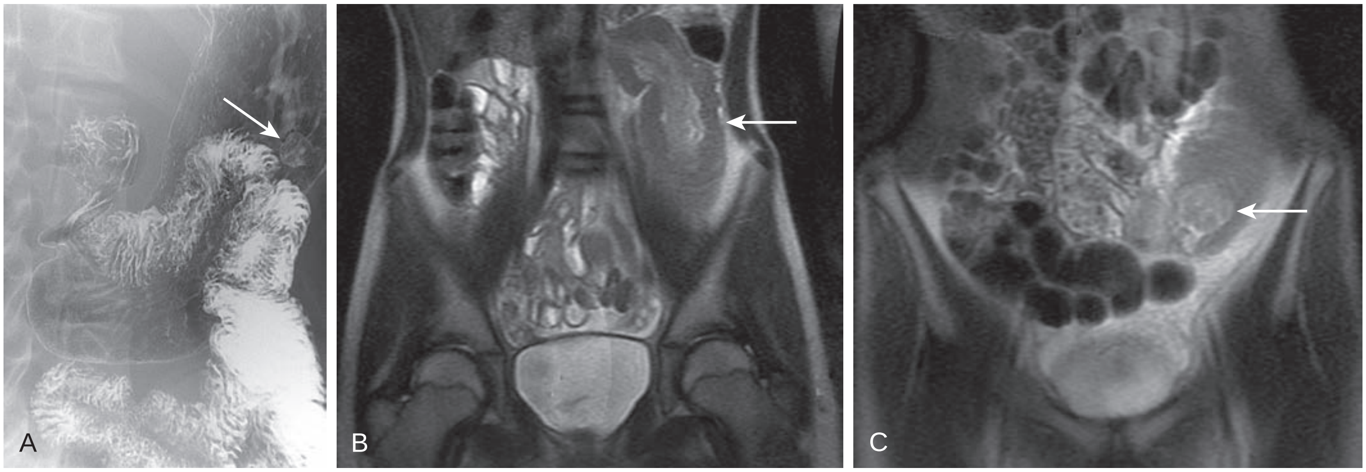

**Figure 108.4. Peutz–Jeghers syndrome in a 14-year-old girl.** (A) A double-contrast upper gastrointestinal series demonstrates a small polyp *(arrow)* arising in the proximal body of the stomach. (B) and (C) Several years later, the patient presented with abdominal pain and was found to have a small bowel intussusception *(arrow)*. (B) A coronal magnetic resonance imaging single shot fast spin echo sequence demonstrates the intussusception along the left flank *(arrow)*. (C) What was believed to be a polyp functioning as a lead point *(arrow)* was seen lower in the pelvis on a more anterior image of the same sequence.

***Treatment.*** The treatment of the polyps is removal, either surgically or endoscopically, when necessary. Anemia is treated with iron supplementation and transfusion if necessary. Although it is not clear whether the polyps themselves have malignant potential, it is now accepted that there is an overall increased risk of neoplasms in patients with Peutz–Jeghers syndrome, typically in adulthood. Colorectal, breast, and ovarian tumors predominate.[21]

## Polyposis Syndromes Associated With Adenomatous Polyps

Several conditions fall under the category of polyposis syndromes associated with adenomatous polyps. These conditions include familial adenomatous polyposis (FAP), attenuated FAP, Gardner syndrome, and Turcot syndrome. In all these conditions, a germline mutation occurs in the adenomatous polyposis coli *(APC)* gene, located on the long arm of chromosome 5.

### Familial Adenomatous Polyposis and Variants

***Overview.*** The prevalence of FAP is between 1:5000 and 1:17,000.[23] Although the condition is defined by the presence of more than five adenomatous polyps, affected persons often will have hundreds, if not thousands, of polyps.

Extraintestinal lesions also are well described. In nearly one in five patients, a desmoid tumor will develop (e-Fig. 108.5), which will be discussed further later in this chapter. About 60% to 90% of patients have congenital hypertrophy of the retinal pigment epithelial cells, which is present at birth and is assessed by fundoscopy. Lesions that can develop later in life include osteomas (often in the skull and mandible), lipomas, fibromas, and epidermoid cysts. An increased risk exists of developing hepatoblastoma (e-Fig. 108.6), thyroid and pancreatic cancers, cholangiocarcinoma, and central nervous system (CNS) tumors, particularly medulloblastoma.[24] It is believed that, with better management of the intestinal manifestations of FAP and subsequent longer life spans of affected patients, the incidence of these extraintestinal processes will likely increase.

In patients with attenuated FAP, fewer polyps are present and the inevitable development of malignancy occurs nearly a decade later than in the classic form. Patients with attenuated FAP manifest similar extraintestinal lesions and also exhibit a propensity for extracolonic polyps.

Gardner syndrome is believed to represent a variant of FAP, rather than a separate syndrome; some clinicians include these patients within the FAP group and agree that the term Gardner syndrome is now obsolete. Others continue to use the term Gardner syndrome in cases where the extraintestinal disease is particularly prominent. In Gardner syndrome, one sees the typical GI manifestations of FAP, including the plethora of polyps and the associated malignancies. Desmoid tumors often are cited as a classic extracolonic lesion in persons with Gardner syndrome; these tumors are a locally aggressive form of fibromatosis and arise from the fascial tissue associated with muscle or from the mesentery. The tumors typically appear in the abdomen or in the abdominal wall.[25] They may develop after trauma, such as after a prophylactic colectomy, and are a major cause of morbidity and mortality in these patients.[25]

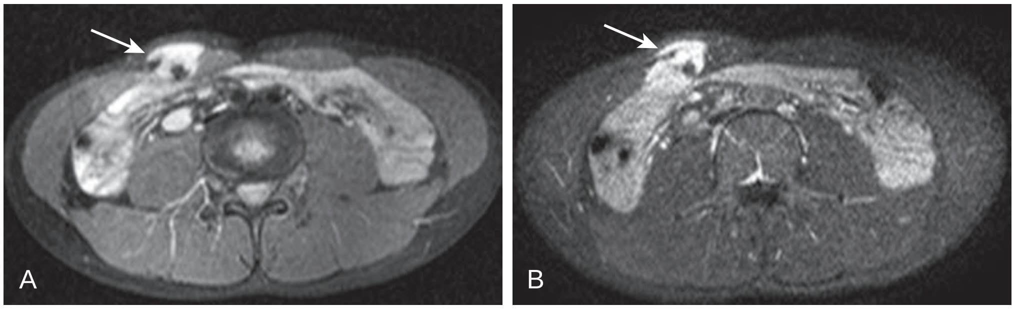
In addition to desmoid tumors, patients with Gardner syndrome develop osteomas (particularly of the mandible), periampullary duodenal polyps, lipomas, fibromas, nasopharyngeal angiofibromas, and epidermoid cysts.

***Etiology, Pathophysiology, and Clinical Presentation.*** FAP is an autosomal-dominant condition in which a mutation is present in the *APC* gene; approximately 30% of cases result from spontaneous mutations.[26] This mutation results in a failure of apoptosis and in uncontrolled cell growth, with the ultimate development of polyps—in this case, adenomatous ones.

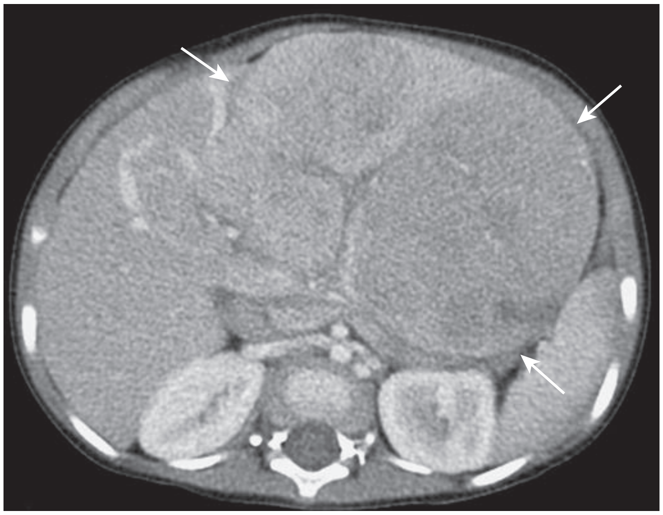
Polyps tend to develop late in the first decade and in the second decade of life, with symptoms arising in the third decade. Therefore, unless screened, patients may not be diagnosed until adulthood. The most common presentation in childhood is rectal bleeding.[23]

***Imaging.*** In classic FAP, the colon is carpeted with lesions. The polyps tend to vary in size and lack the central umbilication often seen in benign lymphoid hyperplasia.

A desmoid tumor is most often hypoechoic and at times nearly anechoic on ultrasound. On CT, the lesion often will be low attenuation, exhibit little enhancement in the portal venous phase, and may show increased enhancement in a delayed phase. Signal characteristics vary on MR although the lesion is usually of low signal intensity on T1-weighted sequences and of high signal on T2-weighted sequences (see e-Fig. 108.5).



**e-Figure 108.5. Desmoid tumor in a patient with familial adenomatous polyposis.** A 16-year-old boy with a history of familial adenomatous polyposis presented with a palpable mass of the abdominal wall. (A) An axial T2-weighted spectral presaturation with inversion recovery MR image demonstrates a lesion with high signal *(arrow)* that has arisen in or infiltrated the right rectus abdominis muscle. (B) A gadolinium-enhanced axial T1-weighted fat-saturated MR image demonstrates mostly avid enhancement. Some areas within the lesion on both sequences are low in signal and may represent areas of fibrosis.



**e-Figure 108.6. Hepatoblastoma in a patient with familial adenomatous polyposis (FAP).** A 22-month-old boy presented with an abdominal mass. The family history included FAP. An axial contrast-enhanced computed tomography image though the upper abdomen demonstrates a large mass *(arrows)* that arises from the left lobe of the liver. A biopsy was performed, and the findings were consistent with hepatoblastoma.

***Treatment.*** Colorectal carcinoma will develop in nearly all patients with FAP if it is left untreated. The accepted standard of care, therefore, is prophylactic colectomy. Polyps also can develop in other parts of the GI tract, and periampullary polyps of the duodenum are well described. Although the development of duodenal carcinoma is rare, particularly in children,[27] surveillance of the upper GI tract is recommended after prophylactic colectomy. Any polyps found are removed endoscopically.

### Turcot Syndrome

***Overview.*** Turcot syndrome originally was described in 1959 in siblings found to have adenomatous polyps of the colon and malignancies of the CNS.[28] It is now understood that the condition is one of adenomatous polyposis, with an increased risk of colorectal carcinoma and of CNS tumors. Within the past decade, the syndrome has been reclassified to include two separate conditions with distinct genetic and molecular abnormalities and phenotypes: brain tumor-polyposis syndrome-1 and -2.

***Etiology, Pathophysiology, and Clinical Presentation.*** Brain tumor-polyposis syndrome-1 is inherited as an autosomal-recessive condition and is the result of a defect in mismatch repair *(MMR)* genes, which correct deoxyribonucleic acid replication errors. This genetic abnormality is unusual in that, when heterozygous, the gene expresses a different phenotype, termed Lynch syndrome, also known as hereditary nonpolyposis colorectal cancer syndrome. Brain tumor-polyposis syndrome-2 is inherited as an autosomal-dominant condition, with mutations in the *APC* gene.[29,30]

The clinical presentation is similar to that seen in FAP. Patients also can exhibit café au lait–type lesions and multiple lipomas. Patients with brain tumor-polyposis syndrome-1 are characterized by development of primarily astrocytomas and glioblastomas, as well as hematologic malignancies. Colorectal carcinomas arise at a mean age of 16 years; colon adenomas and carcinomas of the small bowel also develop in persons with this syndrome. Myriad colonic polyps occur in patients with brain tumor-polyposis syndrome-2, with carcinoma typically developing by 40 years of age; medulloblastoma is the more common CNS tumor that develops in these patients.[29]

***Imaging.*** The imaging of colonic polyps has been described earlier. The appearance of the polyps in patients with Turcot syndrome does not differ from that seen in other polyposes. The CNS malignancies typically are investigated with MRI.

***Treatment.*** The treatment in patients with Turcot syndrome depends on the individual clinical presentation and concerns. Polyps can be removed by snare polypectomy; however, given the risk of colorectal carcinoma, the patient may undergo a prophylactic colectomy. The CNS malignancies or other tumors are treated accordingly.

## OTHER COLONIC NEOPLASMS

### Benign Neoplasms

Rarely, other benign neoplasms can arise in the pediatric colon; they are largely sporadic and are not associated with other conditions. Lipomas (e-Fig. 108.7), leiomyomas, and neurofibromas have all been described. Hemangiomas and vascular malformations were discussed earlier in this chapter.

### Malignant Neoplasms

Isolated malignant colorectal neoplasms are quite rare in pediatric patients, and large series are limited and tend to represent years and decades of collected cases, during which time diagnostic methods and treatment protocols changed. In addition, such reports tend to represent the experience of referral centers where more complicated patients with more advanced disease might be treated.

### Adenocarcinoma

***Overview.*** Adenocarcinoma of the colon is exceedingly rare in children, with a prevalence of 1 in 1,000,000 persons younger than 19 years of age.[31] Mucinous carcinoma is the most common subtype described in sporadic cases of pediatric colon cancer. The tumor is more often associated with underlying predisposing conditions, such as FAP and its variants, hereditary nonpolyposis colorectal cancer syndrome, Peutz–Jeghers syndrome, and JPS, as well as Crohn disease and ulcerative colitis (Fig. 108.8).[31]

***Etiology, Pathophysiology, and Clinical Presentation.*** The etiology of colorectal adenocarcinoma is not completely understood although there are a number of risk factors that relate to age, ethnicity, diet, other medical conditions, smoking, and alcohol consumption.

Presenting symptoms include abdominal pain, an abdominal mass, "constipation," weight loss, and GI bleeding. Whereas these symptoms might lead to immediate consideration of a GI malignancy in adults, the clinical suspicion of colon cancer in children is low and may result in delayed diagnosis.[32]

***Imaging.*** Radiographs may be normal or suggest a bowel obstruction. Rarely one might see a mass or mass effect. Calcifications can be seen in the mucinous forms, both in the primary tumor and in the metastatic lesions. Contrast enema may show irregularity of the bowel wall, a mural lesion, or circumferential narrowing (Fig. 108.9). CT and MRI are the modalities used to evaluate for local and distant spread. The most common sites of metastases are lymph nodes, liver, lung, and adrenal glands.

***Treatment.*** The treatment is primarily surgical, followed by chemotherapy and, at times, radiation therapy. In some cases of metastatic disease, particularly to the liver, locally directed therapy is used.

### Neuroendocrine Tumors

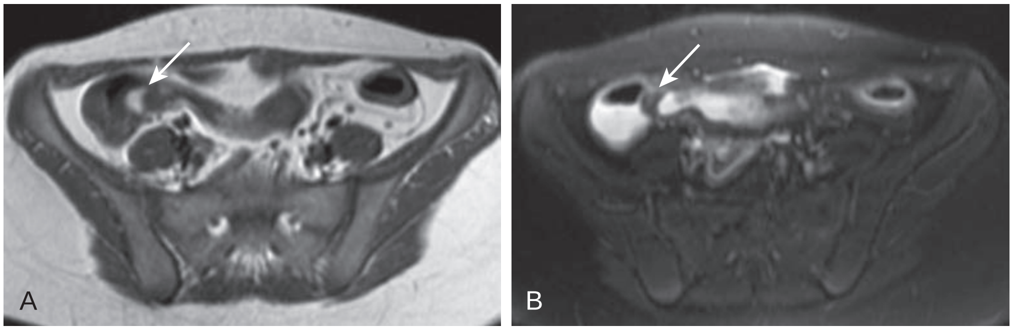
***Overview.*** Well differentiated neuroendocrine tumors, previously referred to as "carcinoid tumors," are neoplasms of epithelial origin, which, when they arise in the colon, are most commonly periappendiceal (Fig. 108.10). Attempts have been made to establish a staging system that would help predict prognosis.[33] The most important prognostic criteria appear to be patient age, tumor size, histology, and the presence or absence of lymph node involvement or distant metastases. In larger series, approximately 40% of lesions are well differentiated. The remainder are almost equally split between moderately and poorly differentiated lesions.[33]

***Etiology, Pathophysiology, and Clinical Presentation.*** The inciting event for the development of carcinoid tumor is not yet clear. These tumors may be seen in patients who have other malignant neoplasms. Appendiceal neuroendocrine tumors are the most common pediatric GI neuroendocrine tumors.[34]

Patients can present with abdominal pain. Commonly the lesion is discovered incidentally at appendectomy in a patient thought to have acute appendicitis. In some cases the lesion may act as a lead point for an intussusception. Patients with liver metastases can manifest the carcinoid syndrome (flushing, tachycardia, diarrhea), although it is extremely rare in the pediatric age group.

***Imaging.*** The imaging findings depend on the size of the mass, its location, and the extent of disease. If it is sufficiently small, the lesion can occlude the appendiceal lumen, resulting in a distended/obstructed appendix (see Fig. 108.10) mimicking acute appendicitis. Otherwise a nonspecific mass is seen with or without metastatic spread. As with adenocarcinoma, CT and MRI can be used to assess for extent of disease. The tumor can metastasize to the liver, lungs, and bone.

***Treatment.*** If the lesion is small (less than 2 cm) and localized, treatment is surgery alone. Chemotherapy is administered for metastatic disease.



**e-Figure 108.7. Lipoma at the ileocecal valve.** A 14-year-old girl presented with abdominal pain. T1-weighted (A) and fat-saturated T2-weighted (B) magnetic resonance images through the pelvis demonstrate a small mass at the level of the ileocecal valve *(arrows)*. The lesion is high in signal on the T1-weighted sequence and low in signal on the fat-saturated T2-weighted sequence.

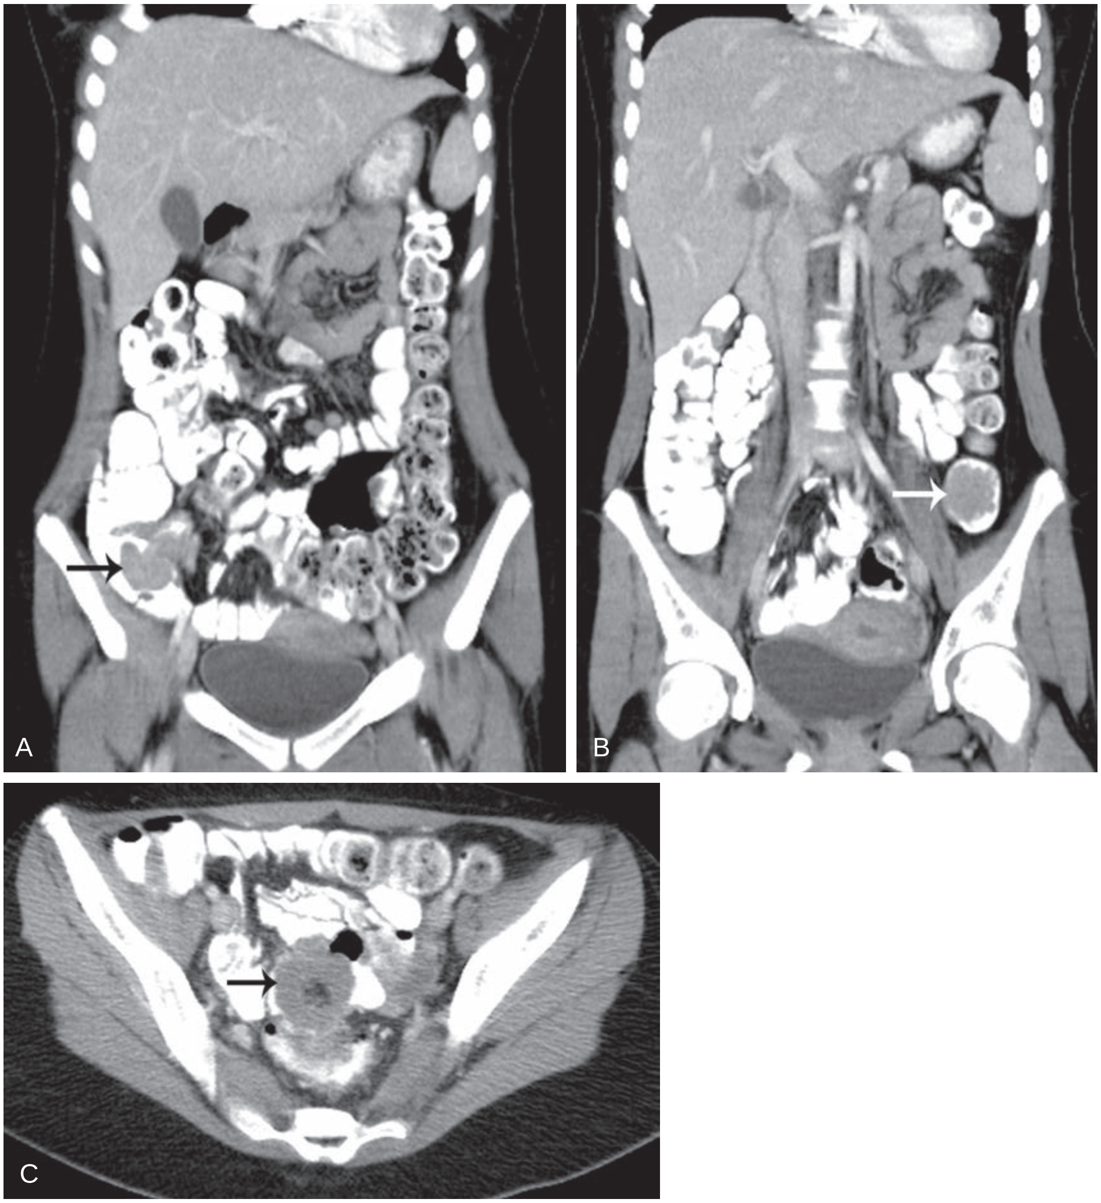


**Figure 108.8. Adenomatous polyps and rectal mucinous adenocarcinoma.** Screening colonoscopy in a 13-year-old girl with constitutional mismatch repair deficiency syndrome and anaplastic astrocytoma revealed several adenomatous polyps and rectal adenocarcinoma. Coronal reconstructed contrast-enhanced CT images demonstrate large, solid filling defects (A) at the ileocecal junction *(arrow)* and (B) in the descending colon *(arrow)*. Biopsy showed these to be adenomatous polyps. (C) Axial image from same CT examination shows an adenomatous polyp in the rectum that had undergone transformation to mucinous adenocarcinoma *(arrow)*.

## Lymphoma

***Overview.*** The colon can be a site of involvement in patients with lymphoma, although the small bowel is more commonly involved. Primary colorectal lymphoma accounts for less than 1% of all colorectal malignancies and occurs most often in the cecum.[35] Disorders predisposing to bowel lymphoma include ataxia-telangiectasia, Wiskott–Aldrich syndrome, agammaglobulinemia, severe combined immunodeficiency, and solid organ or bone marrow transplantation. There also appears to be an association between inflammatory bowel disease (IBD) and lymphoma. IBD may result in chronic antigenic stimulation.[35] Recent data shows that, when these patients are treated with immunosuppressive and biologic agents, they are at greater risk of developing lymphoma.[36] The risk of developing a neoplasm must be weighed against the risks associated with not adequately treating the primary disease.

***Etiology, Pathophysiology, and Clinical Presentation.*** As noted above, lymphoma arising in the colon may result from conditions such as immunosuppression after transplantation. Some investigators postulate a genetic component because a family history can sometimes be elicited. Others suggest a role for infectious agents, particularly the Epstein–Barr virus in patients with underlying IBD.[37]

The presenting symptoms in patients with GI lymphoma are often nonspecific and include abdominal pain and weight

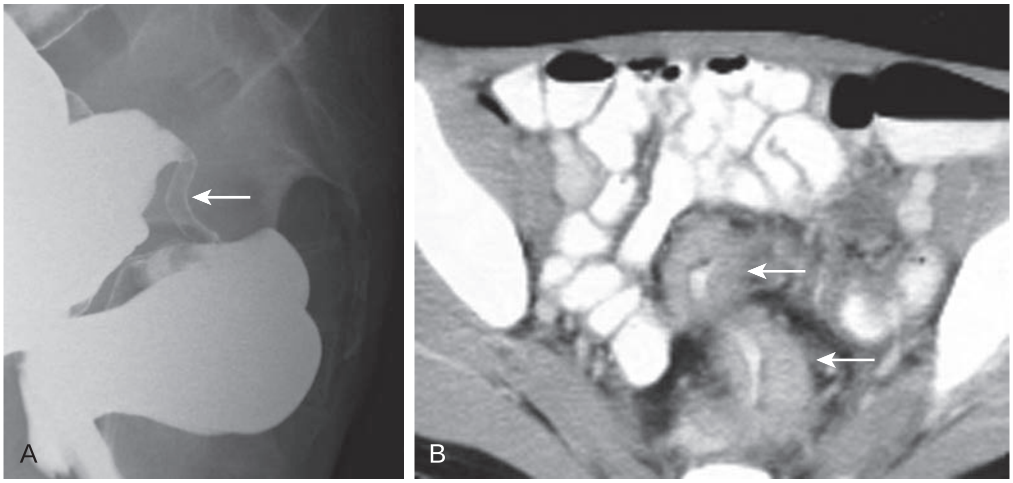

**Figure 108.9. Rectosigmoid adenocarcinoma.** A 14-year-old boy presented with rectal bleeding. (A) Lateral projection from a double-contrast barium enema demonstrates an area of circumferential narrowing *(arrow)* near the junction of the sigmoid colon and rectum. (B) A contrast-enhanced computed tomography scan also demonstrates circumferential soft tissue narrowing the lumen *(arrows)*. The lesion was resected and found to be an adenocarcinoma.

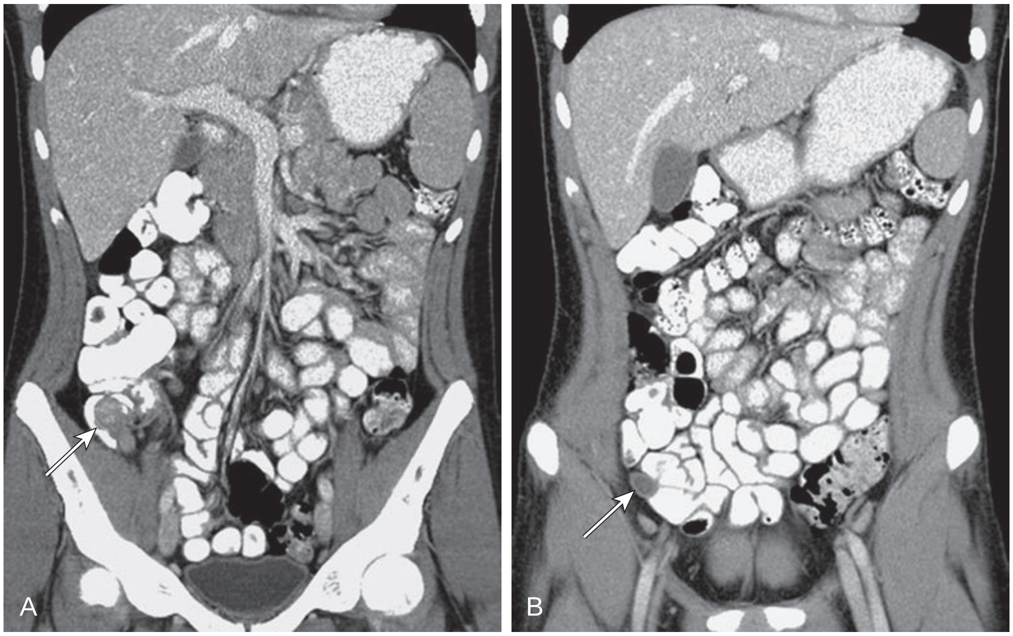

**Figure 108.10. Appendiceal neuroendocrine tumor.** A 16-year-old boy presented with intermittent right lower quadrant pain. (A) Contrast-enhanced coronal reformat CT demonstrates a mass at the base of the appendix invaginating into the cecum *(arrow)*. (B) The obstructed appendix is distended to its tip with fluid *(arrow)*.

loss. Bleeding and a change in bowel habits occur less frequently. If the lesion is large enough, it can present as a palpable mass. In some cases, the presentation is one of a colocolic intussusception.[38]

***Imaging.*** If contrast enema is performed, the appearance can be one of irregularity of the bowel wall, a smooth or lobulated mural mass, or circumferential narrowing. A long segment of the bowel can be affected. On ultrasound, the lesion is typically, although not always, hypoechoic, but is proved to be a solid mass by demonstration of flow on Doppler imaging. On CT or MRI an enhancing soft tissue mass is seen, which can be associated with adenopathy and/or solid visceral involvement (Fig. 108.11).

***Treatment.*** Treatment consists of chemotherapy and radiation therapy. In cases of relapse, high-dose chemotherapy followed by stem cell transplantation has been used.

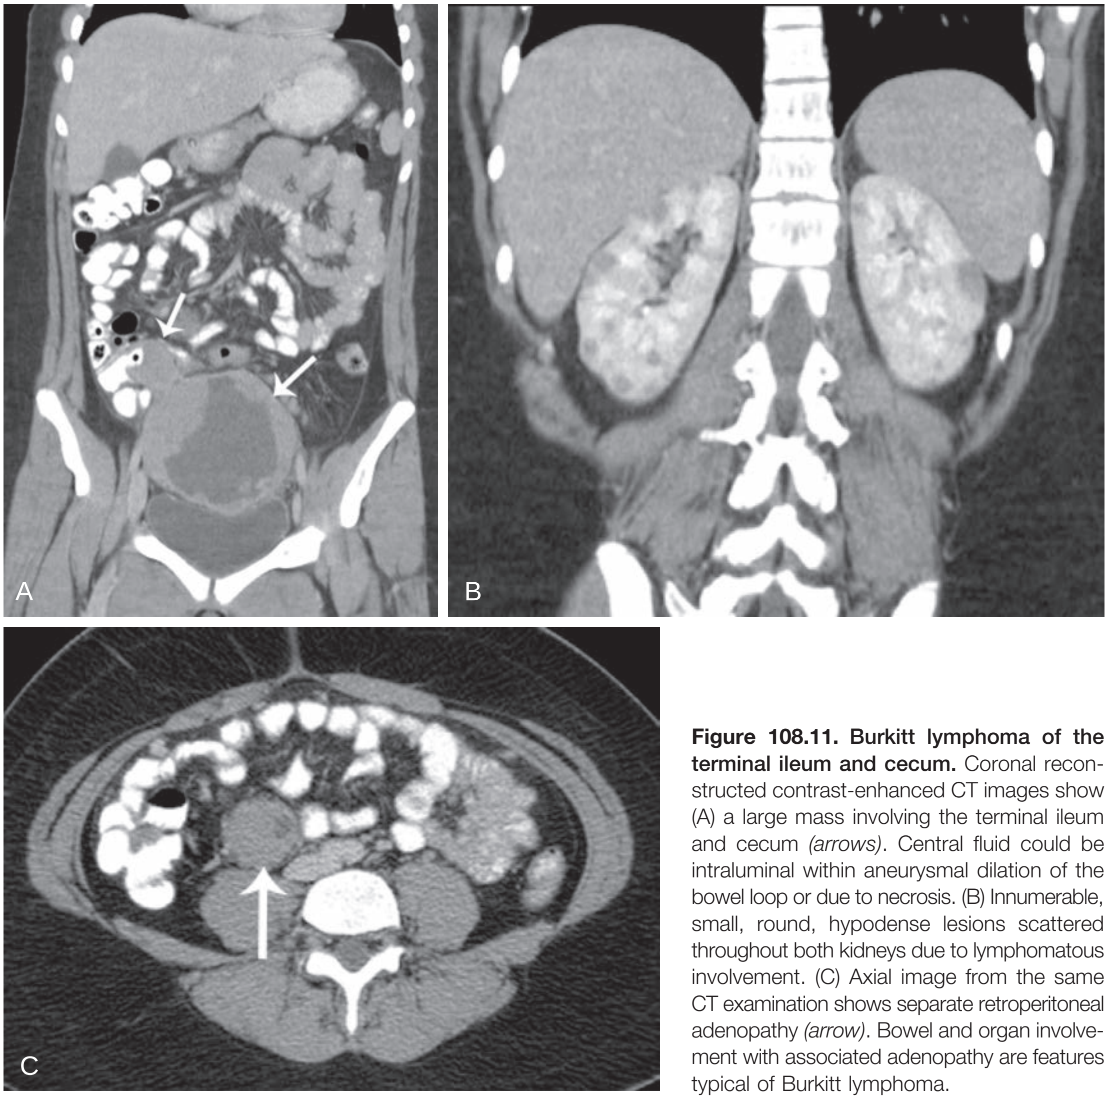

**Figure 108.11. Burkitt lymphoma of the terminal ileum and cecum.** Coronal reconstructed contrast-enhanced CT images show (A) a large mass involving the terminal ileum and cecum *(arrows)*. Central fluid could be intraluminal within aneurysmal dilation of the bowel loop or due to necrosis. (B) Innumerable, small, round, hypodense lesions scattered throughout both kidneys due to lymphomatous involvement. (C) Axial image from the same CT examination shows separate retroperitoneal adenopathy *(arrow)*. Bowel and organ involvement with associated adenopathy are features typical of Burkitt lymphoma.

## KEY POINTS

- Benign lymphoid hyperplasia most frequently involves the terminal ileum and colon. On double-contrast enema, the lesions are uniform in size (usually 2–3 mm) and can be umbilicated.
- Vascular lesions of the colon are rare but can present as lower GI bleeding. They can be difficult to demonstrate with imaging, although cross-sectional imaging may be useful, particularly arterial phase CT.
- The isolated juvenile polyp is the most common intestinal tumor in childhood. It has no known malignant potential and is treated with polypectomy alone.
- The hamartomatous syndromes include JPS, Peutz–Jeghers syndrome, and Cowden syndrome.
- The adenomatous syndromes include classic FAP, attenuated FAP, Gardner syndrome, and Turcot syndrome. Most persons believe that the term Gardner syndrome is obsolete and include the condition in FAP.
- Benign tumors of the colon tend to be sporadic and include lipomas, leiomyomas, and neurofibromas.
- Malignancies are rare but include lymphoma, adenocarcinoma, and well differentiated neuroendocrine tumors.

# 109 Abdominal Trauma

*George A. Taylor and Carlos J. Sivit*

## OVERVIEW

Trauma in children accounts for more than 500,000 hospital admissions and 20,000 deaths per year. After cranial trauma, the abdomen is the second most common site of injury, and approximately 80% of abdominal injuries are due to blunt force trauma. The most common reported mechanism is motor vehicle crashes, followed by automobile–pedestrian injuries. Other common causes of injury include bicycle trauma and falls from a height. In young children, injuries also may result from intentional or nonaccidental trauma.[1]

## CLINICAL PRESENTATION

Clinical variables that have been associated with a high risk of injury include gross hematuria, abdominal tenderness, seat belt ecchymoses, and a high trauma score. Seat belt ecchymoses across the lower abdomen or flank represent an important high-risk marker for injury.[2,3] Such ecchymoses are associated with an injury complex to the lumbar spine, bowel, and bladder that accounts for most injuries to belted motor vehicle passengers.

Several points to be noted regarding hematuria and abdominal injury include the following: (1) most children with hematuria do not have a urinary tract injury; (2) a nonurinary tract injury is observed more frequently than a urinary tract injury in children with hematuria; (3) a negative urinalysis is associated with a very low risk of genitourinary (GU) injury; and (4) asymptomatic hematuria is a low-risk indicator for abdominal injury.

## IMAGING

Computed tomography (CT) is the imaging method of choice in the evaluation of abdominal and pelvic injury after blunt trauma in hemodynamically stable children. Evaluation with CT allows accurate detection and characterization of injury to solid and hollow viscera. CT also identifies and quantifies intraperitoneal and extraperitoneal fluid and blood, and can detect active bleeding. Additionally, CT reveals associated bony injury to the ribs, spine, and pelvis. The role of CT in the assessment of injured children includes establishing the presence or absence of visceral and bony injury, identifying injury that requires close monitoring and operative or endovascular intervention, and estimating associated blood loss. Normal CT findings also serve an important function in management of the injured child and in exclusion of an intraabdominal or pelvic source of blood loss.

The rapid and accurate evaluation of injured children with CT has resulted in improved triage, has contributed to reduced morbidity and mortality, and, along with improvements in supportive care, has played a critical role in the success of nonoperative management of solid organ injuries. While CT is the preferred imaging test in the setting of blunt abdominal trauma, intraabdominal injuries are only present in 5% to 15.5% of children sustaining blunt trauma. Yet, CT findings have been shown to change the initial management plan in nearly half of children assessed after blunt abdominal trauma.[4–6]

### Computed Tomography Technique

Children should be hemodynamically stable before undergoing a CT scan. An unstable patient must be stabilized or should proceed directly to surgery for evaluation and treatment.

A precise size-based protocol is important in minimizing the length of the examination and radiation dose exposure and in maximizing the information obtained. Sedation is rarely required before performing a CT scan in an injured child. However, because excessive patient motion results in image degradation, in select instances, a short-acting sedative may be necessary if diagnostic images are to be obtained.

The use of intravenous (IV) contrast material by rapid bolus injection is essential for maximizing the opacification of solid viscera and ensuring adequate injury detection (commonly 2 mL/kg to a maximum amount of 120 mL). Without appropriate IV administration of contrast material, solid organ laceration or hematoma may be relatively inconspicuous or missed. Additionally, the use of IV contrast material permits the detection of active hemorrhage. Multiphase and "total body" imaging are not necessary for the detection of abdominal injury and add an unnecessary radiation burden.

The use of oral contrast material in CT scanning after blunt abdominal trauma has not been found to improve the detection of intraabdominal injuries in children.[7] In our experience, the potential advantages of enhanced detection of small intramural or mesenteric hematomas and the detection of oral contrast extravasation as a sign of bowel rupture are small and outweighed by its potential disadvantages, including delay in performance of the examination and possibility of aspiration. If oral contrast material is used, diluted (2%) water-soluble contrast material should be administered at least 30 minutes before the scan is performed.

### Sonography in the Assessment of Abdominal Trauma

Sonography remains widely used in the screening of injured children and adults, and has been shown to have high sensitivity and specificity in the detection of hemoperitoneum; however, its utility is limited in comparison with CT. Solely identifying fluid does not necessarily reveal the cause or the site of injury, and the presence of hemoperitoneum in a hemodynamically stable child typically does not affect clinical management decisions. Furthermore, sonography provides no diagnostic information regarding injury to the bony pelvis or lumbar spine, it cannot be used in the diagnosis of hollow viscus injury, and it has been shown to miss approximately one-fourth to one-third of solid organ injuries.[8] Thus if one relies on identification of peritoneal fluid as a marker for hepatic and splenic injury, one will miss a significant number of injuries. Nevertheless, sonography has a potential role in diagnosing hemodynamically unstable patients because it can be performed rapidly at the bedside before the patient is taken to the operating room. In this role, it serves as a fast, noninvasive replacement for diagnostic peritoneal lavage. Recent studies suggest that contrast-enhanced sonography may have improved accuracy in delineating solid organ injuries.[9]

## Abstract:

Background: Blunt abdominal trauma is a common occurrence in children, and imaging plays an important role in initial medical management.

Findings: The most common mechanisms of injury are due to motor vehicle crashes and automobile-pedestrian injuries.

Contrast-enhanced CT is the imaging method of choice for identifying both solid and hollow visceral injuries. Contrast-enhanced sonography has also shown promise in evaluation of solid organ lacerations. The grade of injury has poor correlation with the need for surgical intervention.

Conclusions: CT information is currently most frequently used in deciding on admission to hospital, as well as the intensity and duration of hospitalization, and activity restriction.

spleen injury
kidney injury
bowel injury

## COMPUTED TOMOGRAPHY FINDINGS

### Splenic Injury

The spleen is the most commonly injured organ after blunt trauma, and frequently is associated with other organ injuries (Fig. 109.1). Because the spleen is much smaller than the liver, complex injury results in shattering or fragmentation of the organ (Fig. 109.2). Associated intraparenchymal or subcapsular hematoma may be present. As with hepatic injury, associated intraperitoneal hemorrhage is not always present, especially when the splenic capsule remains intact. Absence of hemoperitoneum is observed in approximately 25% of splenic injuries. After injury involving the splenic hilum, blood also can track along the splenorenal ligament into the anterior pararenal space surrounding the pancreas.

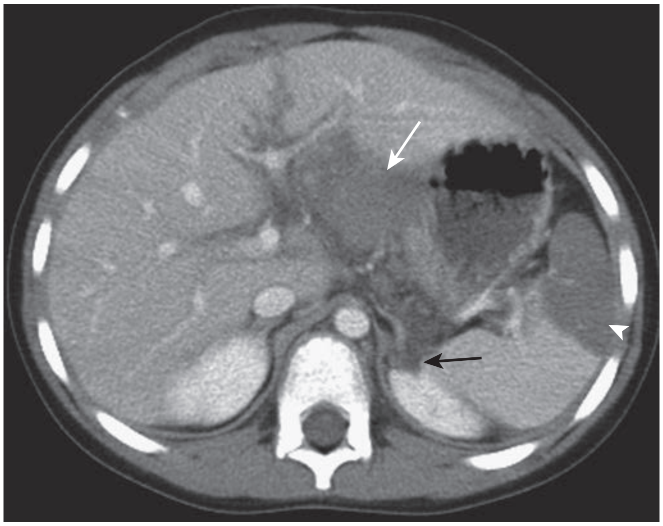

**Figure 109.1. Hepatic, splenic, and renal injury.** Contrast-enhanced axial CT image through the upper abdomen reveals a laceration to segment III of the left hepatic lobe *(white arrow)*, a splenic hematoma *(arrowhead)*, and a small laceration to the left kidney *(black arrow)*.

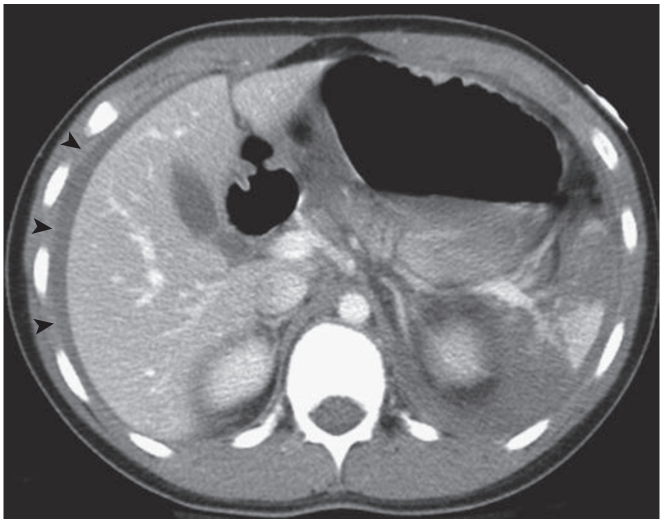

**Figure 109.2. Shattered spleen.** Contrast-enhanced axial CT image through the upper abdomen shows a shattered spleen with only a small amount of central contrast enhancement. Note right perihepatic hemoperitoneum *(arrowheads)*.

Pitfalls that may result in false-positive diagnosis of splenic injury include heterogeneous early splenic enhancement and splenic lobulations or clefts that mimic a laceration. The heterogeneous splenic enhancement is due to differences in enhancement between red and white pulp in the spleen. This artifact can be avoided by instituting a delay of at least 70 seconds after IV contrast material administration before scanning. Splenic clefts and lobulations typically have smooth contours and thus can be differentiated from lacerations, which typically have irregular contours.

***Treatment.*** Various injury grading scales have been described to objectively quantify injury to the spleen. As is true for hepatic injury, these scales are not predictive of surgical treatment in children because bleeding typically stops spontaneously, and nonoperative management is successful in most splenic injuries. Grade of injury often is used for nonoperative clinical decision making, similar to the use of grading in hepatic injury.[10,11]

### Hepatic Injury

Hepatic injury also is common after blunt trauma in children, in whom this organ is poorly protected from injury by overlying ribs because the immature chest wall is easily deformed by external forces. A hepatic laceration appears as a nonenhancing region of varying configuration (Figs. 109.1 and 109.3) that may be linear or branching. Lacerations may be associated with a parenchymal or a subcapsular hematoma.

The liver is surrounded by a thin capsule that, in turn, is covered by a peritoneal reflection of thin connective tissue. The presence of hemoperitoneum associated with hepatic injury principally relates to violation of the liver capsule at the site of injury. In several large series, hepatic injury was associated with hemoperitoneum in approximately two-thirds of cases. Associated hemoperitoneum may be seen throughout the greater peritoneal cavity. Often, the largest fluid pockets are located in the pelvis. Hepatic injury may not be associated with intraperitoneal hemorrhage if the injury does not extend to the surface of the liver, if the hepatic capsule is not disrupted, or if the injury extends to the liver surface in the bare area of the liver, which is devoid of peritoneal reflection (Fig. 109.4). Injury that extends to the bare area may lead to associated retroperitoneal hemorrhage, with blood often surrounding the right adrenal gland or extending into the anterior pararenal space.

Circumferential zones of periportal low attenuation may be seen in the liver after trauma. The presence of these low attenuation zones does not indicate hepatic injury. They most likely represent distended periportal lymphatics as a result of intravascular third-space fluid losses that occur after fluid resuscitation.[12,13]

***Treatment.*** A number of grading scales have been proposed to quantify the severity of hepatic injury. These scales emphasize the anatomic extent of the injury, including capsular integrity, extent of subcapsular collection, extent of parenchymal disruption, and involvement of the vascular pedicle. The most widely used grading scale was developed by the American Association for the Surgery of Trauma. It was devised initially to reflect surgical findings but often is used to report severity of organ injury upon CT scanning. In children, these scales are not predictive of the need for operative management because, in the vast majority of hepatic injuries, bleeding typically stops spontaneously and the injuries can be managed successfully without surgery regardless of the severity.[10] This response likely is a result of the relatively smaller size of blood vessels and the enhanced vasoconstrictive response in children relative to adults. Between 1% and 3% of children with hepatic injury require surgical or endovascular hemostasis. However, injury grading scales often are used in the decision algorithm of patient management regarding intensity and length of hospitalization and activity restriction.

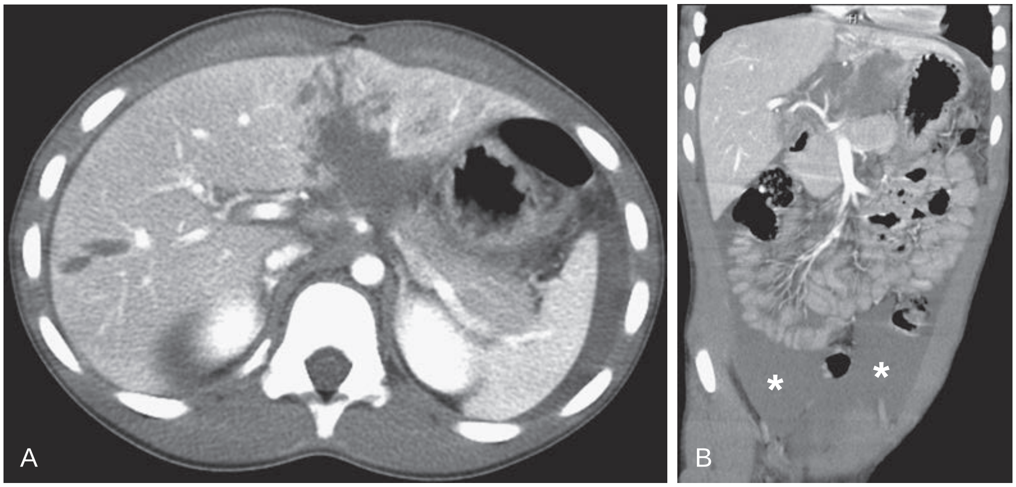

**Figure 109.3. Hepatic laceration and hemoperitoneum.** Contrast-enhanced axial CT image through the upper abdomen (A) reveals a complex hepatic laceration involving segment IV and a simple laceration of segment V. A coronal reformat image (B) shows a large associated hemoperitoneum in the pelvis *(asterisks)*.

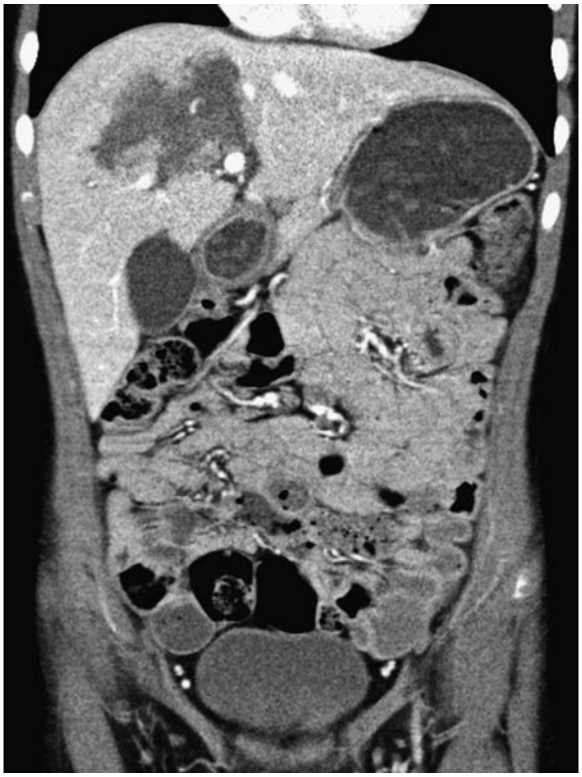

**Figure 109.4. Hepatic laceration without hemoperitoneum.** Coronal reformat of a contrast-enhanced CT scan reveals a laceration of segment VIII. No associated hemoperitoneum is present.

## Pancreatic Injury

Pancreatic injury is relatively uncommon in children. Injury to the body of the pancreas typically results from direct compression of the gland against the vertebral column, whereas injury to the head or tail of the pancreas results from a blow to the flank. Impact by bicycle handlebars is a common mechanism of injury to the pancreas. Direct signs of injury may be difficult to identify because of the small size of the gland, the paucity of surrounding fat, and the minimal separation of fracture fragments.

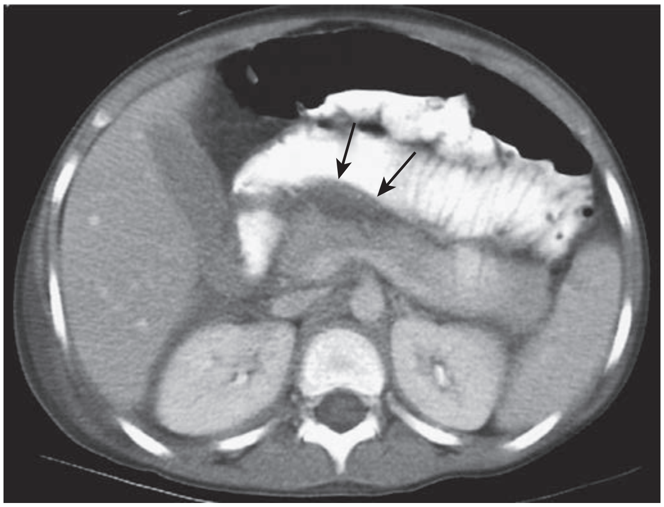

**Figure 109.5. Pancreatic injury with associated peripancreatic fluid.** Contrast-enhanced axial CT image through the upper abdomen shows fluid in the anterior pararenal space surrounding the pancreas *(arrows)*.

The best indicator of pancreatic injury at CT is unexplained peripancreatic fluid (i.e., fluid in the anterior pararenal space or lesser sac) (Fig. 109.5). This finding may be seen more often than the actual laceration. When fluid collects in the anterior pararenal space, it also may dissect between the pancreas and the splenic vein. However, pancreatic injury is only one cause of fluid in the anterior pararenal space.[1] Other causes include third-space intravascular fluid loss, blood that extends from injury to the spleen or to the bare area of the liver, blood or bowel contents from a duodenal injury, and blood or urine that exudes from a renal injury after disruption of the renal fascia.

Additional CT signs of posttraumatic pancreatitis include focal or diffuse gland enlargement, stranding of peripancreatic and/or mesenteric fat, thickening of the anterior renal fascia, and free peritoneal fluid.

A false-positive diagnosis of pancreatic injury may result from the partial volume effect caused by the gland's small size and undulating nature. This pitfall may be avoided by obtaining thin-section axial reconstructions and by creating coronal reformatted images.

Pancreatic injury may be complicated by peripancreatic fluid collections, which may evolve into pancreatic pseudocysts. Approximately half of focal fluid collections that develop after pancreatic injury spontaneously resolve, and half evolve into pseudocysts that may require percutaneous or surgical drainage. The most common location for pseudocyst formation is the intrapancreatic or peripancreatic anterior pararenal space, or lesser sac (Fig. 109.6). However, pseudocysts may develop anywhere in the abdomen or pelvis.

MR can be very useful in subsequent imaging evaluation of pancreatic injury, (Fig. 109.7); the addition of cholangiopancreatography may be of additional value in transection of the pancreatic duct.

***Treatment.*** Currently, there are divergent opinions regarding the management of pancreatic injury. Some practitioners have shown that nonoperative management of most pancreatic injury is successful, even when the pancreatic duct is involved. Others believe that distal pancreatectomy for transections occurring to the left of the spine is the treatment of choice because it is definitive and accompanied by an acceptable level of morbidity.[14–16]

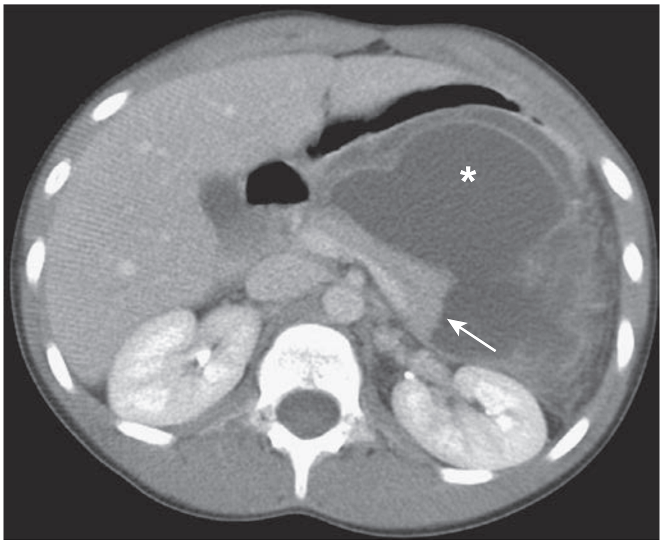

**Figure 109.6. Pancreatic pseudocyst.** Contrast-enhanced axial CT image through the upper abdomen shows a laceration of the pancreatic tail *(arrow)* with a large, thick-walled focal fluid collection *(asterisk)* representing a pancreatic pseudocyst in the anterior pararenal space.

## Peritoneal Fluid and Hemorrhage

Attenuation values of blood in the peritoneal cavity vary widely, depending on whether it is unclotted blood (hemoperitoneum), clotted blood, or active hemorrhage. Furthermore, several factors affect measured attenuation values for peritoneal fluid on CT, including measurement technique, fluid location within the field, artifacts, and delayed fluid enhancement after IV administration of contrast material. Unclotted hemoperitoneum has attenuation values that range from 20 to 60 Hounsfield units (HU). Approximately one-third of fluid pockets exhibit attenuation values lower than 30 HU. Low attenuation fluid (<60 HU) in an acutely injured child also may represent bile, urine, bowel contents, third-space fluid losses, or preexisting ascites.

Clotted blood has higher attenuation values (60–90 HU) than does free-flowing blood because of its greater density and hemoglobin content. Because clotted blood typically is seen adjacent to the site of injury, the presence of focal, higher attenuation clotted blood has been described as the "sentinel clot" sign; it is a marker for the principal site of hemorrhage and occasionally may be useful in localizing the site of injury.

Occasionally, CT may reveal active hemorrhage in children who appear hemodynamically stable. The amount of hemoperitoneum noted on CT is not a measure of ongoing hemorrhage; rather, it reflects the cumulative amount of bleeding that occurred between the time of injury and the time the CT scan was obtained. The only sign of active hemorrhage on CT is the presence of focal or high attenuation areas (>90 HU) (Fig. 109.8), referred to in the literature as a contrast blush.[17] The rate of active bleeding required for detection on CT is unclear. CT is useful in identifying active bleeding but may have difficulty in localizing the site of the hemorrhage. The torn blood vessel may be difficult to see because of diminished contrast enhancement caused by vasoconstriction and loss of blood containing contrast material. Occasionally, this finding may be observed only on delayed scanning.

The absence of peritoneal fluid or blood does not exclude the presence of hepatic or splenic injury. More than one-third of hepatic injuries and one-fourth of splenic injuries in children have no associated peritoneal fluid. The relatively high prevalence of hepatic and splenic injury without associated peritoneal fluid has significant implications for imaging strategies in the assessment of injured children.

***Treatment.*** Most children with active hemorrhage detected on CT do not require operative intervention. It has been reported that 20% or fewer children with hepatic or splenic injury and active hemorrhage have required operative hemostasis.[17–19]

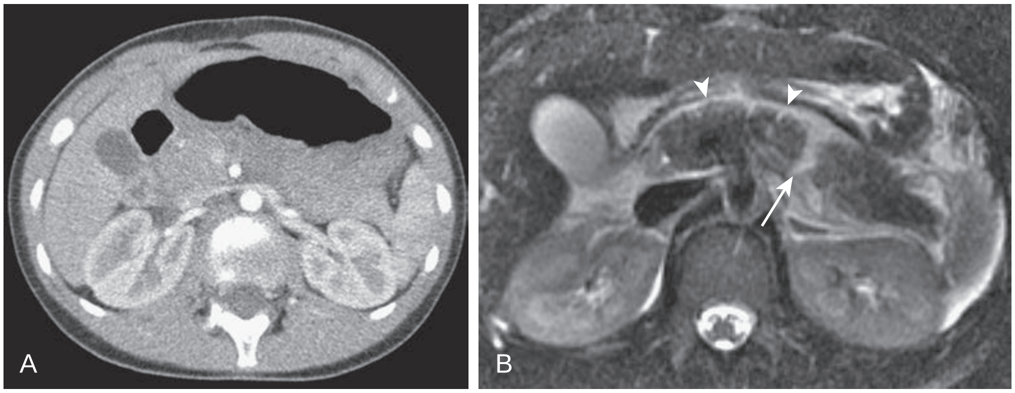

**Figure 109.7. Pancreatic injury missed on an initial CT scan.** A contrast-enhanced CT image through the upper abdomen (A) shows a heterogeneous ill-defined pancreas but no focal laceration. Axial T2-weighted fast spin echo MR image with fat saturation obtained the same day (B) shows peripancreatic fluid *(arrowheads)* and a laceration of the pancreatic body *(arrow)*.

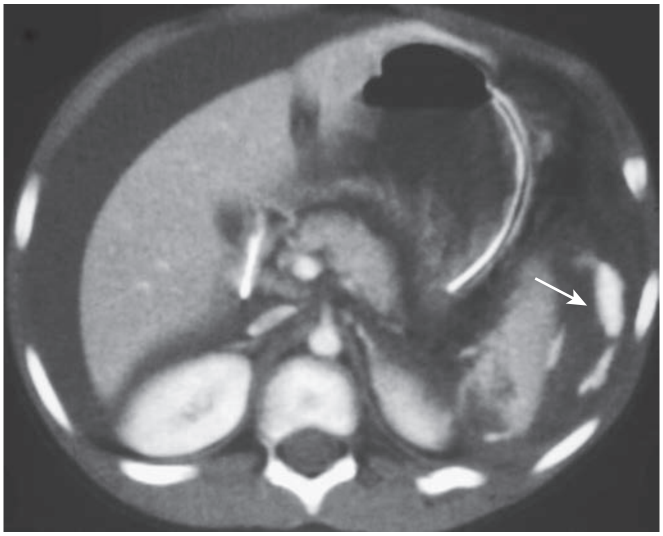

**Figure 109.8. Active hemorrhage.** Contrast-enhanced axial CT image through the upper abdomen shows a focal high attenuation collection representing intravenous contrast extravasation from a splenic arterial tear *(arrow)*.

## Bowel and Mesenteric Injury

Bowel and mesenteric injuries are uncommon after blunt trauma, occurring in 6% to 16% of injured children. The most common mechanisms of injury associated with bowel and mesenteric injury are motor vehicle crashes, handlebar injuries, nonaccidental trauma, and falls. Intestinal injury is the result of direct force on the gastrointestinal tract and mesentery leading to a crush injury, rapid deceleration producing a shearing force between fixed and mobile portions of bowel or mesenteric attachments, and a sharp increase in intraluminal pressure resulting in rupture of the gut.[20] Bowel rupture most commonly occurs in the mid to distal small intestine. The presence of seat belt ecchymosis and an acute hyperflexion (Chance) fracture of the lumbar spine are the only physical findings found to have a strong and significant association with bowel and mesenteric injury.[3] Nonaccidental injury always must be considered in a child with a history of minor blunt trauma who has a bowel perforation.[20,21]

Clinical signs and symptoms may be absent, minimal, or delayed, and CT plays an important role in early and accurate diagnosis. Delayed diagnosis can result in bowel ischemia, peritonitis, and, in rare cases, death as a result of sepsis. The main challenge for the radiologist is to distinguish between injuries that do and do not require surgical intervention. CT findings specific to bowel injury include the presence of extraluminal gas, extravasation of oral contrast material, and bowel discontinuity (Fig. 109.9).[22–24] The latter two findings are very uncommon in pediatric practice. Extraluminal gas, however, is present in 20% to 30% of children with bowel injury and is a highly specific finding, albeit with low sensitivity. In a supine patient, extraluminal gas tends to accumulate at the convexity of the abdominal wall and in the porta hepatis (Fig. 109.10). Blunt abdominal injury also can lead to intravasation of gas into the mesenteric and portal venous system, presumably through mucosal disruption, or because of ischemic changes resulting from mesenteric tears.[25] Injury to the retroperitoneal duodenum often results in localized bubbles of gas immediately adjacent to a thickened and distorted duodenum and pancreas. Review of the examination at a wide window setting is helpful in the detection of small amounts of extraluminal gas. Several other CT findings are common in injured patients but are less specific for significant bowel injury; these findings include focal bowel wall thickening and mesenteric fluid or stranding.

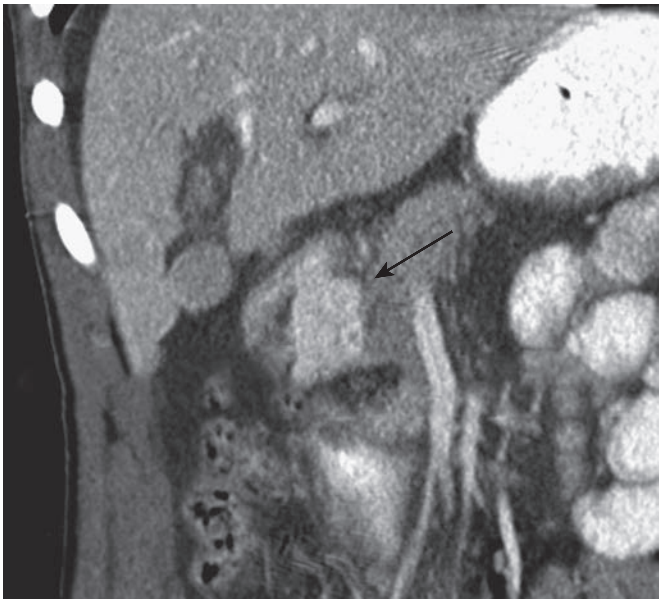

**Figure 109.9. Duodenal perforation with extravasation of oral contrast material.** Coronal reformat of a contrast-enhanced CT scan shows extravasation of oral contrast in the retroperitoneum *(arrow)* medial to the duodenal sweep.

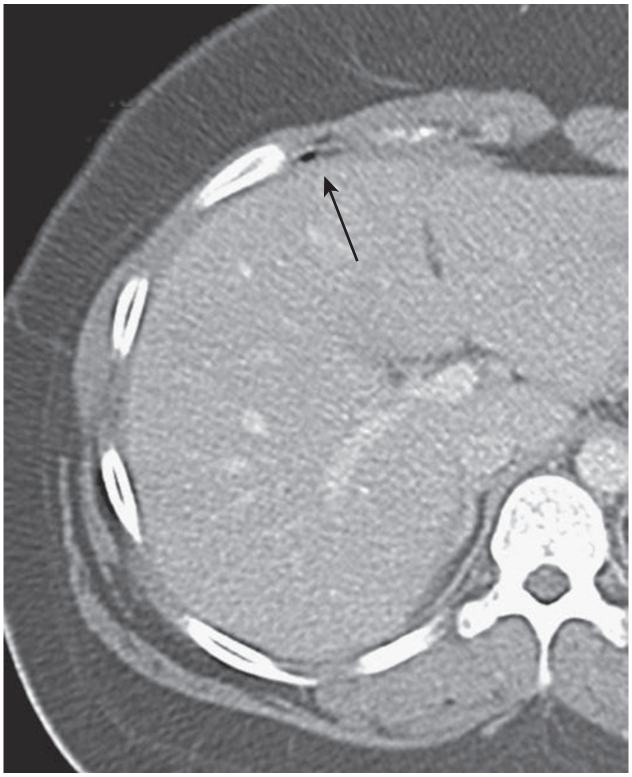

**Figure 109.10. Ileal perforation and extraluminal gas.** Contrast-enhanced CT image through the liver shows a small collection of extraluminal gas anterior to the right hepatic lobe *(arrow)*.

Intramural hematoma results from hemorrhage into the bowel wall after a partial-thickness tear has occurred; these injuries usually can be managed nonoperatively. The most common location is the duodenum. The CT appearance is that of focal bowel wall thickening that often is eccentric (Fig. 109.11). Large duodenal hematomas may appear dumbbell-shaped. Because the injury is

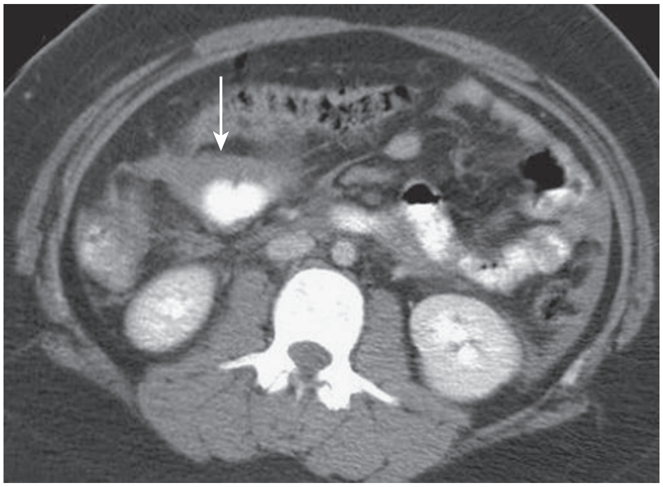

**Figure 109.11. Mesenteric tear and ischemic bowel.** Contrast-enhanced axial CT image through the mid abdomen shows a focal area of eccentric bowel wall thickening *(arrow)* due to a mesenteric tear. Ischemic bowel was confirmed at surgery.

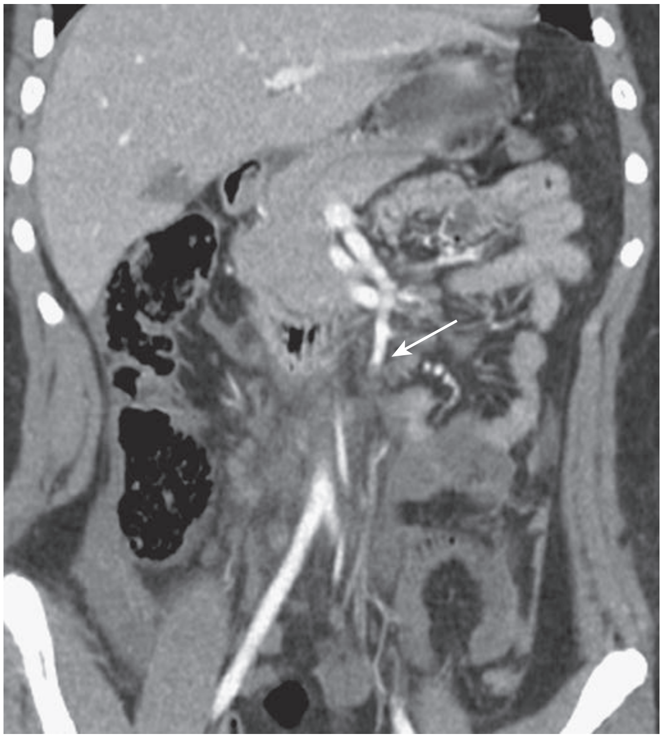

**Figure 109.12. Superior mesenteric artery occlusion.** Coronal reformat of a contrast-enhanced CT scan shows abrupt termination of the superior mesenteric artery *(arrow)*. The patient had subsequent mesenteric ischemia and bowel perforation.

intramural, no extraluminal air or extravasated contrast material should be present. Large hematomas can result in obstruction of the bowel proximal to the injury.

CT signs that are highly specific for significant mesenteric injury are related to vascular injury and include mesenteric vascular beading, abrupt termination of mesenteric vessels, and mesenteric vascular extravasation (Fig. 109.12 and Box 109.1).[24] These findings are rare in children, and their sensitivity and specificity are not known. Abnormalities that are less specific for the need for surgical intervention in mesenteric injury are mesenteric stranding and hematoma; these findings may represent a range of injuries from minor mesenteric bruising to underlying vascular disruption.

The most frequent CT finding associated with bowel rupture and mesenteric injury is "unexplained" peritoneal fluid (i.e., moderate to large amounts of fluid in the absence of solid viscus injury or bony pelvic fracture) (Fig. 109.13). Although nonspecific, unexplained peritoneal fluid is an important marker of potentially serious bowel or mesenteric injury. Approximately half the children with a moderate to large quantity of peritoneal fluid as the only finding on CT after blunt trauma have intestinal injury.[25] Follow-up CT imaging in patients with initially equivocal findings and persistent abdominal symptoms has been reported to improve the detectability of intestinal injuries.[23]

Multidetector scanners have improved the accuracy of CT for the diagnosis of bowel and mesenteric injuries. However, the reported sensitivity values (80%–95%) and specificity values (48%–84%) vary widely among studies.[24,26]

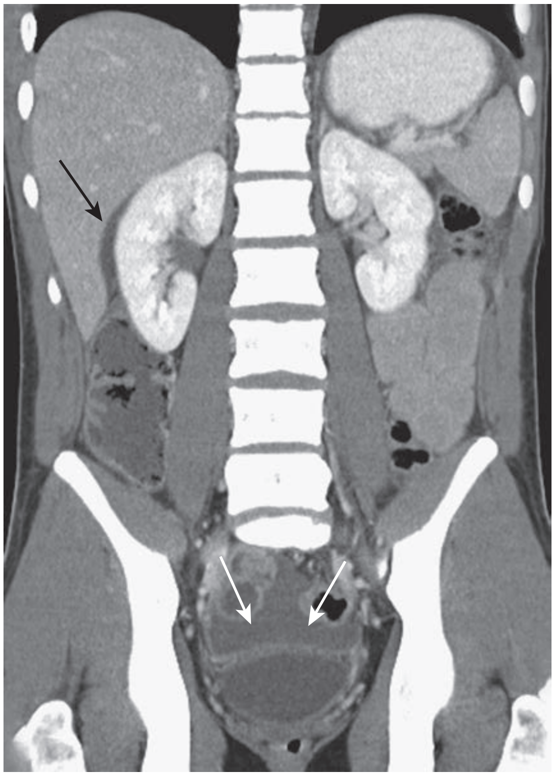

**Figure 109.13. Bowel rupture with a moderate amount of "unexplained" peritoneal fluid.** Coronal reformat of a contrast-enhanced CT scan shows a moderate amount of peritoneal fluid in the cul-de-sac *(white arrows)*, and in the subhepatic space *(black arrow)*. No other abnormalities were noted on CT. A jejunal rupture was identified at surgery.

**BOX 109.1** High-Specificity Computed Tomography Findings in Bowel and Mesenteric Injury

Extraluminal gas
Extraluminal oral contrast material
Bowel discontinuity
Mesenteric vascular beading
Abrupt termination of mesenteric vessels
Mesenteric vascular extravasation

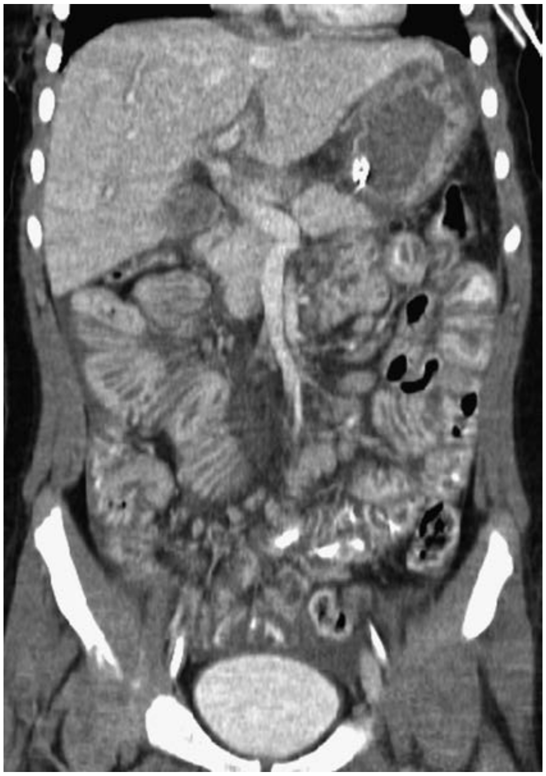

**Figure 109.14. Hypoperfusion complex.** Coronal reformat of a contrast-enhanced CT scan shows diffuse intestinal thickening, dilation with fluid, intense contrast enhancement of the bowel wall, low periportal attenuation, and ascites indicative of partially compensated shock.

## Hypoperfusion Complex

A characteristic complex of CT findings associated with partially compensated hypovolemic shock in severely injured children has been characterized as the "hypoperfusion complex." Most of these children have required extensive resuscitation for arterial hypotension on admission.[27]

CT findings in all children with the hypoperfusion complex include diffuse intestinal dilation with fluid. Abnormally intense contrast enhancement of bowel wall, mesentery, kidneys, aorta, and inferior vena cava is present, as well as diminished caliber of the aorta and inferior vena cava (Fig. 109.14). Variable findings include periportal low attenuation zones; intense adrenal, pancreatic, and mesenteric enhancement; decreased pancreatic and splenic enhancement; peritoneal and retroperitoneal fluid; and bowel wall thickening.[27,28]

The hypoperfusion complex is a marker for a tenuous hemodynamic state and a predictor of a poor outcome. The mortality rate in children with this constellation of findings on CT approaches 80%.[27]

### KEY POINTS

- Clinical variables associated with a high risk of injury include gross hematuria, abdominal tenderness, and seat belt ecchymoses.
- Multiphase CT scanning is not necessary in children who have sustained blunt trauma.
- Hepatic injury extending to the bare area of the liver may be associated with retroperitoneal hemorrhage.
- Heterogeneous early splenic enhancement, splenic lobulations, or clefts may mimic a splenic laceration.
- Most hepatic and splenic injuries in children can be treated safely without operative intervention.
- Pancreatic injury may be difficult to identify in children because of a paucity of surrounding fat and the minimal separation of fracture fragments. The best indicator of pancreatic injury at CT is unexplained peripancreatic fluid.
- The size of hemoperitoneum on CT reflects the cumulative amount of bleeding; it is not a measure of ongoing hemorrhage.
- The absence of peritoneal fluid or blood does not exclude the presence of hepatic or splenic injury.
- A sentinel clot can indicate the site of injury.
- The most frequent CT finding associated with bowel rupture and mesenteric injury is "unexplained" peritoneal fluid.

## PART 1 Overview

# 110 Embryology, Anatomy, and Variants of the Kidneys and Genitourinary Tract

*Sally J. Smith, Brooke S. Lampl, and Jonathan R. Dillman*

The urinary system and the genital system are closely associated embryologically and begin to develop during the fourth week of gestation.[1,2] Both develop from the intermediate mesoderm along the posterior wall of the abdominal cavity. A longitudinal elevation of the mesoderm, the urogenital ridge, forms on both sides of the abdominal aorta. Part of the urogenital ridge gives rise to the nephrogenic cord, which will form the urinary system, and another part gives rise to the gonadal ridge, which will form the genital system.[1]

The nephrogenic cord gives rise to the mesonephros, which consists of glomeruli and mesonephric tubules. The mesonephric tubules open into the mesonephric duct, which soon opens into the cloaca.[1,3] The mesonephros degenerates toward the end of the first trimester, although their tubules persist in males and participate in the formation of the genital system.[2] During the fifth week of gestation, the metanephros begins to develop. The definitive kidneys develop from the ureteric bud (metanephric diverticulum), an outgrowth of the mesonephric duct, and the metanephric blastema, which is derived from the nephrogenic cord.

The ureteric bud is responsible for the development of the collecting system (ureter, renal pelvis, and calyces).[1,2,4] The stalk of the ureteric bud forms the ureter. The ureteric bud grows into the metanephric blastema, where branching leads to the formation of the renal pelvis, major and minor calyces, and the collecting tubules (Figs. 110.1 and 110.2). Nephrons form in the metanephric blastema as the result of induction by the collecting tubules. The embryonic kidneys initially lie in the pelvis. As the abdomen grows, the kidneys “ascend” and rotate 90 degrees. By the ninth week of gestation, the kidneys come in contact with the adrenal glands as they attain their final position. The fetal kidney has a lobulated external contour that will disappear as the nephrons continue to grow. The full complement of glomeruli is present by 36 weeks’ gestation.

Congenital anomalies of the kidney and urinary tract are common.[1,4] Early degeneration of a ureteric bud or involution of the metanephros leads to regression of the metanephric blastema and renal agenesis. Bifurcation of the ureteric bud results in urinary tract duplication. When the location of the origin of the ureteric bud is abnormal or if the origin itself is maldeveloped, the potential for vesicoureteral reflux (VUR) or ureteral ectopia exists (Fig. 110.3).

The bladder arises from the most superior portion of the urogenital sinus.[1,2,5] It is initially continuous with the allantois. With constriction of the allantois, the lumen is obliterated, and a fibrous cord, the urachus, remains. The urachus connects the apex of the bladder with the umbilicus. Persistence of the allantoic lumen may result in urachal fistulas, sinuses, or cysts. The ureterovesical junction (UVJ) develops as the distal parts of the mesonephric duct are incorporated into the enlarging bladder. As the mesonephric ducts are absorbed, the ureters come to open separately into the urinary bladder with the orifice moving superolaterally and the distal ureteral segments entering obliquely through the base of the bladder. The middle portion of the urogenital sinus develops into the prostatic urethra in males and the entire urethra in females. The distal portion of the male urethra is derived from a cord of ectoderm that grows from the tip of the glans penis to meet the spongy portion of the urethra derived from the caudal (phallic) portion of the urogenital sinus. Development of the ureters and bladder is complete by the fourth gestational month.

The fetus begins to make urine by the ninth week of gestation, and the urine contributes the largest component of the amniotic fluid.[6] Oligohydramnios is often a marker of renal or urinary tract abnormalities, and severe oligohydramnios may lead to pulmonary hypoplasia.

During the first few days after birth, the neonate has a low glomerular filtration rate (GFR) and low urine output.[7] This is especially true of premature infants. The newborn kidney also has a limited ability to concentrate urine and decreased tubular reabsorption of sodium. GFR and urine output increase significantly over the first week of life. This immaturity of renal function is an important factor to keep in mind in the ordering and interpretation of renal imaging studies in the setting of antenatal hydronephrosis.

## NORMAL ANATOMY

### Kidney

Multiple renal lobules fuse to form the kidney. Each lobule is composed of two distinct regions: (1) the outer cortex and (2) the inner medulla (Fig. 110.4). The medulla is composed of 8 to 13 pyramids, which terminate in the renal papillae at the level of the calyces. Two or more pyramids may drain into the same papilla (confluent papilla), and two or more papillae may drain into a single calyx (compound calyx). Occasionally, when lobules fuse, the renal cortex remains and extends centrally between the pyramids, representing a column of Bertin (e-Fig. 110.5). A column of Bertin often occurs at the interpolar region or between the two moieties of a duplex kidney.[8,9] Additionally, the junction of these lobules may persist and be seen as a scalloping or lobation of the cortical border (Fig. 110.6). The junctional parenchymal defect is similarly derived from a variation in the fusion of the fetal lobules. It appears as a thick, triangular, echogenic notch in the anterosuperior or posteroinferior aspect of the kidney (more often on the right) and mimics a cortical scar. The junctional parenchymal defect may be connected to the renal hilum by an echogenic line called the *interrenuncular septum* (Fig. 110.7). The left kidney is apt to be more triangular, with a distinct bulge along its lateral aspect, the *dromedary hump* (Fig. 110.8).[10–13]

## Abstract:

The kidneys, upper urinary tract, and genital tract are closely associated embryologically. These structures begin to develop in the embryo very early in gestation from the intermediate mesoderm along the posterior wall of the abdominal cavity. The urinary bladder develops separately, arising from the most superior portion of the urogenital sinus. While these structures most often develop normally, a variety of congenital anomalies can occur, with varying frequencies and degrees of clinical importance. In this chapter we will present in detail the normal embryology of the kidneys and urinary tract as well as review normal anatomy and a variety of developmental variants (congenital anomalies).

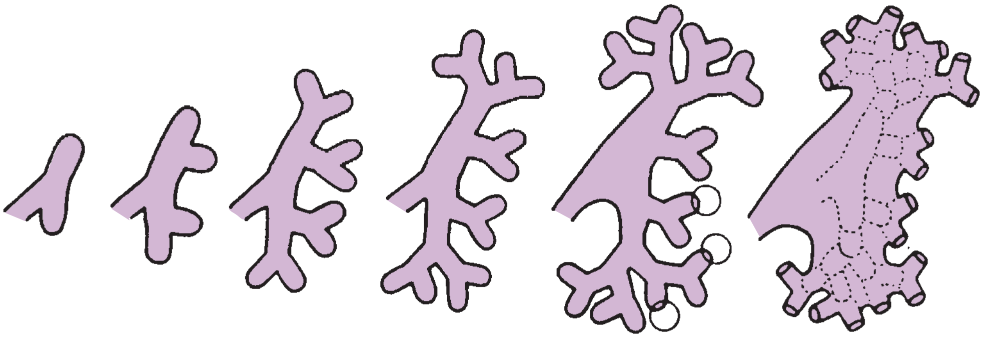

**Figure 110.2. Ureteric bud with multiple divisions leading to development of the pelvicalyceal system.** *(Adapted from Parrott TS, Skandalakis JE, Gray SW. The kidney and ureter. In: Skandalakis JE, Gray SW, eds.* Embryology for Surgeons: The Embryological Basis for the Treatment of Congenital Anomalies*. 2nd ed. Baltimore: Williams & Wilkins; 1994.)*

In newborns and infants, the kidneys have a larger medullary and smaller cortical volume than in later life. On ultrasonography, the neonatal renal cortex is moderately hyperechoic, close to the echogenicity of adjacent liver and spleen and can be greater than that of the liver in newborns and premature infants (see Fig. 110.8). The pyramids are relatively hypoechoic, maintaining corticomedullary differentiation. Between ages 6 months and 2 years, the echogenicity of the medulla and cortex resembles that of adult kidneys.[14–17]

The kidney is usually supplied by a single artery arising from the abdominal aorta. After the renal artery enters the renal hilum, posterior and slightly superior to the renal vein, it divides into

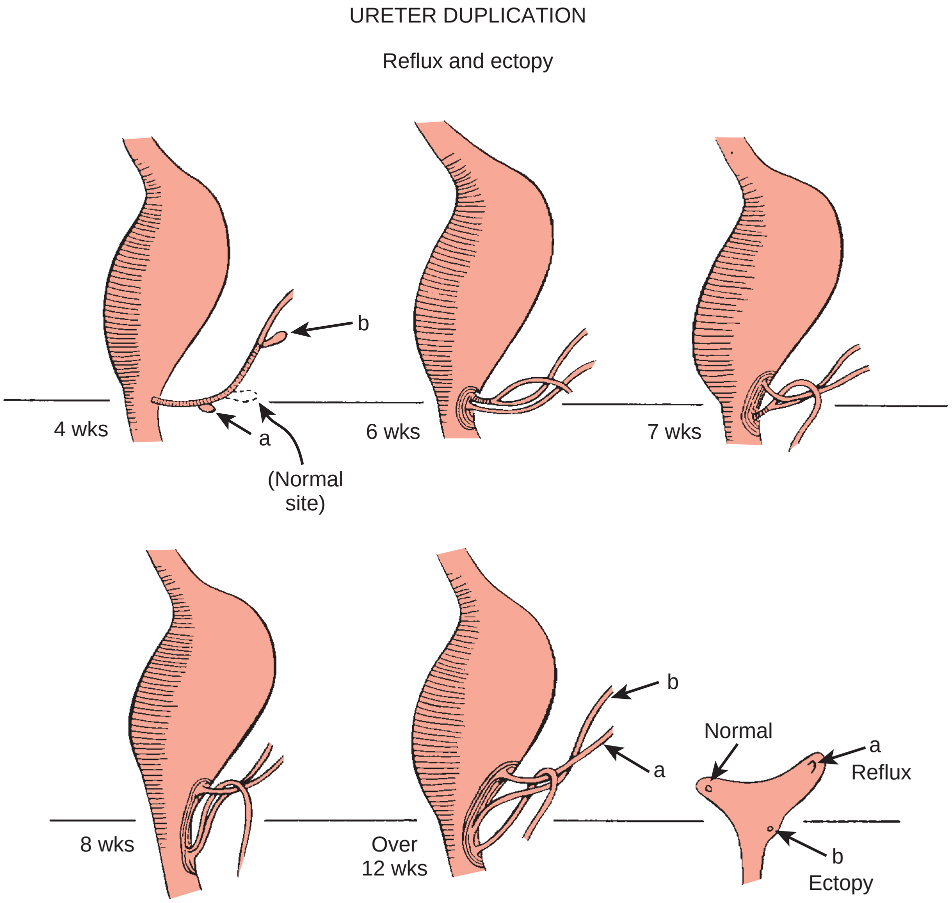

**Figure 110.3. The ureteric bud and its relationship to the bladder.** The drawing shows how ectopia and vesicoureteral reflux may occur.

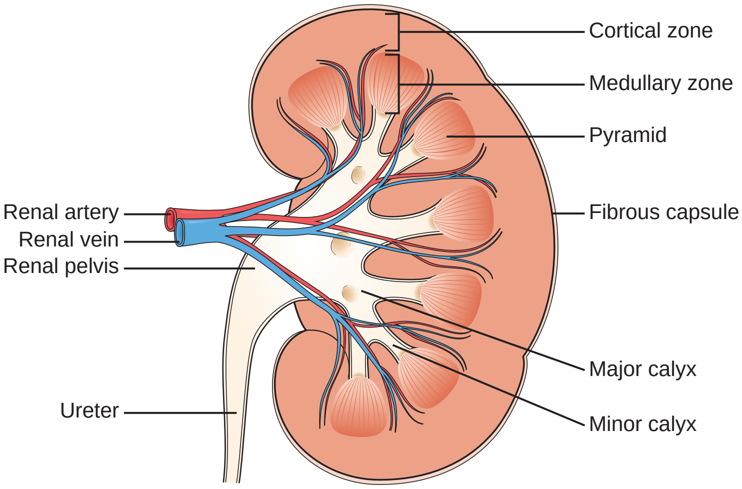

**Figure 110.4. Macroscopic anatomy of the kidney in longitudinal section.** The left kidney as viewed anteriorly. *(Redrawn from Kelly HA, Burnam CF.* Diseases of the Kidneys, Ureters and Bladder. *2nd ed. New York: Appleton; 1922.)*

anterior and posterior branches, which, in turn, generally divide into superior and inferior branches (e-Fig. 110.9). About 20% to 30% of kidneys have a second or accessory renal artery arising from the aorta. The left renal vein is longer than the right, courses anterior to the aorta, and receives the ipsilateral suprarenal and gonadal veins before entering the inferior vena cava.[8,18] Variations exist at all levels.

Renal length is the most commonly measured morphologic parameter and has been correlated to age, body height, and body weight. Standards for renal length have been developed for ultrasonography (e-Fig. 110.10). The left kidney may be slightly longer than the right. Kidneys with complete or partial collecting system duplication are often longer than normal kidneys. The width of the kidney is approximately 50% of its length and is relatively thicker in neonates than older children. Cortical thickness of the upper renal pole is normally slightly thicker than the lower pole. Extra cortical tissue may be noted about the renal hilum and may impinge on the renal pelvis (suprahilar/infrahilar bulge, or hilar lips).[17,19–25]

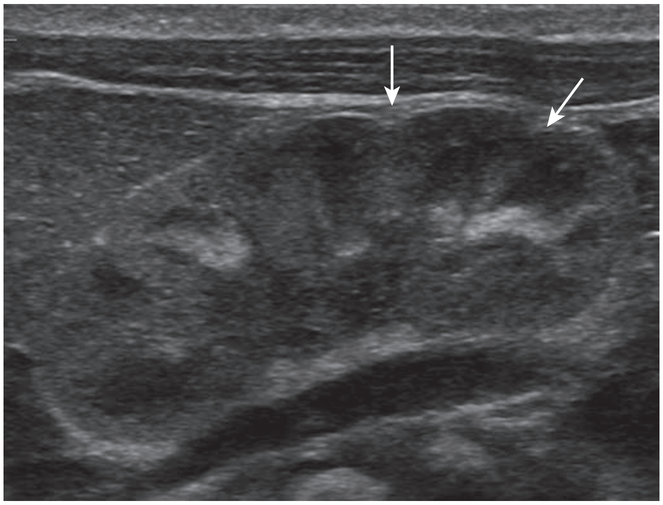

**Figure 110.6. Fetal lobulations.** Residual fetal lobations are responsible for the scalloped border of the kidney *(arrows)* on this sagittal sonogram.

## Pelvocalyceal System

The renal pelvis varies in size and shape and may lie entirely within (intrarenal) or partly beyond (extrarenal) the renal sinus. In most kidneys, the pelvis branches into two major infundibula (or major calyces). The inferior infundibulum is commonly broad and short and is connected with a larger number of minor calyces compared with the upper infundibulum. Each kidney has about 8 to 13 minor calyces. These have a cup-shaped appearance that results from the protrusion of the renal papilla into the calyx. Most calyces are directed laterally and either slightly anteriorly or posteriorly within the kidney.[4,6,18,24,26]

## Ureter

The ureter is a tubular structure that courses through the retroperitoneum from the kidney to the bladder and has three major components: (1) the ureteropelvic junction (UPJ) and proximal ureter, (2) the midureter, and (3) the distal ureter and UVJ (including the transmural ureter and the ureteral orifice). The proximal ureter starts at the UPJ with a smooth tapering from the renal pelvis. The ureter lies adjacent to the psoas muscle and is crossed by the gonadal vessels before passing over the iliac vessels. The lower ureter lies along the lateral pelvic wall, coursing behind the bladder. The ureter enters the bladder wall at an oblique angle and opens into the bladder. Its course through the bladder wall may be seen (called the *plica ureterica* at cystoscopy) and constitutes the lateral border of the bladder trigone. Three muscular layers constitute the ureteral wall, with a thick outer adventitial layer containing vessels and lymphatics.[4,6,27–29]

The vascular supply of the ureter is primarily from the inferior vesical artery inferiorly, and the gonadal artery (e.g., testicular artery) and renal artery superiorly. Nerves supplying the ureter follow the arteries. Rhythmic peristaltic ureteral contractions transport urine from the renal pelvis into the urinary bladder two to seven times per minute.[4,6]

The anatomic relationship of the distal ureter to the bladder wall at the UVJ is important in preventing VUR. Normally, the distal ureter courses through the bladder musculature at an oblique angle and then continues inferomedially and submucosally to its ostia in the lateral corner of the trigone (Fig. 110.11). The UVJ acts as a passive flap valve. Continence is ensured by apposition of the roof and floor of the submucosal tunnel when intravesical

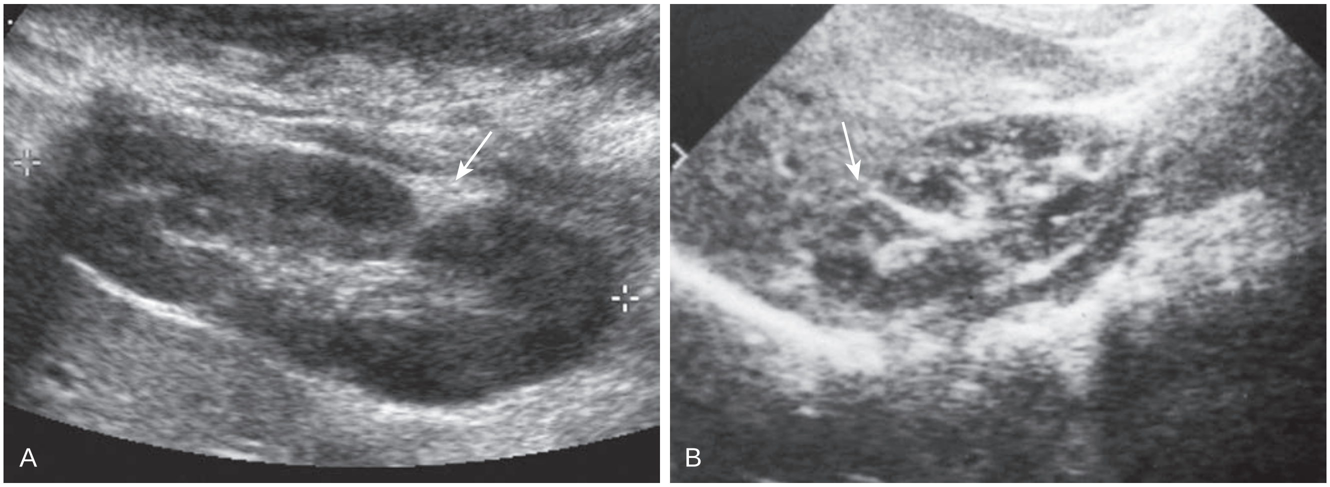

**Figure 110.7. Junctional parenchymal defects.** (A) Longitudinal prone sonogram shows a fat-filled cleft *(arrow)* in the posterior kidney. (B) Longitudinal supine sonogram in another patient shows a renicular septum *(arrow)*. Both are normal findings, probably related to a demarcation of embryonic reniculi.

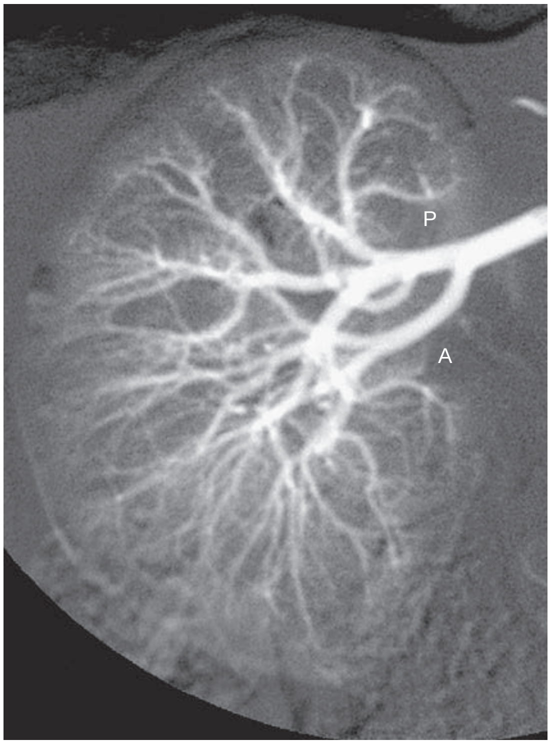
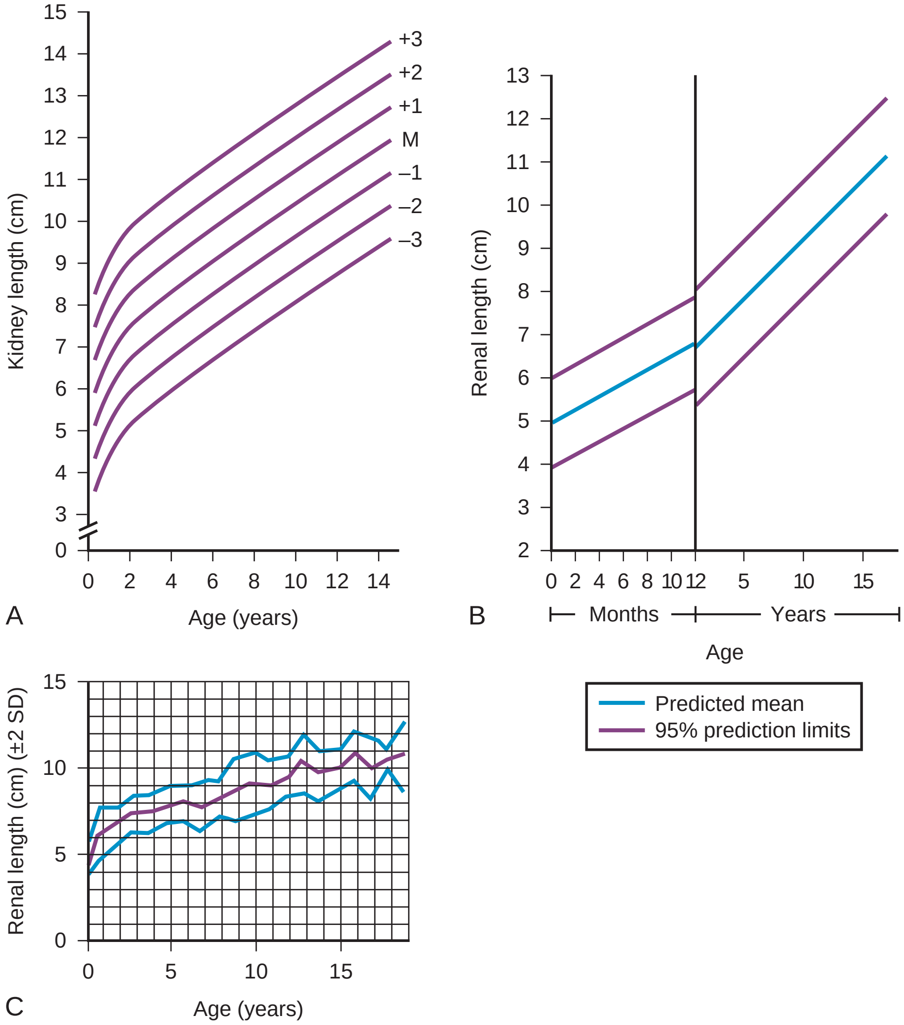


**e-Figure 110.9. Normal renal arterial anatomy.** Digital subtraction arteriogram of the right kidney in a 6-month-old shows a single main renal artery dividing into anterior *(A)* and posterior *(P)* branches. Normal opacification and distribution of vessels to the level of the arcuate arteries are seen.



**e-Figure 110.10. Kidney length in centimeters.** (A) Measurements obtained from supine urographic films and correlated with age, including values for three standard deviations (SD) above and below the mean *(M)*. The SD is 0.75 cm. (B) Ultrasonographic measurements correlated with age; the values are slightly lower than those obtained from urographic films. (C) Ultrasonographic measurements correlated with age, including ± 2 SD. *(A, Modified from Currarino G, Williams B, Dana K. Kidney length correlated with age: normal values in children.* Radiology*. 1984;150:703; B, From Han BK, Babcock DS. Sonographic measurements and appearance of normal kidneys in children.* Am J Roentgenol*. 1985;145:611; C, From Rosenbaum DM, Korngold E, Teele RL. Sonographic assessment of renal length in normal children.* Am J Roentgenol*. 1984;142:467.)*

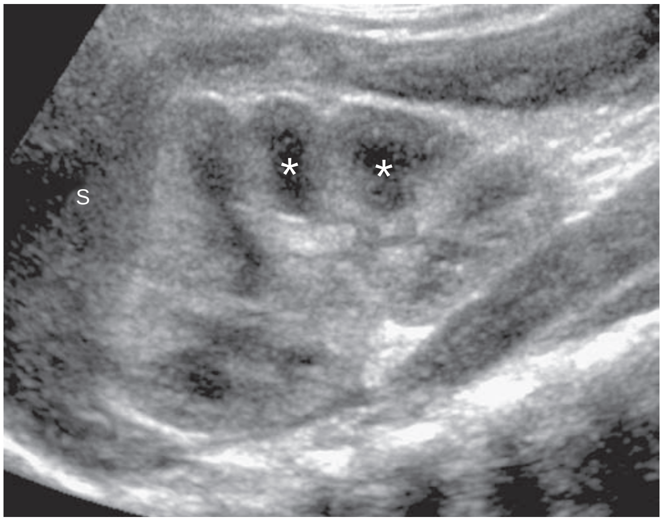


**Figure 110.8. Normal neonatal kidney.** Supine longitudinal sonogram of the left kidney shows the sharp corticomedullary differentiation common in infancy and early childhood. The hypoechoic triangular renal pyramids *(asterisks)* are surrounded by cortex that is more echogenic than the adjacent spleen *(S)*. The spleen has flattened the upper renal contour and produces the appearance of a dromedary kidney.

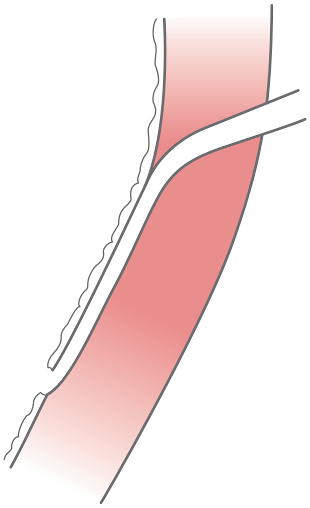

**Figure 110.11. Course of the distal segment of ureter within the bladder wall.** The ureter at first traverses the bladder musculature almost perpendicularly and then descends submucosally for a much longer segment (submucosal tunnel).

pressure increases and is enhanced by contraction of the intrinsic local musculature.

## Bladder

In the neonate and young child, the dome and body of the bladder are located primarily in the abdomen while the base is intrapelvic. Bowel impressions are common and may impress on the intra-abdominal bladder when it is distended. This normal appearance should not be confused with a pelvic mass. A urachal remnant may be seen at the bladder dome, best seen on ultrasound and computed tomography (CT). Normal bladder capacity can be predicted on the basis of weight in infancy and by age for the older child. For infants under 1 year of age, bladder capacity in milliliters is predicted by multiplying the weight in kilograms by 7. The predicted bladder capacity in milliliters of children more than 1 year old is the age in years plus 2 multiplied by 30. Ultrasonography best demonstrates normal bladder wall thickness, which should be no more than 3 mm when distended and 6 mm when collapsed.[5,30–38]

## Urethra

The female urethra is equivalent to the posterior urethra of the male. Anatomic features of the female urethra include the internal sphincter at the bladder neck, intermuscular incisura, membranous urethra at the level of the urogenital diaphragm or external urethral sphincter, and the fossa navicularis, although only the impressions of the sphincters are usually seen at imaging (e-Fig. 110.12).[5,39,40]

The components of the normal male urethra include the prostatic, membranous, bulbous, and penile urethra. Normal anatomic features of the male prostatic urethra include the internal sphincter, the intermuscular incisura, and the verumontanum. The verumontanum is a focal elevation in the posterior wall of the prostatic urethra, where the paired ejaculatory ducts enter, seen as a small ovoid filling defect in the posterior portion of the prostatic urethra. The plicae colliculae are normal folds that extend from the distal verumontanum and may produce circumferential impressions on urethral images.[5,39,41–45]

The membranous urethra runs through the urogenital diaphragm or the external urethral sphincter and becomes the anterior urethra, consisting of the bulbous and penile segments, and the fossa navicularis (e-Fig. 110.13). The muscles related to bladder continence and micturition are the detrusor muscle of the bladder, the musculature of the bladder neck and proximal urethra at the internal urethral sphincter, and the external urethral sphincter. The external sphincter is composed of striated voluntary muscles of the pelvic floor.

## CONGENITAL ANATOMIC VARIANTS AND ANOMALIES

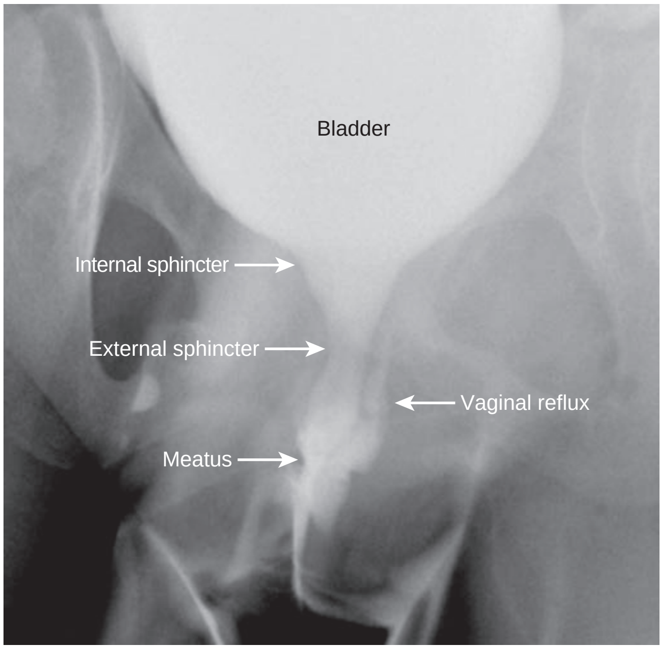
## Kidney

### Renal Agenesis (Unilateral and Bilateral)

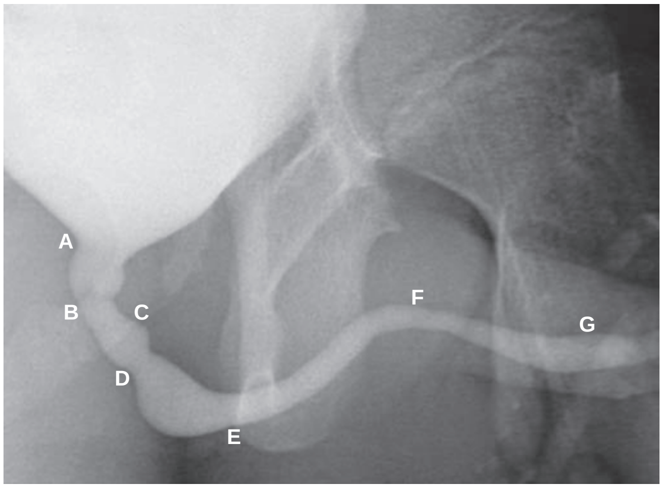
True renal agenesis is thought to be caused by failure of the ureteric bud to contact the ipsilateral metanephric blastema. Unilateral renal agenesis is present in about 1 : 1000 live births. Children with true unilateral renal agenesis lack the ipsilateral ureter and hemitrigone of the urinary bladder. Those children with an absent kidney but a normally developed bladder and a distal ureter of varying length probably represent the involution of a multicystic dysplastic kidney.[31] Associated anomalies include VACTERL (vertebral defects, anorectal malformation, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities) association (e-Fig. 110.14), unicornuate uterus (e-Fig. 110.14), uterus didelphys (obstructed hemivagina with ipsilateral renal agenesis, or OHVIRA), and Mayer-Rokitansky-Küster-Hauser syndrome in girls, and seminal vesicle cysts, absence of the vas deferens, and cystic dysplasia of the rete testis in boys (Box 110.1).[31,46–53]

Bilateral renal agenesis is almost always lethal with an incidence of 1 : 10,000 to 3 : 10,000 live births. Boys are affected more commonly compared with girls. Pulmonary hypoplasia is generally the cause of death and may be associated with neonatal pneumothorax and pneumomediastinum. The Potter sequence is manifest at birth: small chest, abnormal facial features (micrognathia, beaked nose, epicanthic folds, low-set ears), and limb deformities (tightly apposed fingers, dislocated hips, clubfeet).[31]

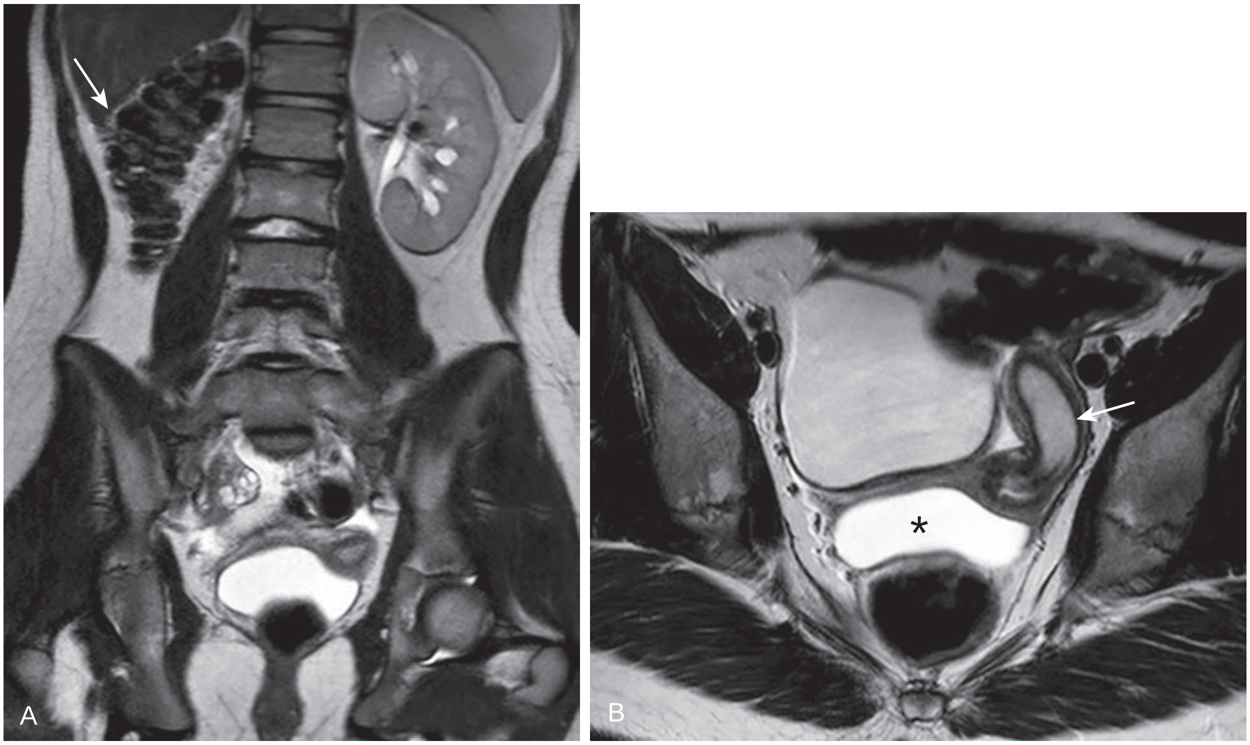
***Imaging.*** Ultrasonography demonstrates the absence of the kidney (and excludes renal ectopia) and the presence of an abnormally configured (elongated or elliptical) adrenal gland,



**e-Figure 110.12. Normal female urethra.** Voiding cystourethrogram in a young girl shows a normal urethra.



**e-Figure 110.13. Normal male urethra.** Voiding cystourethrogram in a 15-year-old boy shows a normal urethra. *A,* Internal urethral sphincter. *B,* Site of the verumontanum. *C,* Prostatic urethra. *D,* Membranous urethra. *E,* Bulbous urethra. *F,* Penile urethra. *G,* Fossa navicularis. *(From the* Radiographic atlas of the pediatric urethra*. Available at: www.nationwidechildrens.org/gd/applications/radiology/atlas/Urethra%20Atlas/Welcome.html.)*



**e-Figure 110.14. Renal agenesis in teenage girl.** (A) Coronal T2-weighted MR image shows absence of the right kidney. Bowel is present in the right renal fossa *(arrow)*; the left kidney is normal. (B) Axial T2-weighted MR image shows a left unicornuate uterus *(arrow)*. The vagina is obstructed and contains fluid *(asterisk)*.

rather than its normal triangular or inverted Y-configuration (Fig. 110.15).[31,54–56] Because the embryology of the adrenal gland is independent of that of the kidney, it is usually located in its expected position, even when the kidney does not reach the renal fossa. Ultrasonography and magnetic resonance imaging (MRI) are most commonly used to evaluate associated uterine and vaginal anomalies in girls and seminal vesicle cysts in boys (Fig. 110.16).[45–49]

### BOX 110.1 Genital Anomalies Associated With Unilateral Renal Agenesis

**FEMALE**

- Absence or hypoplasia of vagina
- Absence of uterus
- Failure of fusion of midline structures (Müllerian derivatives)
  - Bicornuate uterus, uterus didelphys
  - Obstructed hemivagina +/– hemiuterus, fallopian tube
- Gartner duct cyst
- Ipsilateral absence of uterine horn and fallopian tube (unicornuate uterus)

**MALE**

- Ipsilateral anomalies
  - Absence of epididymis
  - Absence of seminal vesicle
  - Absence of vas deferens
  - Absence or hypoplasia of testis
  - Seminal vesicle cysts
  - Cystic dysplasia of rete testis

Because of the increased incidence of VUR into the remaining solitary kidney and the need to protect its parenchyma, a study to exclude vesicoureteral reflux is recommended early in life.

## Renal Ectopia

Renal ectopia is diagnosed when a kidney fails to migrate to its appropriate renal fossa, occurring with an incidence of 1 : 800 to 1 : 1000.[57] The pelvic kidney is the most common type of renal ectopia (accounting for ~60% of cases). Pelvic kidneys are prone to VUR and in about 10% of children may be the only kidney. In some children, both kidneys are in the pelvis and may be fused into a single unit, the so-called *cake kidney* or *lump kidney*. Ectopic intrathoracic kidney is the least common form of renal ectopia, representing less than 5% of cases.[58,59] This condition may occur as an isolated lesion with an intact diaphragm but is more often part of a larger intrathoracic herniation through the foramen of Bochdalek.[58] Anomalies of rotation and blood supply are to be expected with renal ectopia.[31]

***Imaging.*** On ultrasonography, the pelvicalyceal system of the pelvic kidney may be predominantly extrarenal, resulting in images in which the kidney lacks the usual central renal echo complex.[57] Corticomedullary differentiation may be indistinct (Fig. 110.17). UPJ obstruction is common in pelvic kidneys because the abnormal orientation of the ureter relative to the renal pelvis impedes drainage. Renal scintigraphy is often used to both locate and define the morphology of ectopic kidneys, but CT, MRI, and excretory urography are also effective (e-Fig. 110.18).[60] The thoracic kidney is located in the posterior mediastinum and on chest radiographs may be mistaken for neurogenic tumors that develop in this region (e-Fig. 110.19).

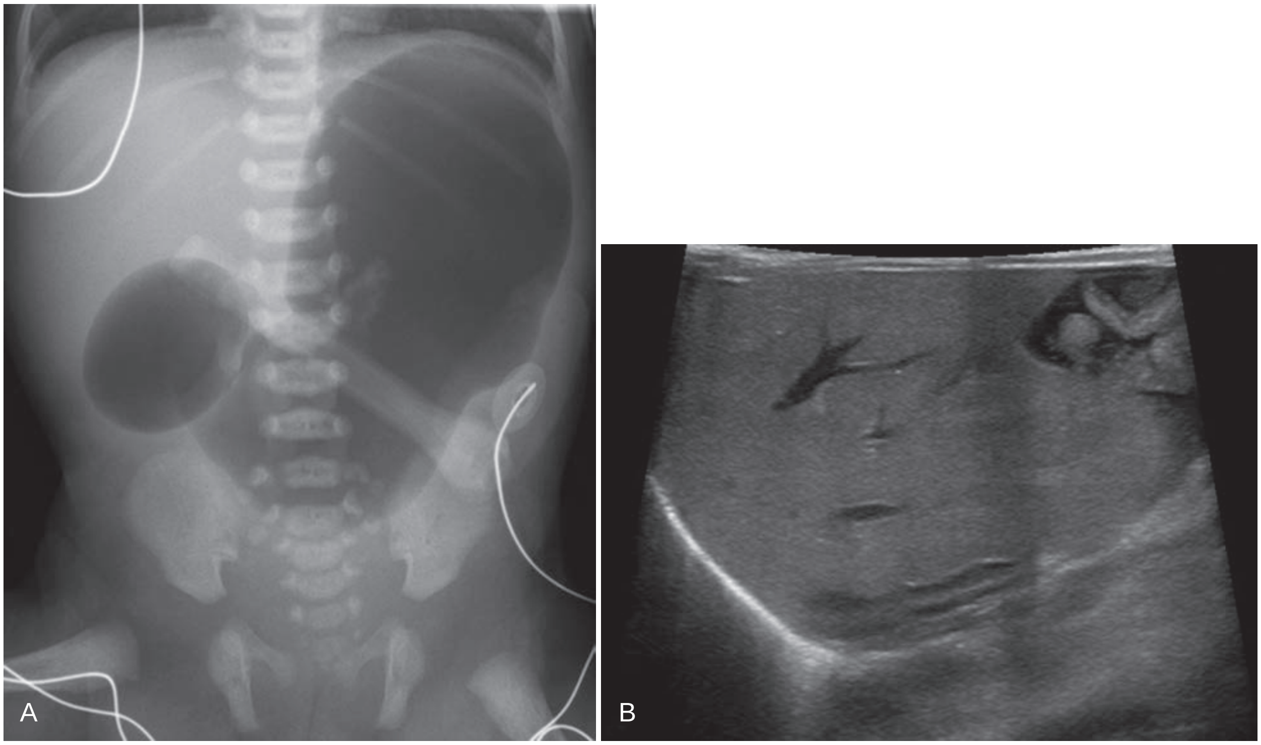


**Figure 110.15. Newborn with unilateral renal agenesis and VACTERL association.** (A) Supine abdominal radiograph shows marked gastric and proximal duodenal gaseous distention, the so-called "double bubble sign." No identifiable distal bowel gas exists. Both esophageal atresia (with distal fistula) and duodenal atresia were confirmed at surgery. (B) Longitudinal sonogram through the right renal fossa confirms congenital absence of the right kidney. The right adrenal gland is abnormally elongated.

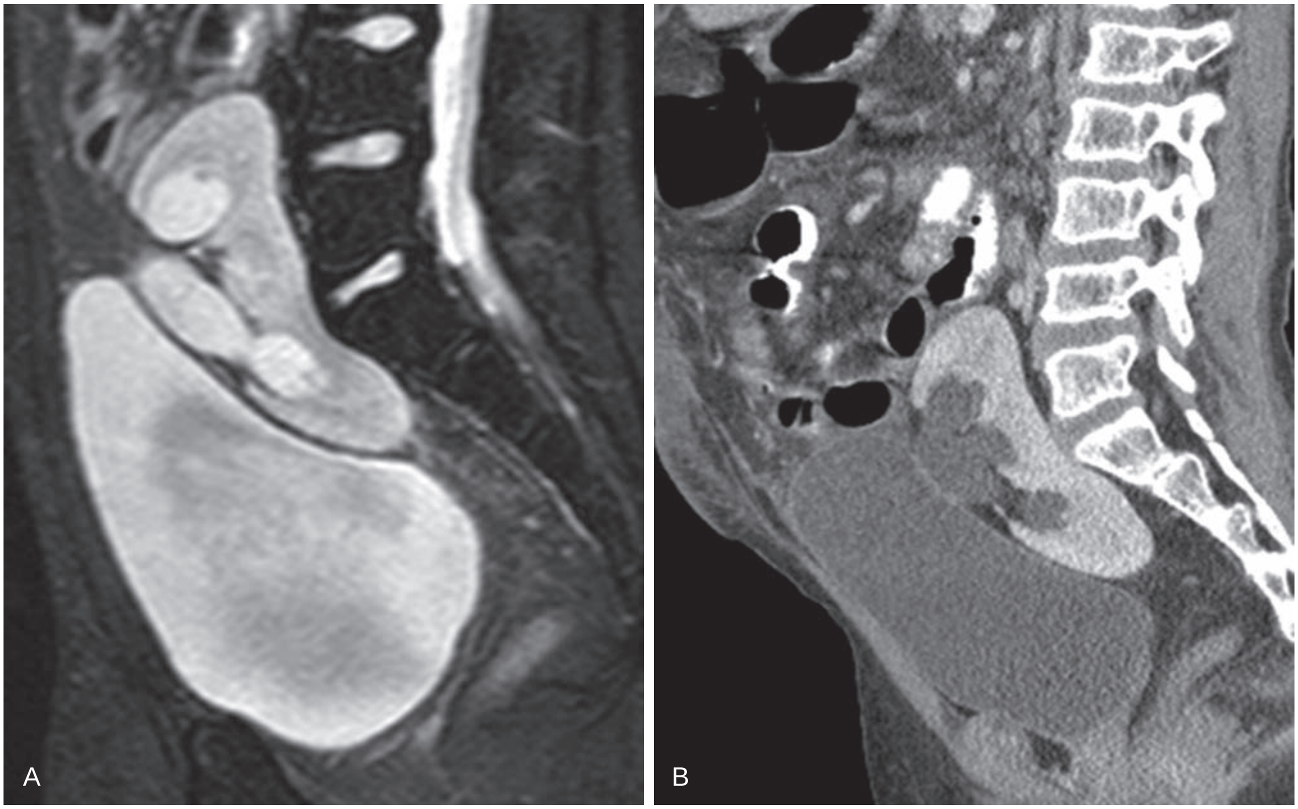
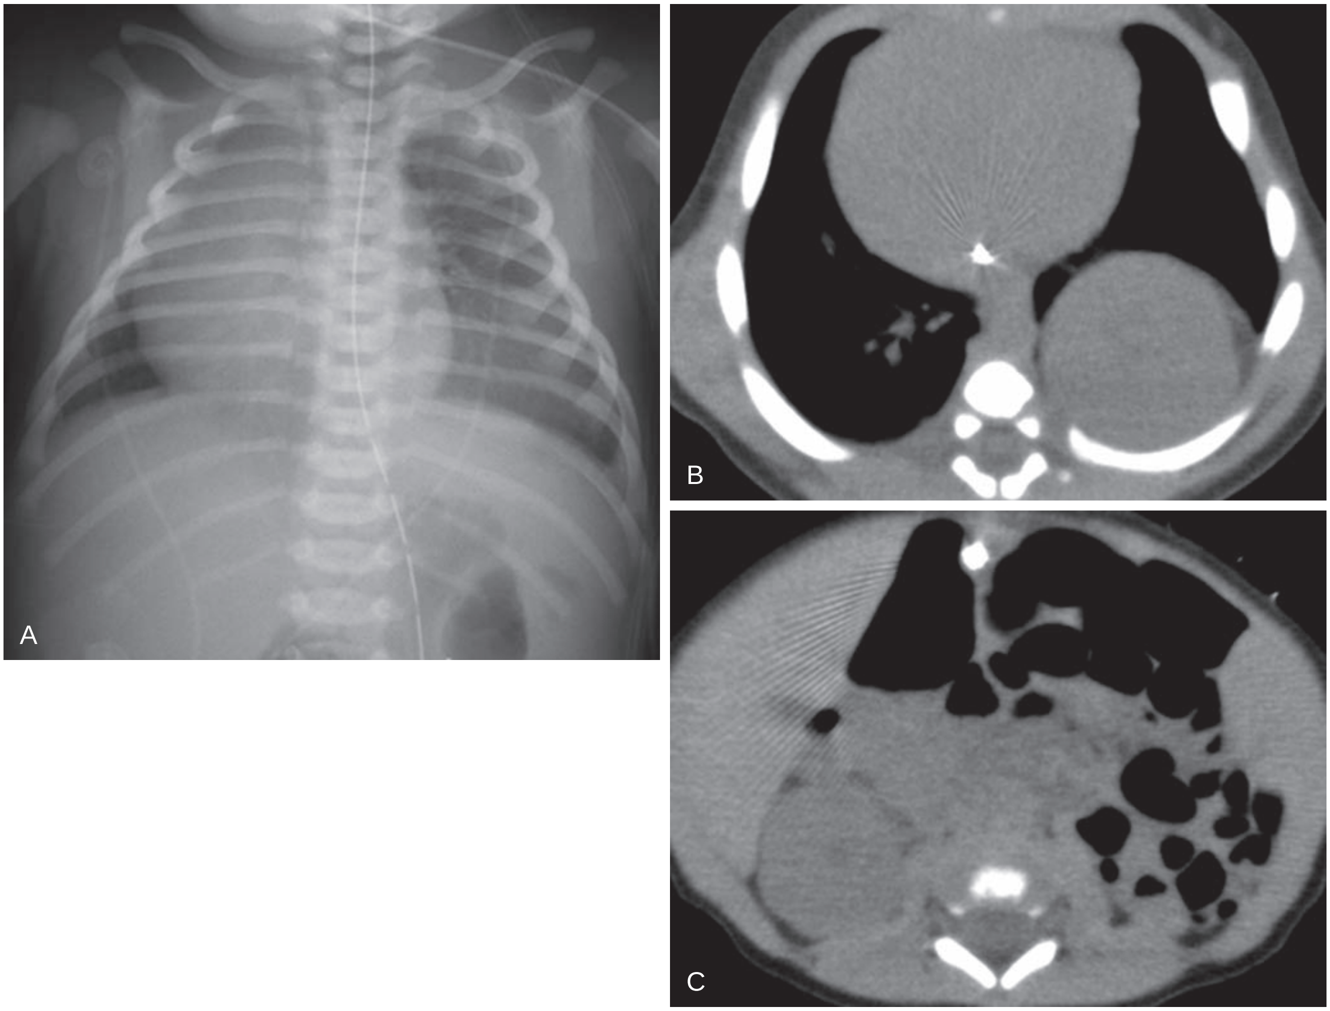


**e-Figure 110.18. A 7-year-old boy with pelvic kidney.** (A) Sagittal T2-weighted magnetic resonance and (B) sagittal contrast-enhanced computed tomography images from the same child in Fig. 110.17 reveal a pelvic kidney located posterior to the urinary bladder. There is mild pelvicaliectasis without actual obstruction, and the pelvic kidney is nonrotated with its pelvis oriented anteriorly.



**e-Figure 110.19. A newborn boy with superior renal ectopia caused by left congenital diaphragmatic hernia.** (A) Anteroposterior chest radiograph shows increased opacity at the left lung base and rightward shift of mediastinal structures. (B and C) Axial computed tomography images without intravenous contrast material show a posteriorly located intrathoracic left kidney. Small bowel loops are located in the left renal fossa. The right kidney resides in its normal location. This neonate was proved to have a left Bochdalek-type congenital diaphragmatic hernia at surgery.

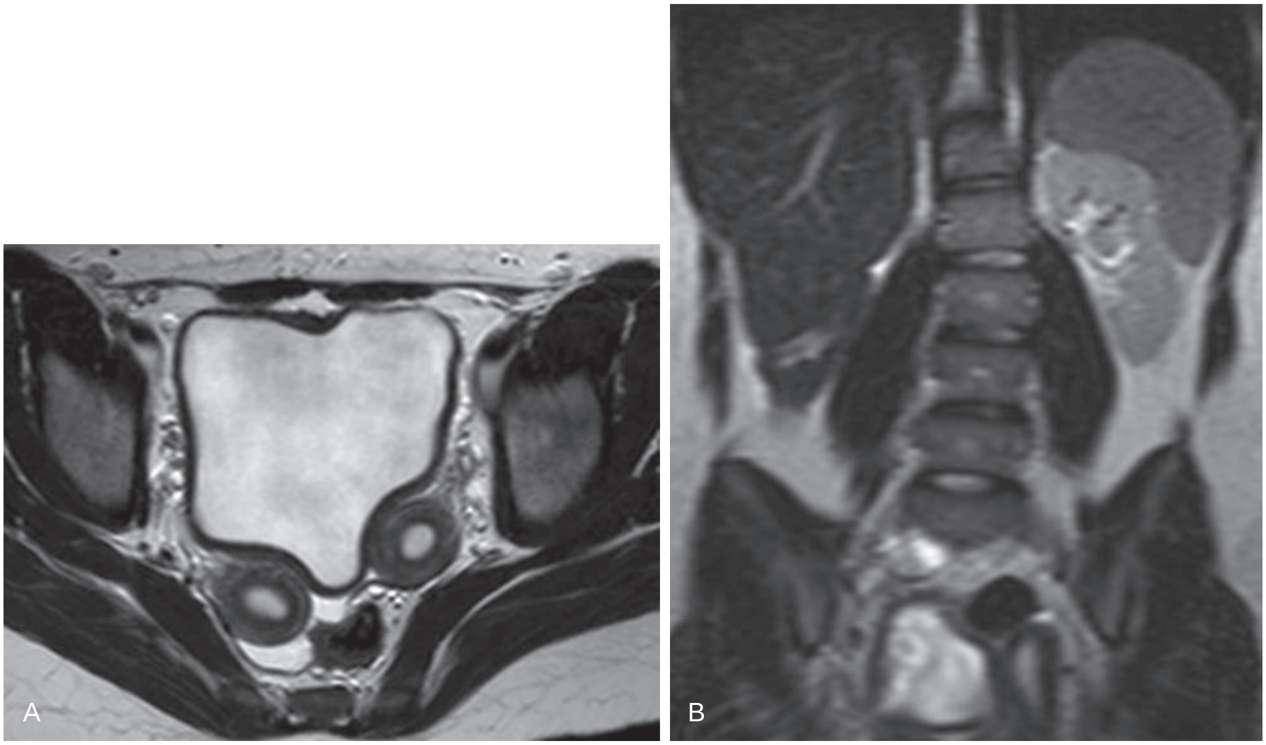


**Figure 110.16. Unilateral renal agenesis and Mullerian anomaly in a 14-year-old girl.** (A) Axial T2-weighted MR image through the pelvis shows two separate uterine horns, proven to be uterus didelphys. (B) A coronal single-shot fast spin-echo image through the retroperitoneum confirms congenital absence of the right kidney.

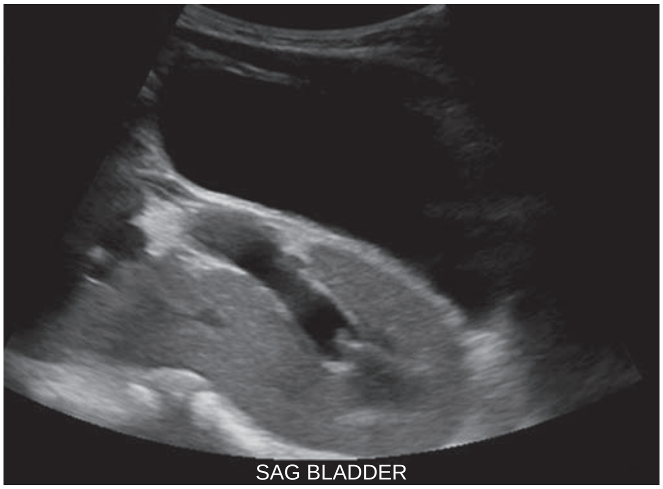

**Figure 110.17. Pelvic kidney.** Longitudinal sonogram through the pelvis of a 5-year-old boy reveals an ectopic kidney located posterior to the urinary bladder. The kidney is nonrotated with its hilum and extrarenal pelvis oriented anteriorly. Corticomedullary differentiation is diminished.

## Anomalies of Fusion: Horseshoe Kidney and Crossed Renal Ectopia

### Horseshoe Kidney

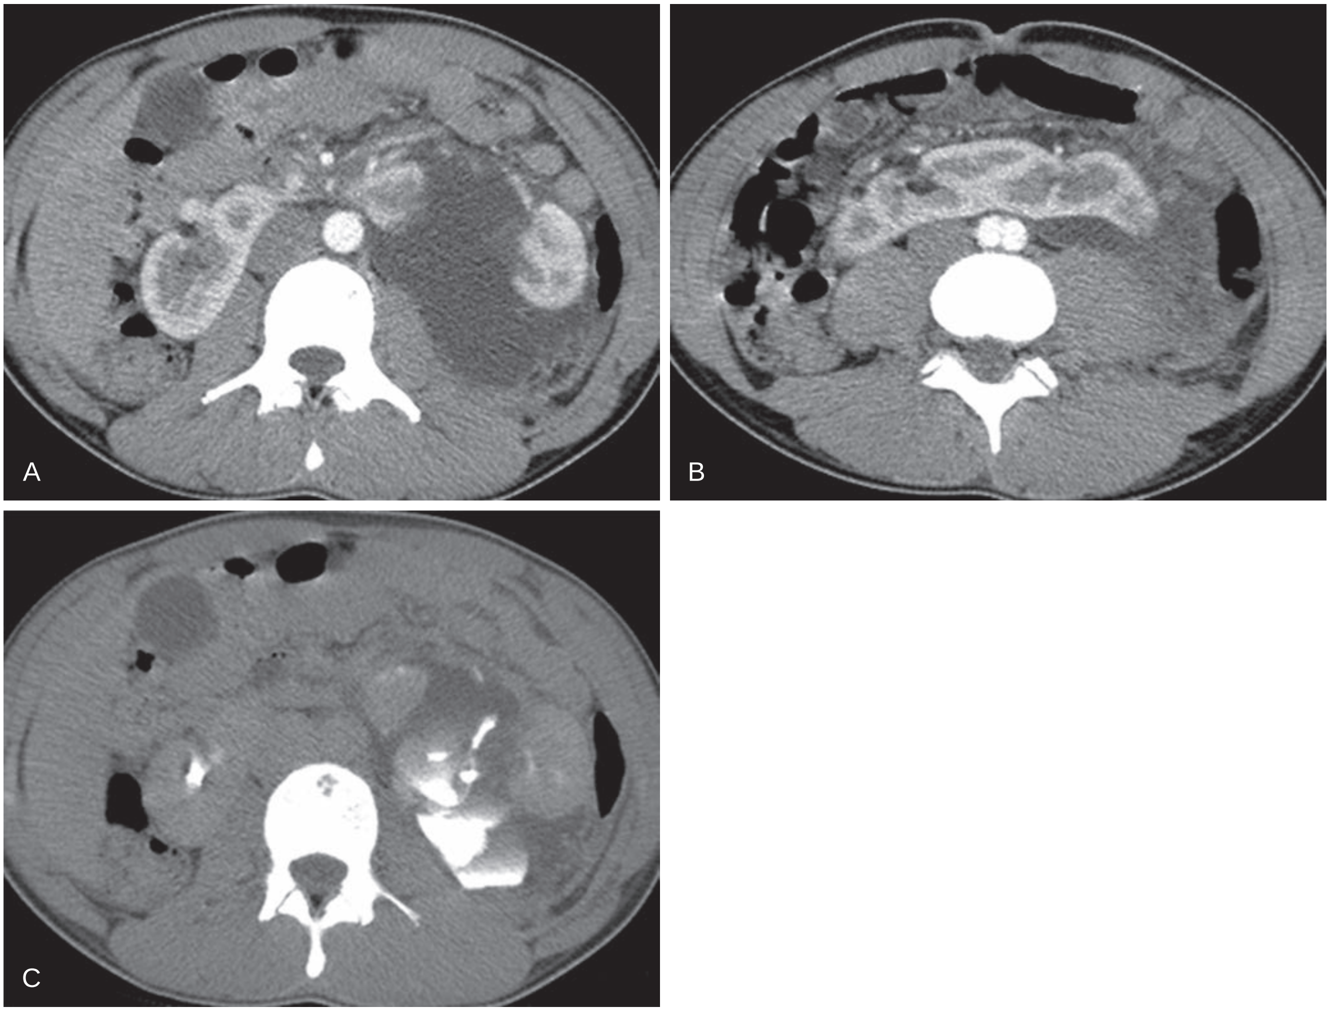
Horseshoe kidney is the most common renal fusion anomaly, noted in 1 : 400 to 1 : 1000 autopsies.[31,61–63] It derives its name from the U-shape configuration of the kidneys, produced by the fusion of the lower pole moieties, which are more medially located than the upper poles (Fig. 110.20).[61–63] The bridging tissue, known as the *isthmus*, is more commonly composed of functioning renal parenchyma than fibrous tissue.[31,61,64] The isthmus is located just below the origin of the inferior mesenteric artery.[31,63] This condition is caused by in utero fusion of the metanephric blastemas in the pelvis during the sixth or seventh week of gestation.[62] The vascular supply of horseshoe kidneys is quite variable, arising from the abdominal aorta, iliac arteries, and inferior mesenteric artery.[61,63,64]

***Clinical Presentation.*** Horseshoe kidneys may be asymptomatic; however, an increased incidence of UPJ obstruction, VUR, and ureteral duplication predispose affected individuals to both urolithiasis and infection.[31,63–65] Because horseshoe kidneys overlie the spine and lack protective surrounding ribs, they are prone to injury from direct trauma.[63] A slight increased risk of Wilms tumor in horseshoe kidneys compared with normal kidneys has been reported.[31,62,63,66,67]

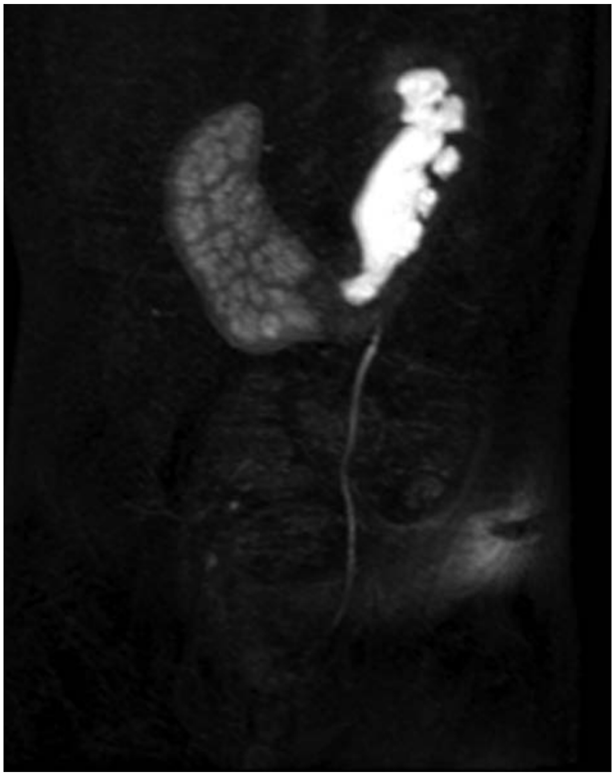
***Imaging.*** Ultrasonography demonstrates the upper portion of each kidney in a low paraspinal location. The isthmus may be identified in many cases anterior to the lumbar spine, especially when mild compression is used to displace interposed bowel loops. The renal long axis is abnormal and may be curved (Fig. 110.21).[68] Anterior orientation of the renal pelvis from nonrotation/malrotation is common as are extrarenal pelves.[64,68] CT and magnetic resonance (MR) angiography may be used to establish renal artery anatomy. CT also excellently depicts renal parenchymal and collecting system injuries in the setting of abdominal trauma (e-Fig. 110.22). MR urography or renal scintigraphy may be performed to assess for suspected UPJ obstruction (e-Fig. 110.23).[63] Voiding cystourethrogram (VCUG) may help assess for VUR.

### Crossed Renal Ectopia

***Clinical Presentation.*** Crossed renal ectopia occurs when both kidneys are located on one side of the spine; a portion of the lower kidney, usually the one that has moved from its normal



**e-Figure 110.22. Horseshoe kidney, traumatic injury.** (A and B) Axial contrast-enhanced computed tomography (CT) images through the abdomen confirm the presence of a horseshoe kidney with a thick parenchymal isthmus. A large amount of fluid is present within the left perinephric space, and there is a large laceration involving the left renal moiety. (C) An axial excretory phase CT image acquired 10 minutes later shows multiple fluid-contrast material levels in the left retroperitoneum caused by renal collecting system injury.



**e-Figure 110.23. Horseshoe kidney and magnetic resonance imaging.** A coronal T1-weighted postcontrast magnetic resonance urogram maximum intensity projection image shows abnormal long-axis of the kidneys and fusion of the lower renal poles. A delayed nephrogram is seen on the right, consistent with upper urinary tract obstruction. Normal excretion of contrast material is present by the left moiety. *(Courtesy Damien Grattan-Smith, MD, Atlanta, GA: Scottish Rite Children's Medical Center.)*

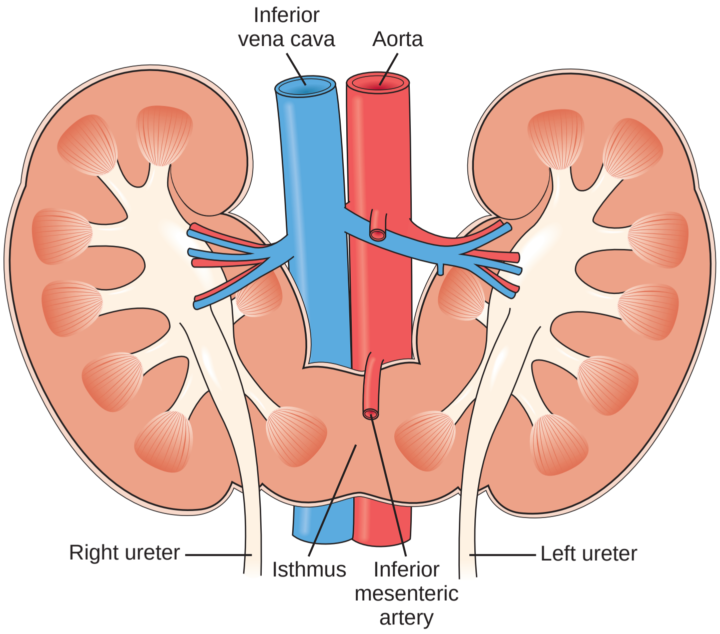


**Figure 110.20. Horseshoe kidney with fusion of the inferior poles, separation of the superior poles, and failure of rotation.** The renal pelves enter the kidneys on their anterior aspect. *(Redrawn from Kelly HA, Burnam CF.* Diseases of the Kidneys, Ureters and Bladder. *2nd ed. New York: Appleton; 1922.)*

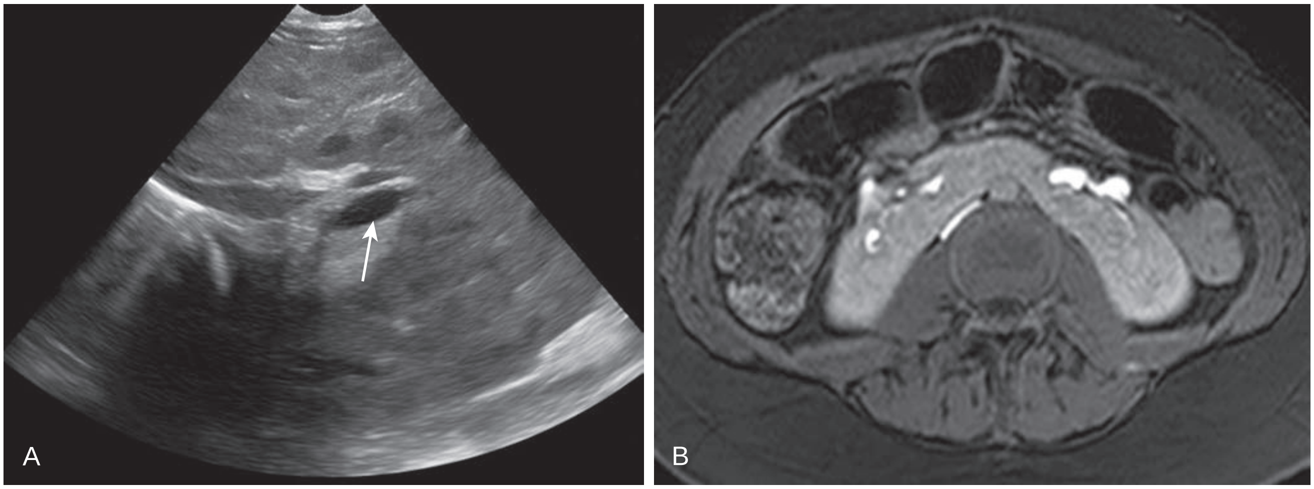

**Figure 110.21. Horseshoe kidney.** (A) Coronal oblique sonogram through the retroperitoneum shows a horseshoe kidney with a parenchymal isthmus overlying the abdominal aorta *(arrow)*. Abnormal longitudinal axis of the kidneys is seen. (B) An axial T1-weighted postcontrast magnetic resonance image with fat saturation shows fusion of the kidneys in the midline just below the level of the inferior mesenteric artery *(arrow)*. The kidneys are malrotated with the collecting systems oriented anteriorly.

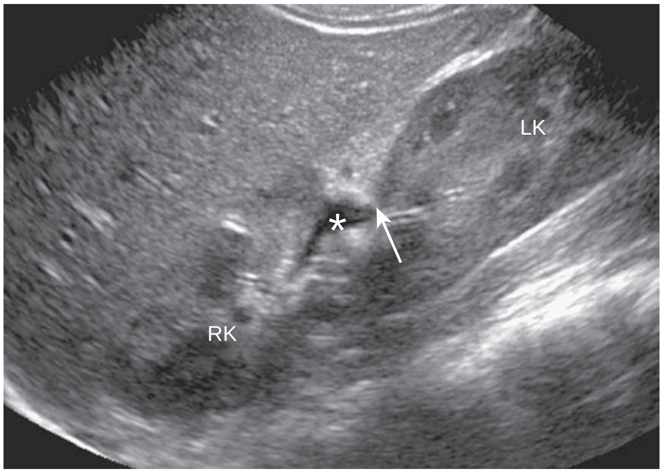
position (most commonly the left kidney), may extend over the spine.[31,69] This anomaly is seen in 1:7500 children, affects boys more often than girls, and is the second most common renal fusion anomaly after horseshoe kidney.[31,61,69,70] The ureter from the lower kidney crosses the midline to insert into the bladder in its normal position.[69] Although most are oriented in a relatively vertical axis, the lower kidney may be obliquely or horizontally related to the superior kidney (Fig. 110.24). The position of the upper (uncrossed) kidney may also be ectopically low. Approximately 85% of crossed kidneys are fused and encompassed by a common renal fascia—hence the term *crossed fused renal ectopia*.[31] As expected in any type of ectopia, the arterial vascularity and venous drainage may be anomalous, and the renal pelvis, especially of the lower kidney, may be malrotated.[59,69,71]

***Imaging.*** Imaging demonstrates an empty renal fossa on one side and both kidneys located on the opposite side of the spine (Fig. 110.25).[72] MRI and CT show two separate ureters, each entering its appropriate trigone.[31] Doppler ultrasonography may be used to demonstrate jets of urine emanating from the normally positioned UVJs. Ultrasonography, MRI, and CT may allow visualization of a small indentation at the site of renal parenchymal fusion (e-Fig. 110.26).[72,73]



**e-Figure 110.26. Crossed fused renal ectopia.** Longitudinal ultrasonographic image of the right upper quadrant shows a well-defined indentation or notch *(arrow)* at the junction between the right kidney *(RK)* and the crossed, fused left kidney *(LK)*. The right renal pelvis has a small amount of visible urine within it *(asterisk)*.

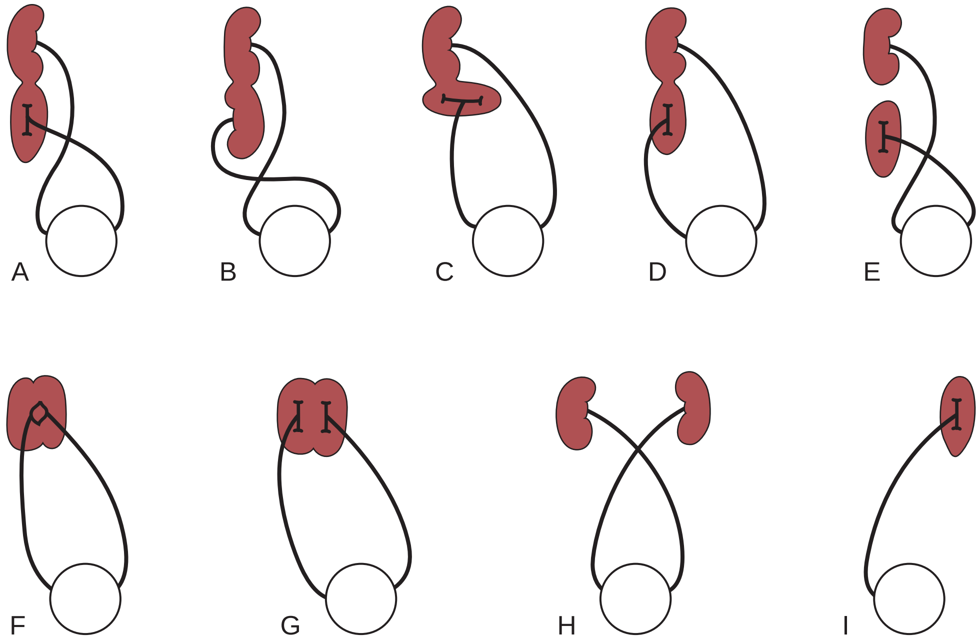


**Figure 110.24. Various types of crossed renal ectopia.** (A) Unilateral fused kidney (inferior renal ectopia), the most common form. (B) Sigmoid or S-shaped kidney. (C) L-shaped kidney. (D) Unilateral fused kidney (superior renal ectopia). (E) Crossed ectopia without fusion. (F) Unilateral disk kidney. (G) Unilateral lump kidney. (H) Bilateral crossed ectopia. (I) Crossed ectopia of a solitary kidney (solitary crossed renal ectopia).

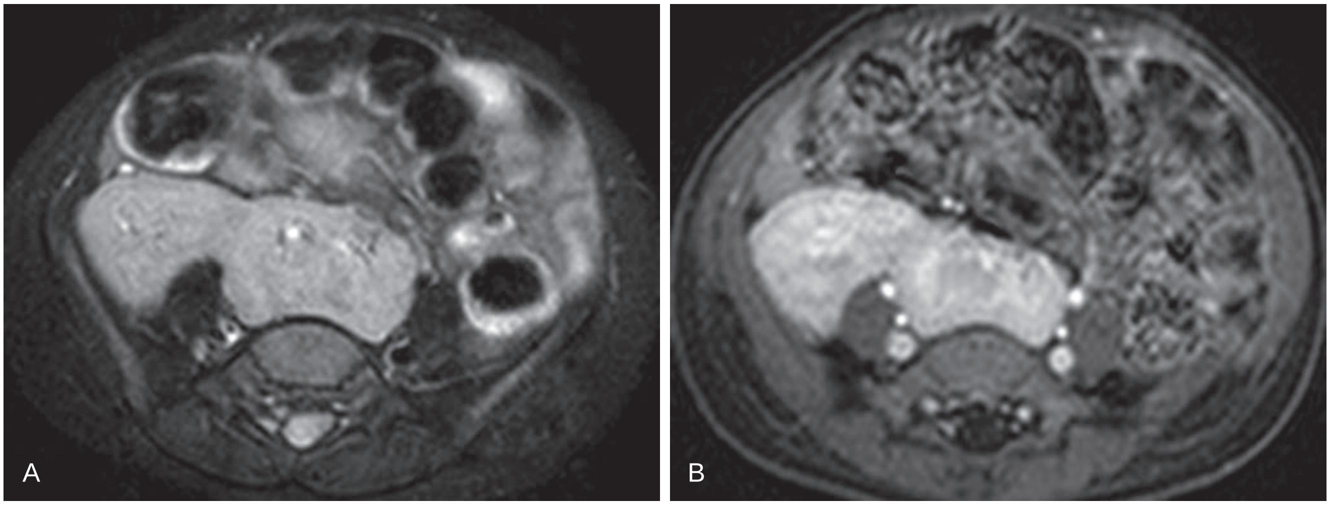

**Figure 110.25. Crossed fused renal ectopia in a 2-year-old girl.** (A) Axial T2-weighted and (B) postcontrast T1-weighted MR images with fat saturation show renal fusion, with both kidneys located to the right of the midline. The left (lower) moiety partly overlies the spine.

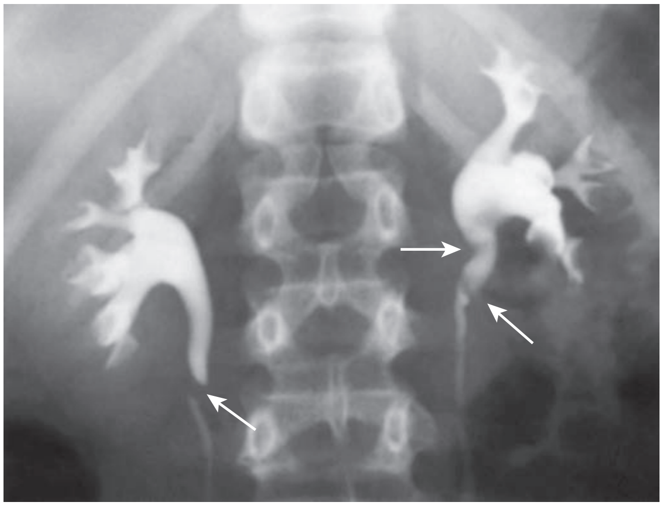
# URETER

## Ureteropelvic Junction and Proximal Ureter

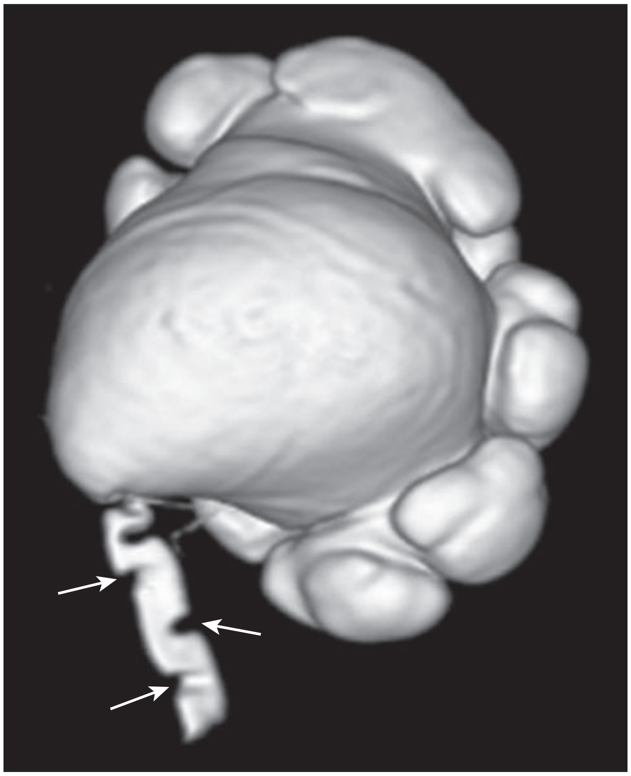
The transition between the renal pelvis and the ureter, or the UPJ, may be sharply or poorly defined. Both extrinsic filling defects and local narrowing are commonly observed at the UPJ without resultant hydronephrosis. An inferior polar artery may produce a small extrinsic defect or notch in the ureter near the UPJ (e-Fig. 110.27). A sharp kink without obstruction is occasionally seen in the proximal portion of the ureter as a transient or constant finding. Retained fetal folds in the upper ureter (e-Fig. 110.28), mild elongation and tortuosity of the ureter, and mild widening of the midureter may all be seen normally in the urogram in the infant. They are believed to represent a persistence of fetal characteristics and disappear in early childhood.[74–78]

## Duplication

Ureteral duplication (duplication of the renal pelvis ± ureter) is one of the most common anomalies of the urinary tract (Fig. 110.29). Incomplete duplication ranges from a bifid renal pelvis



**e-Figure 110.27. Renal arterial impressions.** Intravenous urography in a 14-year-old girl shows several defects at the ureteropelvic junction and proximal ureter *(arrows)*, presumably caused by nonobstructing crossing arteries.



**e-Figure 110.28. Retained fetal folds.** 3D rendering from an MR urogram in a child with UPJ obstruction shows multiple nonobstructive filling defects *(arrows)* in the proximal portion of the ureter. In most children, these disappear over time.

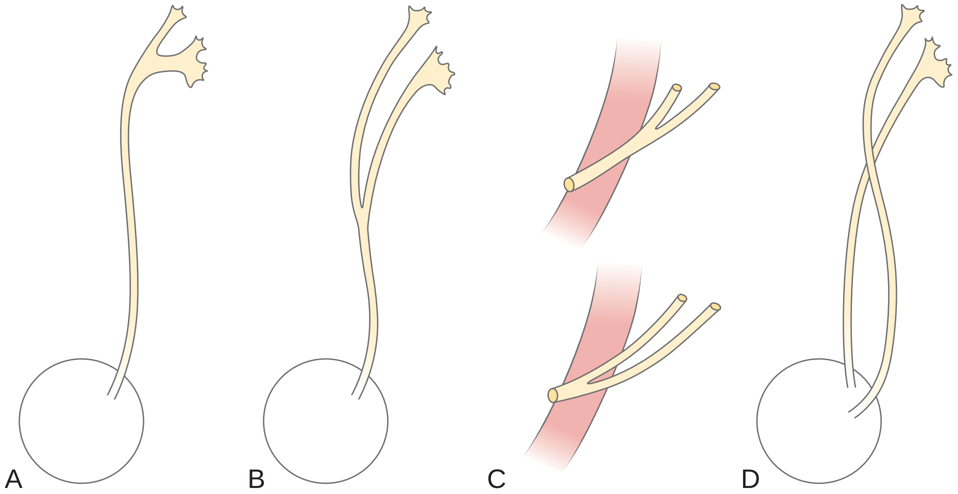


**Figure 110.29. Various forms of ureteral duplication.** (A) Bifid pelvis. (B) Partial ureteral duplication (Y-ureter). (C) Incomplete ureteral duplication with the ureters joining near the bladder or within the bladder wall (V-ureter). (D) Complete ureteral duplication with separate ureteral orifices. The upper pole ureter inserts distally and medially to the lower pole ureter (Weigert-Meyer rule).

to two ureters joining anywhere along their course and continuing inferiorly as a single structure. In completely duplicated systems, the two ureters are separate throughout their entire course. The ureter draining the upper pole of the kidney normally inserts into the bladder more caudad and more medially than the lower pole ureter (Weigert-Meyer rule) and has a longer submucosal tunnel than the lower pole ureter. Ureteral duplication is more commonly unilateral, although it may be bilateral. Ureteral duplication is of no clinical importance unless complicated by another congenital lesion or an acquired process. These conditions, such as ureteral ectopia, ureterocele, VUR, urinary tract infection, and UPJ obstruction, are addressed in later chapters.[79–86]

Other variants probably related to ureteral duplication include the accessory ureter or a ureteral stump. The accessory ureter is a tubular structure originating from a distal normal ureter at the bladder and extending cephalad along the normal ureter to end blindly proximally, without connection to a pelvocalyceal system or renal parenchyma. The ureteral stump varies in length from a few centimeters to a narrow but patent cord that extends almost to the kidney (e-Fig. 110.30).[87–91]

Ureteral triplication (e-Fig. 110.31) is another rare anomaly in which three ureters arise from the kidney; one from the upper pole, the second from the midzone of the kidney, and the third from the lower pole. The three ureters may drain separately into the bladder, or one may end ectopically; the parenchyma drained by the ectopic ureter is usually small and poorly functioning. In a second type, two of the three ureters may join in the lumbar area to form a single Y-shaped ureter that drains usually into the bladder, together with a normal third ureter. In a third type, the three ureters join in the lumbar area to form a common distal ureter that drains into the bladder. More than half the cases of ureteral triplication defy the Weigert-Meyer rule. Four ureters emanating from a single kidney have been described.[92–95]

## BLADDER

Bladder ears are normal lateral protrusions of the urinary bladder (e-Fig. 110.32). They are most frequently seen in infants less than 6 months of age as transient protrusions that are most apparent when the bladder is partially full. Bladder ears represent extraperitoneal herniations of the bladder through the internal inguinal ring into the inguinal canal. An association of bladder ears with inguinal hernia may reflect the presence of a patent processus vaginalis. Rarely, lateral protrusions of the rectum occur in this same location, producing a normal anatomic variant termed *rectal ears*.[96–98]

## URETHRA

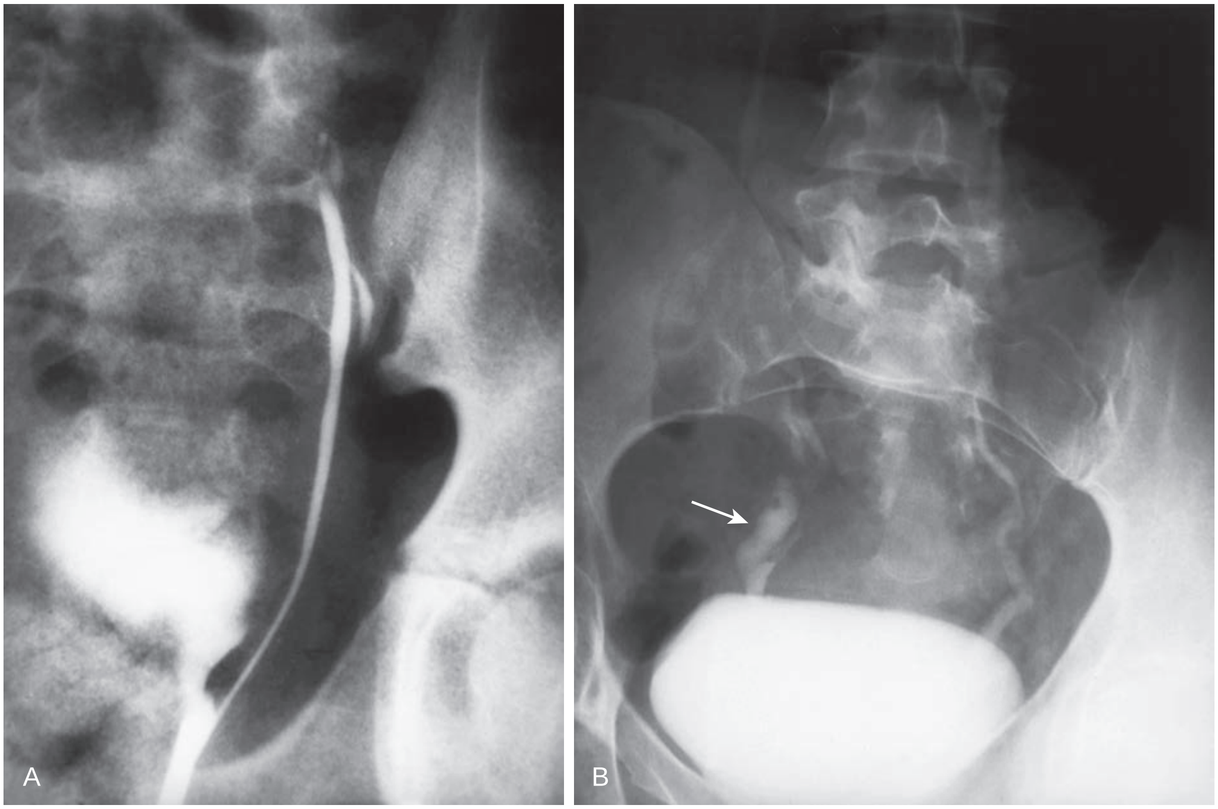
Several normal findings exist and should not be confused with pathologic processes, including normal anatomic folds of the posterior urethra of the male, and urinal and foreskin artifact. Normal anatomic folds are frequently visualized in the posterior urethra of the male and should not be confused with congenital obstructing membranes. Unlike congenital obstructing membranes, these folds do not produce dilatation of the proximal posterior urethra or decrease the urinary stream.[99–103]

Urinal artifact may be produced in the male during voiding. The urethral stream is compressed at the level of the penoscrotal junction by the plastic urinal and should not be confused with a stricture of the penile urethra. A film during voiding without urethral compression by the urinal confirms normal urethral caliber.[104]

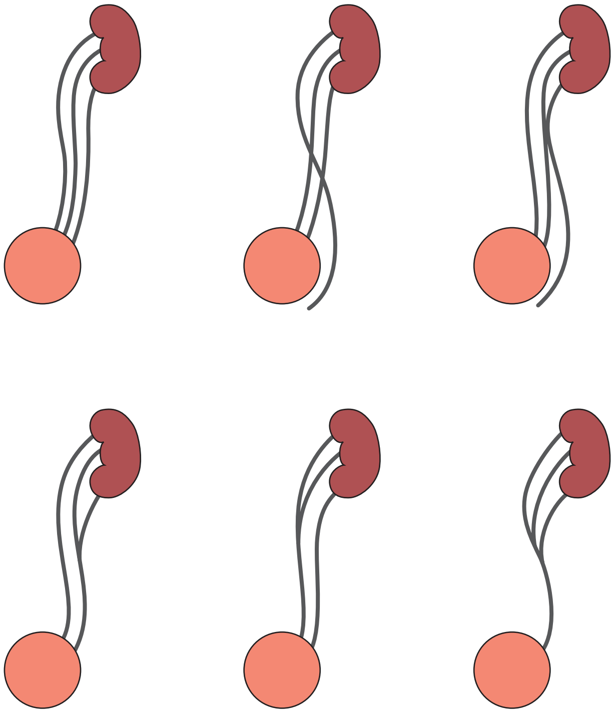
Foreskin artifact is caused by retraction of a tight foreskin and consequent narrowing of the distal urethra. This appearance may also mimic a urethral stricture. Reduction of the foreskin while voiding makes the appearance normal.

### KEY POINTS

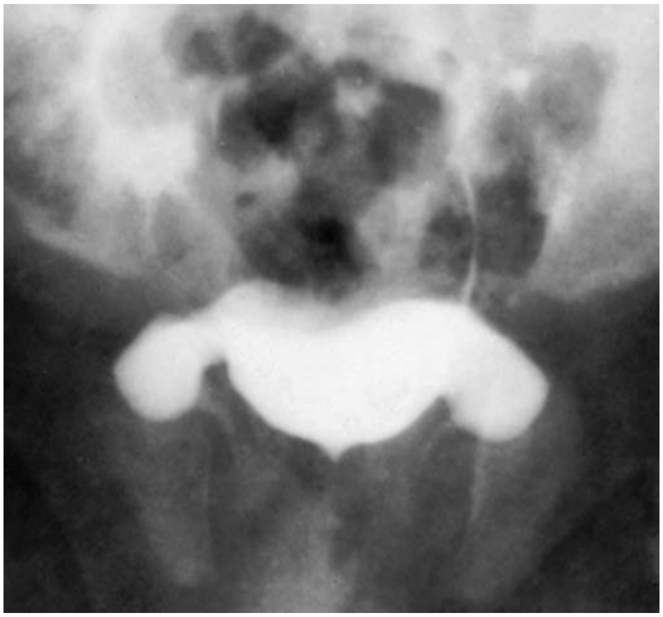
- The kidney, urinary tract, and genital tract are closely associated embryologically.
- The neonatal kidney has immature function during the first days after birth with decreased GFR and urine output, and limited concentrating ability.
- Variants in imaging of the childhood kidney include the column of Bertin, junctional parenchymal defect, scalloping of the cortical border, interrenuncular septum, dromedary hump, hilar lips, and hypoechoic pyramids.



**e-Figure 110.30. Rare forms of ureteral duplication.** (A) A retrograde ureterogram demonstrates a blind-ending accessory ureter. (B) A voiding cystourethrogram demonstrates vesicoureteral reflux into normal right and left ureters and a blind-ending right ureteral stump *(arrow)*.



**e-Figure 110.31. Types of ureteral triplication.** *Top*, Complete triplication: all three ureters enter the bladder separately, or one may insert ectopically. *Bottom*, Incomplete triplication: varying degrees of communication with one or two separate ureteral orifices into the bladder.



**e-Figure 110.32. Bladder ears.** A voiding cystourethrogram shows transient lateral herniation of the bladder ("bladder ears") in a normal infant. *(Courtesy Sandra K. Fernbach, MD, and Kate A. Feinstein, MD.)*

- Renal length is correlated to age, height, and weight.
- Horseshoe kidneys have an increased incidence of UPJ obstruction, VUR, ureteral duplication, and injury from direct trauma. A slight increased risk of Wilms tumor has been reported.
- The ureter from the lower kidney of crossed, fused kidneys crosses midline to insert into the bladder in its normal position.
- Ureteral duplication may be partial or complete. Incomplete duplication ranges from a bifid renal pelvis to two ureters joining anywhere along their course and continuing inferiorly as a single structure. In completely duplicated systems, the two ureters are separate throughout their entire course.

# 111 Imaging Techniques

Amy B. Kolbe, Larry A. Binkovitz, M. Beth McCarville, and J. Damien Grattan-Smith

## RADIOGRAPHIC PROCEDURES

### Intravenous Urography

Intravenous urography (IVU) was historically the imaging method of choice for the kidneys and upper urinary tracts but has been supplanted by magnetic resonance imaging (MRI) and computed tomography (CT). It is rarely the preferred imaging method in current pediatric practice. IVU uses the physiologic excretion of injected iodinated contrast media for anatomic visualization of the renal cortex, medulla, collecting system, and ureter and provides general information about renal function.

Imaging begins with a frontal radiograph of the abdomen to identify any calcifications or masses. Subsequently, low osmolar contrast media with a high iodine content is administered intravenously at a dose of 2 mL/kg (maximum, 150 mL) to obtain adequate iodine concentration in the renal tubules and collecting system. The filming sequence is tailored to the individual examination. An initial frontal radiograph within 1 to 2 minutes of injection images the nephrographic phase. Assessment of this radiograph determines subsequent filming. For routine examination, a radiograph at approximately 5 to 10 minutes allows visualization of the kidneys and their collecting systems, the ureters, and bladder (e-Fig. 111.1). In the prone position, the higher specific gravity of the contrast material allows better visualization of the anteriorly positioned renal pelves and proximal ureters.

The nephrographic phase provides a gross estimate of renal function, as well as information on renal size and parenchymal contour. A poorly visible nephrogram may indicate a technical problem in achieving optimal plasma concentration of contrast material or some degree of renal failure or diminished renal function. A dense and prolonged nephrogram indicates obstruction of the renal collecting system or renal tubules, hypotension, hypovolemia, or acute tubular necrosis.

### Retrograde Urethrography

Retrograde urethrograms are obtained infrequently in children but sometimes are performed in boys to evaluate possible urethral injury or rupture after a straddle injury or pelvic trauma. A small catheter is introduced into the anterior urethra to or slightly past the fossa navicularis, and the meatus is occluded. With the patient in a steep oblique position, a small amount of contrast material is injected through a syringe to allow evaluation of the urethra to the level of the external sphincter. Spasm of the external sphincter sometimes prevents filling of the most proximal portion of the posterior urethra. Although urethrograms are rarely performed in girls, the tip of a small Foley catheter with the balloon distended can be placed into the urethra and then taped to the perineum to allow retrograde evaluation of the urethra.

### Voiding Cystourethrography

Antegrade voiding cystourethrography (VCUG) is the traditional examination of choice for detailed anatomic evaluation of the bladder, study of the anatomy of the male urethra, and identification of vesicoureteral reflux (VUR). The bladder is filled by gravity pressure, using dilute sterile contrast media with an iodine concentration of 80 to 100 mg/mL. The predicted bladder capacity (in milliliters) for children younger than 1 year is the child's weight in kilograms multiplied by 7. In children older than 1 year, the predicted capacity is the child's age in years plus 2, multiplied by 30.[1,2]

An early bladder filling image is obtained to evaluate for ureteroceles or masses. Images with a full urinary bladder are obtained in the lateral oblique projections to look for VUR. Voiding films are useful to evaluate the bladder and urethra (particularly the male urethra) and for the diagnosis of VUR, which may occur only during voiding. After voiding, an image of the bladder documents any postvoid residual, and an image of the kidneys documents any reflux that occurred during the examination. Neonates should undergo at least two filling and voiding cycles to increase the chance of detecting VUR.[3–6] Pulsed fluoroscopy, last image hold recording, and videotaping are important imaging strategies for reducing radiation exposure.[7–10]

## ULTRASOUND

### Contrast-Enhanced Voiding Urosonography

The intravesical instillation of ultrasound contrast agents in the urinary bladder allows the sonographic evaluation of VUR without the use of ionizing radiation.[11–14] These microbubble contrast agents are composed of an outer shell of lipid, protein, or polymer that encases a gas, commonly perfluorocarbon or sulfur hexafluoride.[15] The gas is highly reflective on ultrasound imaging (Fig. 111.2) and can be detected even when administered in very small volumes. The ultrasound transducer is positioned intermittently over the bladder, ureters, and kidneys while the bladder is filled. On gray-scale imaging, the microbubbles appear echogenic. Refluxed contrast material is easily detected in the ureters and kidneys (Fig. 111.3). Although this technique does not avoid catheterization, it does eliminate radiation exposure. Results indicate that the sensitivity for VUR detection is comparable with that of standard techniques. A reflux grading system for contrast-enhanced voiding ultrasonography has been developed and is similar to the international grading system for VCUG.[12] Urethral visualization is possible with contrast-enhanced voiding ultrasonography but remains challenging (Fig. 111.4).

### Renal Ultrasonography

Ultrasonography is an ideal method for examining the kidneys and bladder in infants and children because of their small physical habitus and lack of abdominal fat and because ultrasonography does not utilize ionizing radiation. Variable transducer frequencies and transducer design (e.g., sector, phased, curvilinear, and linear array) allow for individualized approaches. Doppler ultrasound is valuable for the detection of blood flow, to confirm arterial perfusion, or to exclude venous thrombosis. Measurable blood flow parameters from spectral Doppler analysis include peak systolic velocity, end-diastolic velocity, and acceleration time. The normal renal artery has a prompt systolic upstroke with an acceleration time of 70 msec or less and a visible early systolic peak. The normal resistive index depends on the patient's age; it may be as high as 0.9 in a preterm infant and falls to around the adult value

## Abstract:

This chapter describes the radiologic and nuclear medicine imaging techniques available for evaluating the kidneys and urinary system and their disorders in children. Renal ultrasonography is the most widely used and appropriate initial screening exam. Advanced techniques include contrast-enhanced ultrasonography, fluoroscopic voiding cystourethrography, nuclear cystography, diuretic renography, nuclear scintigraphy, and magnetic resonance urography, each having varying ability to assess anatomy and function of the urinary system. Common urinary disorders including hydronephrosis, obstructive uropathy, vesicourethral reflux, and renal cortical scarring are discussed in context of the different imaging modalities and their findings.

**e-Figure 111.1. Normal intravenous urography image.** A 5-minute image shows opacification of the collecting systems with normal thin, delicate calyces, normal nondilated ureters, and filling of the bladder.

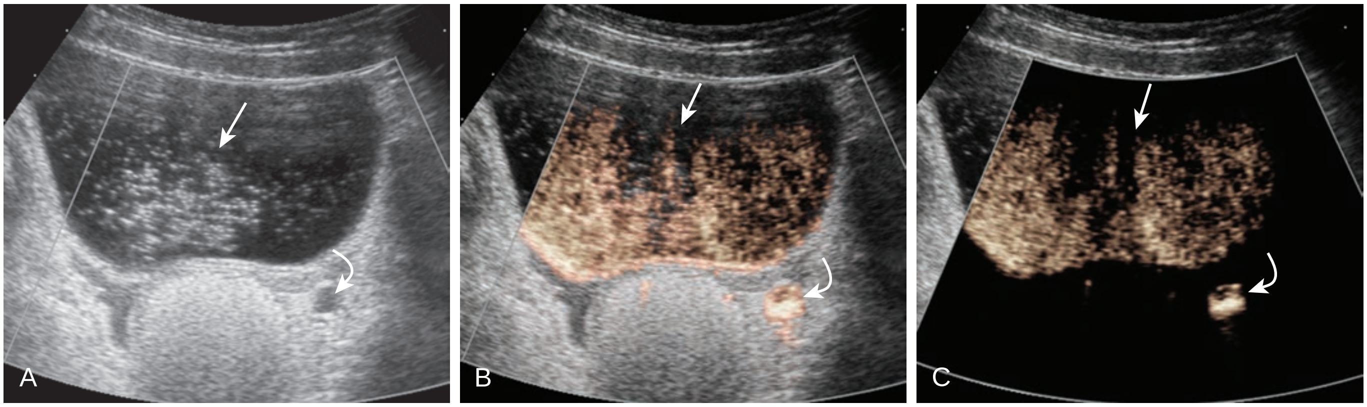

**Figure 111.2. Contrast-enhanced cystosonography.** Transverse ultrasound images after instillation of an ultrasound microbubble contrast agent into the urinary bladder. (A) On gray-scale imaging, the contrast agent appears as hyperechoic material in the bladder *(straight arrow)* surrounded by anechoic urine. Reflux into the distal left ureter *(curved arrow)* is present but somewhat difficult to appreciate. (B) Color overlay technology shows the contrast agent to better advantage as bright orange material in the bladder *(straight arrow)* and distal ureter *(curved arrow)*. (C) Subtraction technology further accentuates the presence of contrast material by eliminating non–contrast-enhanced background tissue. Contrast material in the bladder *(straight arrow)* and ureter *(curved arrow)* are readily apparent. *(Images courtesy Dr. Kassa Darge, Children's Hospital of Philadelphia.)*

of 0.7 in the first few months of life.[16–19] Color Doppler twinkling artifact can also be used to detect urinary tract calculi.[20]

In young children, it is advisable to initiate the urogenital ultrasound examination with an examination of the bladder. The full bladder of an infant commonly empties when the transducer is placed in the suprapubic region. Kidneys are imaged in the longitudinal and transverse planes. The kidneys are ovoid solid organs with fine, medium-level echoes arising from the cortex, a well-delineated corticomedullary junction with brightly echoic arcuate arteries, and pyramid-shaped, relatively large medullary rays that are hypoechoic. Cortical echogenicity in neonates and young infants is higher and the medullary pyramids are more hypoechoic than in older children (Fig. 111.5). The cortical echogenicity is increased compared with the liver and spleen in preterm infants, isoechoic in neonates and young infants, and diminishes progressively in older children. The transition from the infant renal echo pattern to that of the child typically occurs between 6 and 9 months (Fig. 111.6). Normal pediatric sonographic measurements of right and left kidney length, based on height and age, are provided in Table 111.1.[21–26]

## NUCLEAR MEDICINE

### Nuclear Cystography

Nuclear cystography is performed for the assessment of VUR and is an alternative to fluoroscopic VCUG. The examination is performed by direct instillation of radiotracer (technetium-99m–mertiatide [MAG-3] or technetium-99m-diethylenetriaminepentaacetic acid [DTPA]) and sterile saline solution into the bladder after sterile catheterization[27] or indirectly after nuclear renography with planar images obtained during voiding.[28] Dynamic imaging of the bladder and kidney regions is acquired with use of a posterior gamma camera throughout the filling and voiding cycle. The data can be grouped (in 10- or 60-second intervals) and viewed dynamically. VUR is documented when tracer is shown to ascend into a tubular structure corresponding to the ureter or when the renal collecting system is visualized. The dose of tracer is dependent on bladder volume: 300 mCi for bladder volumes up to 300 mL and 600 mCi for larger bladder volumes. A cyclic cystogram is recommended for children younger than 2 years, for children

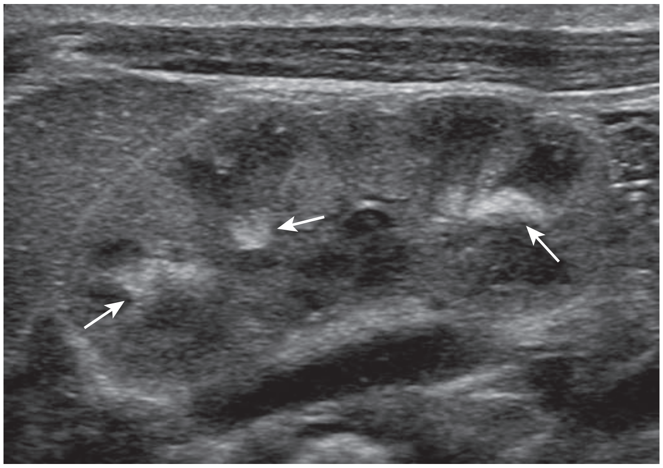

**Figure 111.5. Normal newborn kidney.** A longitudinal sonogram shows that the right renal cortex is isoechoic to the adjacent liver. The hypoechoic medullary pyramids are quite distinct. Areas of medullary pyramid increased echogenicity *(arrows)* are likely due to Tamm-Horsfall protein, a normal finding in a neonate.

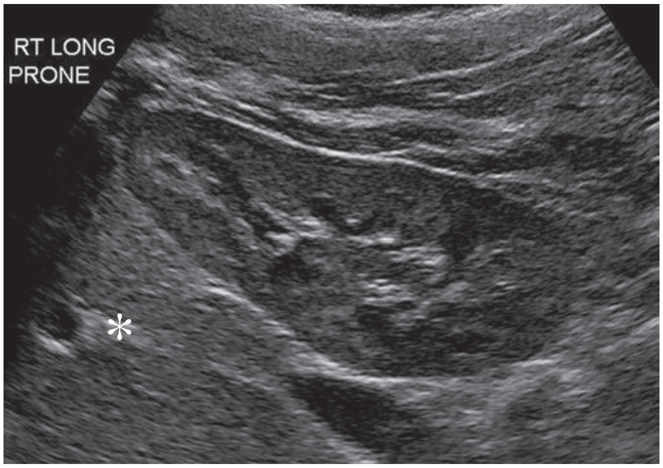

**Figure 111.6. Normal pediatric kidney.** A prone longitudinal sonogram in an 8-year-old child shows that the renal cortex is hypoechoic relative to the adjacent liver *(asterisk)*. The medullary pyramids are still distinct. Note the minimal echogenicity of the renal sinus as a result of a paucity of renal sinus fat.

**TABLE 111.1** Normal Sonographic Renal Lengths in Children Based on Height and Age

| Subjects | | | Left Kidney Length (mm) | | | | | Right Kidney Length (mm) | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | Percentile | | Suggested Limits of Normal | | | Percentile | | Suggested Limits of Normal | |
| Body Height (cm) | No. | Age Range | Mean (SD) | 5th | 95th | Lower | Upper | Mean (SD) | 5th | 95th | Lower | Upper |
| 48-64 | 50 | 1-3 mo | 50 (5.5) | 42 | 59 | 35 | 65 | 50 (5.8) | 40 | 58 | 35 | 65 |

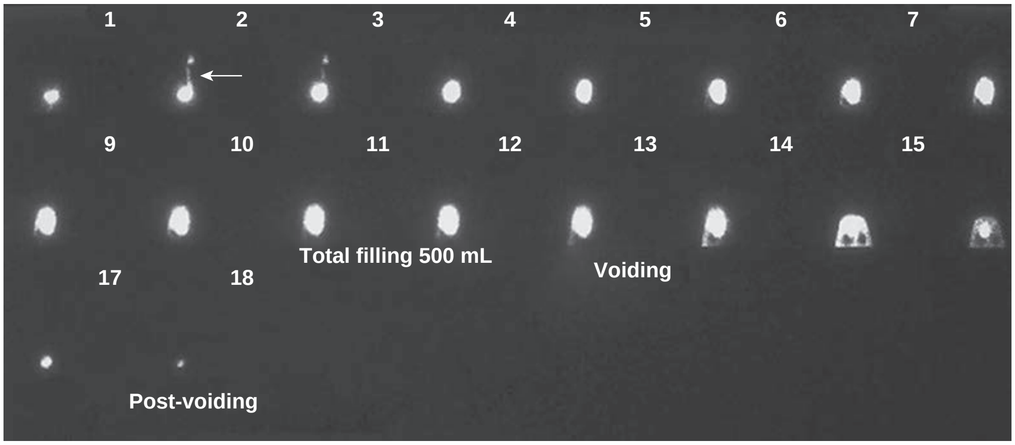

**Figure 111.8. Vesicoureteral reflux.** Early in the study, this nuclear cystogram shows intermediate-grade right vesicoureteral reflux *(arrow)* that later fully drains and does not recur through voiding. Continuous acquisition of the nuclear cystogram allowed the demonstration of this transient reflux, which likely would have been missed with fluoroscopic voiding cystourethrography.

with previously documented VUR or a high suspicion for VUR, and for children who void well before the expected bladder capacity is reached. The procedure is identical to the standard cystogram; however, the catheter is left in the bladder after the first voiding cycle and is used to refill the bladder for a repeat void. As with VCUG, cyclic studies increase the diagnostic yield (e-Fig. 111.7), identifying an additional 10% to 15% of children with VUR compared with noncyclic voiding studies.[29]
